This residence at Venice, indeed, is doubly memorable in the life of Petrarca. It was here that, when driven by the plague from Florence, Giovanni Boccaccio came to share his asylum, and presented to him Leontius Pilatus of Thessalonica, who was then teaching him Greek. Petrarca, though now past sixty, resumed the study of that language, and found, even in the difficulties which opposed his progress, sufficient enjoyment to mitigate the affliction caused by the loss of many valued friends. It was the fortune of Petrarca to survive all those whom he loved. Under the depression occasioned by the loss of his best friends, he became more sensitive to the criticisms which, notwithstanding his reputation, were freely made on his Latin eclogues, and on some parts of his *Africa*. It was then that the poet wept over his laurels, and, in the bitterness of a wounded spirit, confessed that his crown had been to him a crown of thorns.

The homage which was paid to him at Venice might, however, have afforded him some consolation, had not a new revolt in the island of Candia created serious alarm in the mother country. The senate, confiding in the military reputation and experience of Luchino del Verme, a Milanese general, the friend of Petrarca, appointed him to the command of the expedition fitted out against the rebels; and the poet consented to support the application made by the doge to that officer. Luchino put down the insurrection; and Petrarca had a place assigned him on the right hand of the doge, at the equestrian games which were celebrated, in the manner of the ancients, in honour of this victory. Urban V., a virtuous and enlightened pontiff, now attempted to recall the poet to his court, by conferring upon him a canonship at Carpentras,—a favour which he repaid by urging the holy father, in a long and vehement letter, to put an end to celibacy in the Roman Catholic church. Meanwhile, the

[1] Morelli, *Della Publica Libreria di S. Marco*, p. 4, et seq., Venice, 1774, in 4to.

[2] Several of these books, which had lain forgotten for nearly three centuries, fell to dust when touched, and others were found, as it were, petrified. Tomasini, in his *Petrarcha Redivivus* (p. 65), gives a list of those which, in 1635, were found in good condition. Amongst these he remarked a Polyglot Vocabulary in Latin, Persian, and Turkish (*Comanicum*), written in the year 1303, of which he transcribed a small specimen.

Morelli, in the work already referred to, gives a detail of several of these manuscripts, which are still to be seen in the library of St Mark, and accounts for the oblivion into which they had been allowed to fall during so long a period, from the enthusiasm which the acquisition of the Greek manuscripts of Cardinal Bessarion excite in the fifteenth century.

cry of hatred raised everywhere against the Visconti had armed against them the new pontiff, and with him the half of Italy, now menaced by their ambition. Much less alarmed at this danger, however, than apprehensive of a war which would expose his country to the ravages of a foreign soldiery, Petrarca was employed by Galeazzo Visconti to endeavour to avert the storm; and this, which proved the last, was also the most fruitless of all his missions. But the warmth with which he defended the Visconti family in no degree diminished the favour he enjoyed at Rome. Urban wished to see him: and Petrarca was preparing to respond to an invitation conceived in terms the most urgent and flattering, when he was seized with a terrible malady at Ferrara. But though saved by the care of the Este family, who governed that country, he did not recover sufficient strength to continue his journey; and having returned to Padua, reclining upon a couch in a boat, he established himself 4 leagues from that city, at the village of Arquà, situated in the Euganean hills, so celebrated by the Romans for the salubrity of the air, the richness of the pasturages, and the beauty of the orchards. There the poet resumed, with his labours, all the imprudence of his usual course of life. Employing at once as many as five secretaries, he exhausted himself with austerities, restricted himself to a single repast composed of fruits or pulse, abstained from wine, fasted often, and, on days of abstinence, allowed himself only bread and water. An unforeseen event also served to retard his convalescence. Urban V., preferring the peaceful abode of Avignon to the tumultuous agitations of Rome, had returned to die in France. He was succeeded by Gregory XI., who, equally well affected towards Petrarca, chose, as his legate in Italy, Philippo di Cabassole, now cardinal and archbishop of Jerusalem. But this prelate died soon after reaching Perugia, and Petrarca never more beheld the beloved friend of his youth.

Francesco da Carrara, abandoned by his allies, had just concluded a humiliating peace with Venice. Being obliged to send his son to ask pardon and swear fidelity to the republic, he entreated Petrarca to accompany the youth, and address the senate in his behalf. Though sick and old, the poet only recollected his ancient friendship for the lords of Padua, and repaired with young Carrara to Venice. The day after their arrival they had an audience; but the old man, overcome with fatigue, and perhaps awed by the majesty of the assembly, could not utter a word. The following day, however, he took courage, and his harangue was warmly applauded. But this effort proved his last; it was the song of the swan when dying. He returned to Arquà, feeble, exhausted, and as indocile to the counsels of physicians as ever. Boccaccio, who now seemed to supply the place of all the friends he had lost, having sent him the *Decameron*, which had just been completed, Petrarca read it with enthusiasm; got by heart the novel of Griseldis, which he translated into Latin; and transmitted to Boccaccio this version, accompanied with a letter, which appears to have been the last he ever wrote. On the 18th of July 1374, he was found dead in his library, with his head resting upon an open book, an attack of apoplexy having seized him in that attitude. All Padua came to assist at his obsequies. Francesco da Carrara conducted the funeral ceremonies, attended by the nobility and the people; and the family of the poet caused a mausoleum of marble to be erected to his memory before the gate of the church of Arquà.

The illustrious subject of this notice was connected with all the celebrated men of the fourteenth century; he took part in almost every event by which that memorable age was distinguished; and in a life so full of trouble and agitation, the only reproach which he incurred constitutes the finest eulogium on his character. He was born a poet, and always continued so, in his studies, his political missions, his love, his conversation, and his letters. The love of his country was no doubt in him little more than a poetical dream, but it was the dream of his whole life. In the intoxication of glory, as well as in the midst of the most cruel afflictions, ancient Italy was ever present to his thoughts. In the glorious recollections of the past he sought to console himself for the disorders of his own age, and from his worship of antiquity he derived generous inspirations and innocent illusions. That these illusions sometimes misled him in the choice of his friends, cannot reasonably be questioned. His candour exposed him without defence to the calculations of an astute policy, which, masking its real designs under the captivating name of Italy, completed the deception by the interested benefits which it conferred upon letters; but he passed through the courts of the petty Italian tyrants without any one having impeached his character, or cast a shade of suspicion on his memory. In his youth he had a natural daughter, near whom he died soon after her marriage; and his son, whom he survived, was cherished with an affection and bewailed with a sorrow that long served to keep alive the regret which the remembrance of his weaknesses had left in his mind. He seems to have been impressed with a deep sense of religion; and, amongst the habits of a simple and studious life, it is related that he rose regularly at midnight for prayer. Superior to the pedantry which then and long afterwards clung to learning, this great poet was also an amiable man. His conversation was confiding and animated; his manners were frank and polished. His soul, ardent, but open to all the gentler affections, had a natural craving for friendship, which was to him a necessary of life; and he had many friends, all of whom appear to have been faithful to him, and equally swayed by the double authority of his counsel and his example. Boccaccio, whose benefactor he had been, and who had previously been little else than a man of pleasure, became irreproachable, if not austere, in his morals, after his acquaintance with Petrarca. It was by means of his friends that Petrarca exercised a kind of literary dictatorship in France, in Spain, and in England; it was through his friends that he was enabled to carry on that European correspondence which everywhere rekindled the study and admiration of the ancients. He represented in his own person the republic of letters, and his life forms a grand epoch in their history.

He studied with diligence alchemy, astrology, scholastic theology, and Aristotle, with his interpreter Averroes. Even at the time when, by his advice, Galeazzo Visconti founded the university of Pavia, he himself directed the course of study, and formed the mind of Malpighino, who afterwards became so famous amongst the restorers of letters by the name of John of Ravenna. His letters *De Scriptis Veterum Indagandis* and *De Libris Ciceronis* attest the extent of the researches he made to recover manuscripts of the ancient authors, which he then copied with his own hand. It was thus that he restored to the literary world the *Oratorical Institutions* of Quintilian, though incomplete and mutilated, and the letters of Cicero, the manuscript of which is preserved in the Laurentian Library at Florence, with the copy which he had made from it. He equally recovered some of Cicero's orations which had been lost; and it is further known that he had preserved the famous treatise *De Gloria*; but having lent it to his master Convennole, this old man sold it for subsistence, and Petrarca afterwards attempted in vain to trace it out, as well as the *Antiquities* of Varro, which he had seen in his youth, and a book of letters and epigrams ascribed to Augustus. It was he also who first made Sophocles known in Italy; and his avidity for manuscripts had become so generally understood, that he received from Constantinople a complete copy of the poems of Homer. After the gift which he made to Venice, as already mentioned, he lost no time in

forming another library. In an age when chronology and geography were still unknown, he had made a chronological collection of imperial medals, and got together a very considerable number of geographical charts. He himself was the author of a map of Italy, which continued to be consulted a century after his death; and all his biographers have mentioned his researches respecting the island of Thule.

The rest of Europe did not then possess men who had attained the same splendour and universality of fame. France, which had received from her troubadours the oldest modern literature, could only boast of a few learned men; such as Nicolas Oresme, Pierre Berchoire, and Froissart. Chaucer, who was preparing to found a literature in England, saw Petrarca in Italy, and was perhaps indebted to him for the acquaintance of Boccaccio, whom he has so frequently imitated in his works. Another Englishman, Richard de Bury, one of the correspondents of Petrarca, founded a library at Oxford, and diffused throughout his country a taste for books. As yet Spain had only her early historical romancers, and some theologians; but two centuries later, the poetical admirer of Laura found in Boscan an imitator at the court of Castille; whilst Bembo, Tarsia, Molsa, and many others, opened in Italy the dangerous school of the Petrarchists.

The letters of Petrarca, which were printed for the first time in 1484, are now regarded as the most curious portion of his Latin works. These letters, which were not written exclusively, for his friends, contain valuable details in regard to his life, as well as the manners and the history, literary, and political, of the fourteenth century. The court of Avignon is by no means spared; and the author was too good an Italian not in some instances to overcharge a little his portraits. His expression is animated, but not always natural, and his prose often betrays the poet. His books of moral philosophy somewhat resemble those commonplaces which were treated by the Greek rhetoricians of the middle age. The treatise *De Otio Religiosorum* was a tribute of complaisance to the Carthusian friars of Montrieu, amongst whom his brother had taken the habit of the order;[1] and it was at the request of Francesco da Carrara that he collected the principal maxims of Plato and Cicero on politics, under the title of *De Republica optime administranda.* The compilation in question, and his treatise *De Officio et Virtutibus Imperatoris*, were printed separately at Berne, 1602, in 12mo. In his retreat at Arquà, he also wrote a philosophical work against the disciples of Aristotle, under this piquant denomination, *De Ignorantia sui ipsius et multorum.* His Historical Essays, of which some fragments have been preserved, entitled *Rerum Memorandarum libri iv.*, in addition to the facts which he has borrowed from preceding writers, contain some particulars belonging to contemporaneous history, which are nowhere else to be found. The perusal of the Confessions of St Augustin appears to have suggested to him the most singular of all his compositions, namely, the three dialogues, *De Contemptu Mundi*, to which he attached so much importance as to call them "his secret."

The harangues of Petrarca are not always exempt from declamation, and, more than any of his other productions, betray the influence of the false taste against which he so successfully strove. But his Latin poetry has particular claims to the attention of men of letters. His poem of *Africa* is a detailed recital of the second Punic war, but almost always cold and colourless. It is a chronicle rather than a poem, and appears as if it had been left unfinished. The *mens divinior* is wanting; invention there is none; and we are astonished to find that the poetry of Virgil produced so little inspiration. His eclogues, like those of Boccaccio, are almost always satirical allegories, having reference to contemporaneous events. The tenth is consecrated to the memory of Laura. In his three books of *Epistles*, versified with more facility than might have been expected in that iron age, there are some interesting and instructive details. In fact, the Latin diction of Petrarca, on which, curious to say, he founded his claims to distinction as an author, though generally superior to the bald and rude style of his contemporaries, is nevertheless far below that of his models.

But Petrarca's best title to distinction rests upon his *Canzoniere.* It is there that he shows himself truly inspired, and displays in profusion all the riches of his original genius. The ancient erotic poets, strangers to any ennobling sentiment, had celebrated pleasure rather than love. Petrarca was the first, and for a long time the only poet, who made a virtue of love. He formed for himself a language, as Dante had done; his turns of expression are almost as bold; above all, he reproduced those graces of colouring and that delicious harmony with which Dante had related the misfortunes of his Francesca; and, after the publication of the *Canzoniere*, the Italian idiom ceased to have in it anything barbarous. When we read the verses of Petrarca, we can almost fancy that we hear the sound of his lyre, from which, on every occasion, he extracts sounds of ineffable sweetness. His sonnets, from their form, frequently remind us of some of the smaller odes of Horace, and, for grace as well as simplicity of details, recall the manner of Anacreon. For this kind of poetry Petrarca was indebted to his predecessors; but it was he who rendered these little poems more perfect and more difficult; and the laws which his example prescribed have not yet been abrogated.

The *Canzoni* of Petrarca are odes the form of which he borrowed from the troubadours, whilst to the substance he imparted the elevation and dignity of epic composition. The Italians have exhausted all the prescriptive terms of admiration upon those which Petrarca appears to have preferred, and which he called the *Three Sisters*, odes which his commentators have since called the *Three Graces.* But whatever may be the perfection of style for which they are distinguished, a reader of the present day will always find difficulty in comprehending the long literary idolatry of which they have been the object. He is often more ingenious than natural, and more elaborate than correct; but a re-perusal of the second half of the *Canzoniere*, which is very generally preferred to the first, must satisfy any reader that nothing short of extreme injustice or inveterate prejudice can construe into a mere play of words or sport of ingenuity a grief which is stamped with all the characteristics of truth, deep feeling, and sincerity.

The most complete edition of the works of Petrarca is that of Basel, 1581, in folio, which wants only a certain number of Letters, comprised in that of Geneva, 1601. The most ancient edition of his Latin works also bears the name of Basel, where it appeared in 1496, in folio. But it is in the libraries of Italy that his Letters and his Autograph Manuscripts must be sought for. The treatise *De Remediis utriusque Fortunæ* was printed at Cologne, 1471, in 4to, and has been thrice translated into French; and the historical work entitled *Vite de' Pontefici et Imperadori Romani*, which has now become exceedingly scarce, appeared at Florence, 1478, in folio, and is still much sought after, as one of the most ancient specimens of Italian prose. In later times, his Italian poems alone have been reprinted. The first edition, containing the Sonetti and the Trionfi, is that of Venice, 1470, in large 4to. Amongst the subsequent editions, the most esteemed are,—*Le Cose Volgari*, by Aldo Manuzio, Venice, 1501, in 8vo, *Il Petrarca*, Lyon, 1574, in

[1] Several biographers have given Petrarca a sister, who, they say, was beloved by Pope Benedict XII. This fable, which has been received without question by many, is disproved by the fact, which Ginguené has clearly established, namely, that Petrarca never had a sister.

16mo; *Le Rime di Petrarca*, Padua, 1722, in 8vo; a reprint of the same, with notes by Muratori, Venice, 1727, in 4to; the editions of Bodoni, 1799, in two vols. folio and 8vo; that of Morelli, the librarian, with remarks by Beccadelli, Verona, 1799, in two small vols. 8vo, that which forms part of the *Biblioteca Poetica Italiana*, published by Buttura, and printed by Didot the elder, Paris, in three small vols.; and the edition, with commentaries, published by Biagioli in 1822, in 8vo. Of the 300 and more editions of the *Canzoniere*, the best is that of Professor Marsand, two vols. 4to, Padua, 1819-20. A careful bibliography of the works of Petrarca, their various editions, commentaries, &c., was published by Domenico de' Rosetti, Trieste, 1828. Petrarca is said to have been the subject of twenty-five distinct biographies, exclusive of the sketches of his life given in collections. (J. B—E.)

PETRIFACTION. See PALÆONTOLOGY.

PETRINIA, a town of Austria, in the Croatian Military Frontier, on the Kulpa, 27 miles S.E. of Agram. It is built chiefly of wood, and has a square planted with mulberries. There are here two churches, two schools, and an hospital. Pop. about 4000.

PETROLEUM. See MINERALOGY, § 499; also BITUMEN.

PETRONIUS, ARBITER, the author of a kind of romance, flourished, if we may judge from the character of his style, in the first or second century. Who he really was has been much disputed, and has never been satisfactorily determined. The only historical personage who seems to have any marks of identity is a certain Caius or Titus Petronius who lived at the court of Nero. This individual, as described by Tacitus, was famous for turning the pursuit of pleasure into a professional art. He slept all day that he might be able to discharge with vigour his voluptuous avocations during night. His great aim was to grovel in sensuality in the most æsthetical manner, and to move under the stiff uniform of a fop, with the simplest and easiest bearing. It is true, indeed, that his mind was for a while engaged with the graver duties of proconsul of Bithynia and of consul; but he returned with fresh eagerness to take a more leading part in his former profession. Promoted to the office of "arbiter elegantiæ," or "umpire of fashion," he daily occupied himself in deciding with pompous gravity what frivolities ought to be introduced at court. Even after another courtier, named Tigellinus, had supplanted him in Nero's favour, and his doom appeared to be fixed, he resolved to remain true to his calling till the last, by departing from the world in as easy and elegant a manner as possible. Continuing at his summer quarters at Cumæ, where he then happened to be, he caused one of his veins to be opened, and bandaged up at intervals. While his heart's blood was thus dripping slowly away, he listened to giddy songs; he sauntered forth among the gay pleasure-seekers on the beach; he returned to his villa, and, reclining on a couch, discussed with his friends the gossip of the day. In this manner the heartless epicure ended his mockery of a life.

The supposed work of this Petronius, which is entitled *Satiricon*, and which now exists only in fragments, is to a considerable extent accordant with the character which we have just drawn. It is the narrative of the adventures of a certain Encolpius and his fellow-debauchees in their travels in the south of Italy. The coarse and vicious personages whom the tourists everywhere encountered are described with great humour and dramatic propriety. The luxurious and licentious scenes which they everywhere witnessed are depicted with minute and shameless fidelity. That part especially which is known as the *Supper of Trimalchio* presents a vivid picture of the profligacy of a Roman gourmand. In fact, there is everywhere throughout the descriptions an obscenity of thought expressed in an elegant and graphic form of diction, which may reasonably be supposed to have proceeded from a professed and accomplished sensualist. The best edition of Petronius is that of Burmann, in two vols. 4to, Amsterdam, 1743. The works of Petronius have been frequently translated into English. The translation of Addison (1736), and that in "Bohn's Classical Library," edited by W. Kelly (1854), deserve special mention.

PETROPAULOVSKI, or "*The Harbour of St Peter and St Paul*," a small town of Asiatic Russia, capital of the territory of Kamtschatka, on the Bay of Awatska, on the S.E. coast of the peninsula; N. Lat. 53. 1., E. Long. 158. 43. There are two good streets; but the general appearance of the town is not fine, as the houses, which are scattered, are built for the most part of wood, and thatched with reeds or dried grass. Many of the houses have gardens, in which a few vegetables are grown; and, except in the governor's house and public buildings, plates of mica are used in the windows instead of glass. There are several government offices, a Greek church in the oriental style, a school, and an hospital. The harbour, which is very good, and capable of containing six or eight ships of the line, is defended by two forts, and has a lighthouse. Fish are caught and dried here, and form the principal article of export. Petropaulovski is the principal military station in this province. It was bombarded by British and French fleets, September 1854. Pop. (1850) 975.

PETROPAULOVSKI, a town of Siberia, in the government of Tobolsk, stands on the Ishim, 160 miles W. of Omsk, on the great post route of Siberia, and on the borders of the country of the Kirghises. A considerable trade is carried on by barter, not only with the other parts of Siberia but with Turkestan and the western part of the Chinese Empire. Petropaulovski, Orenburg, and Troizk are the principal stations by which the commercial intercourse is carried on between Russia and Central Asia. Pop. (1842) 4127.

PETROVSK, a town of European Russia, capital of a circle in the government of Saratov, stands on both sides of the Medveditza, 70 miles N.N.W. of Saratov. It has a ruined castle, seven churches, a convent, two schools, and a benevolent institution. Many bees are reared in the vicinity. Pop. (1848) 7631.

PETROZAVODSK, a town of European Russia, capital of the government of Olonetz, stands on a bay on the west shore of Lake Onega, near the confluence of the small rivers Lossossinka and Neglinka, 192 miles N.E. of St Petersburg. It is meanly built; but is the seat of the governor and of the archbishop of Petrozavodsk and Onega. There are six churches and several schools, an imperial cannon factory, employing about 700 hands, a copper foundry, and other manufactures. There are produced here nearly 3000 tons of iron annually, reckoned the best in Europe. The manufactures of the town are conveyed for sale to St Petersburg. Pop. (1849) 7567.

PETSH, or IPEK, a town of European Turkey, province of Albania, on both sides of the Bistrizza, 56 miles E.N.E. of Scutari. The river, which here flows rapidly in several channels, and turns numerous mills, divides the town into two parts, called respectively Jarin and Csenevia, which are united by a high bridge of five arches. Petsh contains a bazaar with 960 shops, numerous mosques, and the residence of a pasha. Arms of a good quality are largely manufactured here; and a kind of apple of an excellent flavour is raised in the vicinity, and sent to Constantinople. Pop. said to exceed 12,000.

PETTY, SIR WILLIAM, a distinguished political economist, was the eldest son of Anthony Petty, a clothier at Rumsey, in Hampshire, where he was born on the 16th of May 1623. After receiving the rudiments of his education at the grammar-school of Rumsey, he removed to the university of Caen, in Normandy, where he perfected himself in Latin and French, acquired enough of Greek "to serve his turn," studied the arts, and extended his knowledge of the mathematics. On his return from France, he was appointed to some post in the navy, which

Petty.

he soon gave up, and took to the study of medicine. With this design he, in 1643, visited Leyden, Utrecht, and Paris, where he studied anatomy, and read Vesalius with Hobbes, whom he in turn assisted by drawing optical diagrams for the philosopher. Having from his earliest years displayed a decided taste for mechanical invention, Petty, on the 6th of March 1647, patented a sort of copying machine, by means of which "any man, even at the first sight and handling, may write two resembling copies of the same thing at once, as serviceably and as fast as by the ordinary way." But this machine having been found not to promote expedition in writing, Petty did not reap much profit by his invention. His next production was a pamphlet entitled *Advice to Mr Hartlib for the Advancement of Learning*, containing some sensible remarks on national education. In 1648 he went to Oxford, where he gave private instructions in anatomy, became assistant to Dr Clayton, the professor of anatomy, and also practised physic with considerable success. Here he acquired such reputation, that the philosophical meetings which led to the institution of the Royal Society were for the most part held at his lodgings; and, by a parliamentary recommendation, he obtained a fellowship in Brazen-nose College, and was created doctor of physic on the 7th of March 1649. In June 1650, he was admitted a member of the College of Physicians. In 1651 he was appointed professor of anatomy, and soon afterwards professor of music at Gresham College; and in 1652, he went to Ireland as physician to the army in that country, where he served under three successive lords-lieutenant, namely, Lambert, Fleetwood, and Henry Cromwell.

In 1654 Dr Petty was appointed to survey the Irish forfeited lands adjudged to the soldiers after the suppression of the rebellion of 1641. In 1655 Henry Cromwell assumed the lord-lieutenancy of Ireland, and soon afterwards appointed Petty his secretary; in 1657 the viceroy further appointed him clerk of the council, and got him elected to serve as burgess for West Love, in Cornwall, in Richard Cromwell's Parliament, which assembled on the 27th of January 1658. But this last honour speedily involved him in trouble. On the 28th of March following he was impeached of high crimes and misdemeanours in the execution of his office, and obliged to proceed to England. His case was taken up in the House of Commons, but as the Parliament was suddenly dissolved, it never came to an issue. He was removed, however, in the following June from all his employments. He defended himself from the charges of bribery, fraud, &c., which were urged against him, by ingeniously arguing that he might have acquired as large a fortune by other means as by having to do with the Irish lands. At the Restoration he was graciously received by Charles II., and, having resigned his professorship at Gresham College, was appointed one of the commissioners of the Court of Claims. In April 1661 he received the honour of knighthood, with the grant of a new patent constituting him surveyor-general of Ireland; and he was at the same time chosen a member of the Irish Parliament. Being one of the founders of the Royal Society, he was elected a member of the first council; and although he had left off the practice of physic, his name appears in the list of fellows of the College of Physicians in 1663. About this time he invented a double-bottomed ship, which was to sail against both wind and tide, though we are not told by what means; and in 1665 he communicated to the Royal Society, along with a model of his invention, a *Discourse about the Building of Ships*.

Petty.

In 1666 Sir William Petty drew up his treatise, entitled *Verbum Sapienti*, containing an account of the wealth and expenditure of England. In 1667 he married Elizabeth, daughter of Sir Hardresse Waller, and widow of Sir Maurice Fenton. This matrimonial connection, however, did not for a moment distract his attention from his favourite pursuit of money-making; for immediately afterwards he established iron-works and a pilchard-fishery, opened lead mines, and commenced a trade in timber at Kerry, all of which turned to good account. To vary his pursuits, he also composed a piece of Latin poetry, which he subsequently published under the title of *Colloquium Davidis cum Anima sua!* In 1680 he gave to the world his *Politician Discovered*, intended to expose the sinister practices of the French; and afterwards wrote several essays on *Political Arithmetic*, of very great ability. Lord Macaulay remarks of them that "Sir William Petty created the science of political arithmetic, the humble but indispensable handmaid of political philosophy." (*Hist. of England.*) He assisted at the formation of the Dublin Philosophical Society, and in November 1684 was chosen president of that association. On this occasion he drew up a Catalogue of Cheap and Simple Experiments, which was soon afterwards followed by his *Suppellex Philosophica*, containing a description of forty instruments which he deemed necessary to carry forward the design of the institution. He died in London, on the 16th of December 1687, in the sixty-fifth year of his age. His will is perhaps the most curious and characteristic composition of the kind in our language, illustrating at once the habits of thinking and feeling peculiar to the man, and the mode in which he realized the enormous fortune which he left to his descendants.[1]

A few particulars of the personal history of Sir William Petty may be gleaned from Aubrey, who appears to have lived with him on terms of intimacy. He possessed strong, shrewd, natural good sense, flavoured with a tincture of humour, and had a most convenient way of shaking himself rid of the trammels of party when it suited his interest to do so, changing sides with a facility that is altogether edifying. His qualifications were indeed various and peculiar. As a specimen of his fondness for drollery, we are told that, on one occasion, he proposed to fight Sir Jerome Sankey, who had challenged him, in a dark cellar with carpenter's axes; but the soldier knight did not deem it prudent to acquiesce. He would also preach extempore, which Aubrey says he did "incomparably," and that, too, in almost any style, "either in the Presbyterian way, Independent, Capuchin friar, or Jesuit." He had "an admirable inventive head, and practical parts," which he turned to good account, as far as his own interest was concerned; and, like his friend Hobbes, he boasted that he had read but little since he was twenty-five, declaring that "had he read as much as some men have, he had not known so much as he does, nor should have made such discoveries and improvements." He told Aubrey that he had "hewed out his fortune for himself;" and he even managed to obtain a patent

[1] Here is a specimen of this extraordinary composition:—"As for legacies for the poor, I am at a stand; as for beggars by trade and election, I give them nothing; as for impotents by the hand of God, the public ought to maintain them; as for those who have been bred to no calling or estate, they should be put upon their kindred; as for those who can get no work, the magistrate should cause them to be employed, which may be well done in Ireland, where is (are) fifteen acres of improvable land for every head; prisoners for crime, by the king; for debts, by their prosecutors; as for those who compassionate the sufferings of any object, let them relieve them, and relieve themselves by relieving such sufferings, that is, give them alms *pro re nata*, and for God's sake relieve those several species above mentioned where the above-mentioned obligers fail in their duties: Wherefore I am contented that I have assisted all my poor relations, and put many in a way of getting their own bread, and have laboured in public works, and by inventions have sought out real objects of charity; and do hereby conjure all who partake of my estate, from time to time to do the same at their peril. Nevertheless, *to answer custom, and to take the surer side*, I give L.20 to the most wanting of the parish wherein I die."

Petworth || Pewter.

of nobility as Earl of Kilmore, which, however, he suppressed, to avoid envy. The variety of pursuits in which he was engaged shows that he had talents capable of achieving anything to which he chose to apply them; and it is certainly not a little remarkable, that a man of such an active and enterprising disposition should have found time to write so much as he did in the course of his busy life.

The following is a list of the works which appeared in his lifetime:—*Advice to Mr Samuel Hartlib*, 1648, in 4to; *A Brief of Proceedings between Sir Jerome Sankey and the Author*, 1659, in folio; *Reflections on Some Persons and Things in Ireland*, 1660, in 8vo; *A Treatise of Taxes and Contributions*, 1662, in 4to, republished in 1690, with two other pieces, *Apparatus to the History of the Common Practice of Dyeing*, 1667; *A Discourse concerning Duplicate Proportion*, 1674, in 12mo; *Colloquium Davidis cum Anima sua*, 1679, in folio; *The Politician Discovered*, 1681, in 4to; *An Essay on Political Arithmetic*, 1682, in 8vo, *Observations upon the Dublin Bills of Mortality in* 1681, 1683, in 8vo; "Some Experiments relating to Land-carriage," *Phil Trans.*, No 161; "Queries on Mineral Waters," *Ibid.*, No 166; "A Catalogue of Experiments," *Ibid*, No 167; *Maps of Ireland, being an actual Survey of the whole Kingdom*, 1685, in folio; *An Essay concerning the Multiplication of Mankind*, 1686, in 8vo, "A further Assertion concerning the Magnitude of London," *Phil Trans*, No 185; *Two Essays in Political Arithmetic*, 1687, in 8vo; *Five Essays in Political Arithmetic, English and French*, 1687, in 8vo; *Observations upon London and Rome*, 1687, in 8vo. His posthumous productions are:—*Political Arithmetic*, 1690, in 8vo, and 1775, with a Life prefixed, and a Letter never before printed; *The Political Anatomy of Ireland*, to which is added *Verbum Sapienti*, 1691, 1719; *A Treatise of Naval Philosophy*, in three parts, printed at the end of an *Account of Several New Inventions*, 1691, in 12mo; "What a Complete Treatise of Navigation should contain," *Phil Trans.*, No. 198, drawn up in 1685. In Birch's *History of the Royal Society* are contained, "A Discourse of making Cloth and Sheep's Wool," including the History of the Clothing Trade, and also that of Dyeing; and *Suppellex Philosophica*, already mentioned. Many of Sir William Petty's manuscripts are to be found in the British Museum. (J. B—E.)

PETWORTH, a market-town of England, in the county of Sussex, on a branch of the Arun, 14 miles N.E. of Chichester, and 49 S.W. of London. It is irregularly built, though clean and neat; and contains a market-house; court-house; cruciform church, in the perpendicular style, with many relics of the Percies of Northumberland; Independent and Methodist places of worship; several schools, alms-houses, and savings-bank; and a literary institute. Fairs are held here three times a year. In the vicinity of the town stands Petworth House, in the midst of a beautiful and well-wooded park, with a sheet of water in front of the mansion. It is a magnificent edifice, and contains a very fine collection of books, paintings, statues, and busts. The sword used by Hotspur at Shrewsbury is kept here. Pop. (1851) 2427.

PETZKA, or PECSKA, a market-town of Hungary, county of Arad, on the Maros, 10 miles W. of Arad. It consists of two parts, Magyar and Raitzisch Petzka; and contains a Roman Catholic church. The neighbourhood is fertile, producing wine in large quantities; and some trade is carried on in horses, cattle, sheep, and tobacco. Pop. (1846) 13,900.

PEWTER. The theoretical composition of common pewter is 80 parts tin and 20 of lead; but as the manufacturers consider that a better alloy is formed by melting up old pewter with new ingredients, the composition is uncertain. The French legislature sanctions the use of 82 parts tin and 18 of lead, as forming an alloy which is quite harmless in vessels used for wine and vinegar. Antimony is sometimes added for hardening the tin, and for giving a more silvery colour. Zinc is also used to diminish the oxidation; a small lump of that metal being allowed to float on the fluid pewter during the casting; or the fluid is occasionally stirred with a strip composed of equal parts of zinc and tin. The finest pewter, called *tin-and-temper*, consists mostly of tin, with a small proportion of copper, which makes it hard and somewhat sonorous; but the copper is apt to impart a brown colour. The temper is formed by melting the copper, and adding twice its weight of tin, and from $\frac{1}{2}$ lb. to 7 lb. of this alloy is added to each block of tin, which weighs from 360 to 390 lb.

Pezenas.

In the year 1772 the Pewterers' Company made an attempt to regulate the quality of pewter-wares by establishing "A Table of the Assays of Metal, and of the Weights and Dimensions of the several sorts of Pewter Wares." The assay was directed to be made by casting a small button of the metal, to be tried in a brass mould so proportioned that such a button of *pure tin* should weigh 182 grains. All the metals added to the tin being heavier than tin, the buttons would be heavier in proportion as they contained less tin. On these data the following scale was founded:—

	Grains.
Assay of pure tin.	182
„ *fine* or *plate* metal $1\frac{1}{2}$ grains heavier than tin, or	$183\frac{1}{2}$
„ *trifling* metal $3\frac{1}{2}$ grains heavier than tin, or	$185\frac{1}{2}$
„ *ley* metal $16\frac{1}{2}$ grains heavier than tin, or	$198\frac{1}{2}$

Pewters formed of equal parts tin and lead are about 50 grains heavier than tin, or 232 grains. Such pewters, when cast, are black, shining, and soft; and when turned, are dull and bluish. Pewters which contain only one-fifth or one-sixth of lead, cast into wares which are white, hard, and without gloss; they form a good metal, and are but little darker than tin. The French have published a table of specific gravities for testing the quality of the alloy, the legal standard of which is 7·764. An excess of lead is detected by an increased density.

Of the three ordinary kinds of pewter distinguished in the Pewterers' Scale, *plate* pewter is the hardest, and is used for plates and dishes. The pewter called *trifle* is used for beer-pots; and *ley* for the larger wine measures. The best plate pewter is sometimes composed of 100 parts tin, 8 antimony, 2 bismuth, and 2 copper. Trifle consists of 83 of tin, 17 of antimony, and usually a large proportion of lead.

Pewter plates and dishes are formed by hammering, and measures and spoons by casting. The parts are joined together by means of soft solder, assisted by a blast of hot air from a small charcoal furnace. Pewter is also formed into sheets for printing cheap music; the softness of the metal allowing the notes to be formed by means of punches, which is cheaper than engraving with the burin. Laps and polishers of pewter are also formed for the use of lapidaries, jewellers, watchmakers, &c.

Pewter-wares are finished by burnishing with oil, and cleaning off with a rag and whiting. Pewter vessels may be cleaned by means of silver-sand and water, or with a solution of potash or of soda, to remove grease. (C. T.)

PÉZENAS, a town of France, department of Hérault, occupies a beautiful position on the left bank of the Hérault, at its confluence with the Peine, 25 miles W.S.W. of Montpellier. Many of the streets are broad, and lined with handsome and well-built houses. The old castle, now in ruins, commands a beautiful view over a country so distinguished for fertility as to be called the "Garden of Hérault." The principal buildings are the parish church and the theatre; the latter of which was originally a conventual chapel. Linens, napkins, muslin, woollen and cotton fabrics, hats, soap, brandy (for which it is one of the chief markets in Europe), and chemical substances, are among the manufactures of the place. Besides brandy, wine, and spirits, the principal articles of commerce are grain, dried fruit, oil, timber, and cotton, silk, and woollen stuffs. A great fair is held here in September, which is frequented by merchants from the whole of the south of France. It was at Pézenas that Molière wrote the play called *Les Précieuses Ridicules*, while the manager of a company of strolling players. Pop. 7375.

PFEFFEL, GOTTLIEB CONRAD, a German poet, was born at Colmar in 1736, and was educated at the university of Halle. He was destined for the legal profession; but an attack of ophthalmia, which issued in total blindness, gave a new bent to his career. He first, in 1773, established in his native town a military seminary for the education of Protestant youths. When the French revolution put a stop to that enterprise, his attention was then devoted to literature. He was engaged from that time till his death, in 1809, in writing tales, odes, ballads, and poetical epistles, and in translating dramatic pieces from the French. His *Poetische Versuche* were published in 10 vols., 1802–10; and his *Prosaische Versuche* in 10 vols., 1810–13. Pfeffel's elder brother Christian Friedrich was distinguished as a jurisconsult and diplomatist.

PFEFFERS, or PFÄFFERS (Fr. *Favière*), a village of Switzerland, in the canton of St Gall, stands in the wild valley of the Tamina, 31 miles E. of St Gall. It is chiefly remarkable for its hot baths, which are situated in a deep, narrow chasm, through which the Tamina forces its way. The mineral water, which has a temperature of about 100° Fahr., is used both for bathing and drinking, and has great reputation, though it contains but a small proportion of saline particles. The baths are capable of accommodating 200 or 300 patients at a time. Pfeffers was the seat of a Benedictine abbey, which was founded in 713, but suppressed in 1838; and the buildings are now used as a lunatic asylum. Pop. 1315.

PFORZHEIM, a town of Baden, circle of Middle Rhine, near the confluence of the navigable river Enz with the Nagold and Würm, 16 miles S.E. of Carlsruhe. It is an ancient city, inclosed by a wall and moat, outside of which are several suburbs. Pforzheim has an ancient castle, on a rising ground, the church of which contains many interesting monuments, as well as the graves of the grand dukes of Baden. There are other churches, an academy, a deaf-and-dumb institution, hospital, and other charitable establishments. Pforzheim is at present the most important manufacturing town in Baden. Watches, jewellery, cloth, leather, chemical products, and hardware are manufactured; and there are also dye-works, bleachfields, and iron and copper foundries. An active trade is carried on in timber and oil. Pforzheim was the birthplace of the celebrated Reuchlin, the patron of Melanchthon. Pop. 7951.

PFULLINGEN, a town of Würtemberg, circle of the Black Forest, stands on the Echatz, in a beautiful valley at the foot of a mountain, 3 miles S.E. of Reutlingen. It contains a castle and two large paper-mills. Weaving and lace-making are carried on; and wine and vegetables are raised in the vicinity. Pop. 4300.

PHÆDO, a native of Elis, was the founder of the Eliac sect of philosophy, and the person whose name Plato inscribed in one of his most celebrated Dialogues. The exact date of his birth and death is unknown, but he flourished B.C. 399. By the fortune of war he was taken prisoner, and reduced to a state of slavery. He was brought to Athens, where he became known to Socrates, who admired his talents so much that he induced Alcibiades or Crito, or, according to others, Cebes, to release him from servitude. He then became one of the most devoted attendants on his benefactor. It appears that he was not at all satisfied with the manner in which he was introduced by Plato into his dialogue; and he used to declare publicly that he had never spoken in that way, and that he had never heard Socrates use the language which Plato put into his mouth. He composed several Dialogues, the titles of which were, Zopyrus, Simon, and several which it was doubtful if they belonged to him; Nicias; Antimachus; Medus, ascribed by some to Æschines, by others to Polyænus; Sythici Sermones, ascribed also to Æschines; and three others quoted by Suidas. (Diogenes Laertius's *Life of Phædo.*)

PHÆDRUS, the author of five books of Fables, in Latin iambic measure, was a native of Thrace or Macedonia, and brought at a very early age to Rome, where he became the slave of Augustus, and from whom he subsequently received his freedom. The few facts that we know respecting his personal history are to be collected from his Fables, as he is noticed by no earlier writer than Avianus, unless, perhaps, Martial may allude to him in one of his epigrams (iii. 20). If he really existed at this early period, it is strange that he should have been unknown to Seneca (*Cons. ad Polyb.* 27). By his long residence at Rome, Phædrus acquired a complete acquaintance with the language, and wrote it with as much ease as he could have done that of his own country. In the reign of Tiberius, he excited the wrath of Sejanus, and was banished by him, though for what cause we are nowhere distinctly informed. Under Caligula we find him in hopes of being re-instated in his position at court, through the influence of Eutychus. Part at least of these Fables must have been written in the latter years of the poet, and not published till after the death of Sejanus. Schwabe, who has examined this point with great diligence, thinks that the first two books were written after the departure of Tiberius to Capreа, the third under Caligula, and the fourth and fifth under Claudius. One part of these Fables consists of very happy translations of the Greek Fables of Æsop into the Latin language, or imitations of them in verse, similar to that employed in the translations. The other part seems to have been orginal, or at least we have no longer the writers from whom he borrowed his subjects. The style is pure, the language remarkably correct, and the whole is written with simplicity and ease. Yet many have doubted whether these fables can be considered as the genuine productions of Phædrus, the freedman of Augustus, as we have so few manuscripts of the work, and as Seneca was evidently unacquainted with it. Some ascribe them to the pen of Nicolaus Perotti, Archbishop of Manfredonia, who lived about the middle of the fifteenth century; but, in later times, the discovery of some manuscripts, one of which is considered as of the tenth century, has proved the incorrectness of such a supposition. The best edition of the works of Phædrus is that by J. C. Orelli, Zurich, 1831, 8vo. The English translations of Phædrus are as follows:—Philip Ayres (1689), Thomas Dyche (1715), Dan. Bellamy (1734), Anonymous (1745), John Entick (1754), "A Gentleman of the University of Cambridge" (1755), Christopher Smart (poetical translation, 1765), Francis Fowke (1776), H. T. Riley, with C. Smart's metrical version in "Bohn's Classical Library" (1853).

PHAËTHON (Φαέθων, the *shining*), was, according to the most common account, the son of Helios and Clymene, one of the Oceanides, and wife of Merops. Fired by vanity and ambition, the youth had the presumption one day to request his father to allow him to drive the chariot of the sun across the heavens. Helios, after much solicitation from Clymene in her son's behalf, at last yielded; but the audacious lad not having strength sufficient to control the fiery coursers, slackened the reins, upon which Zeus, to prevent his consuming the heavens and the earth, smote him with a thunderbolt, and hurled him from his seat into the River Eridanus or Po. His sisters, called by some *Phaëthontiades*, and by others *Heliades*, who had yoked the horses to the chariot, and who now lamented his loss on the banks of the fatal river, were metamorphosed into poplars, and their tears converted into amber.

PHALANX, in Greek military organization, a close, compact mass of infantry drawn up in files, usually of eight deep (Thuc. v. 68); butt he depth was increased by the Thebans to twenty-five (Thuc. iv. 93). The pha-

lanx was subsequently brought to perfection by Philip of Macedon. But for further details of this celebrated military formation, see ARMY.

PHALARIS, a tyrant of Agrigentum in Sicily, known to fame for his cruelty and inhumanity, but of whom little is definitely known. Ancient writers are not agreed as to the precise period when he began to reign, but Eusebius fixes the commencement of it B.C. 570, and his death B.C. 555. His father's name was Leodamas, a native of Astypalæa, an island in the Ægean Sea, where Phalaris was born. A dream of his mother is said to have prognosticated the cruelty of her unborn son. (Cic. *Div.* i. 23.) When he was grown to manhood, he made an attempt to seize upon the government of his native country, but was obliged to fly. He took refuge at Agrigentum, where he contrived to ingratiate himself with the people, and by a stratagem (Polyæn. v. 1) got possession of the supreme authority, which he exercised at first with much moderation. The Agrigentines, however, refused to submit quietly to his sway, and Phalaris found himself obliged to maintain by severity that power which he had so unjustly acquired. It is not unlikely that the ancients gave an exaggerated account of his cruelties, with a view of inspiring a hatred of tyranny. Athenæus speaks of his roasting children alive, and Aristotle states that he actually ate them; but such accounts can scarcely be credited. Perillus, an Athenian artist, is said to have constructed a brazen bull, in which the victims of Phalaris might be roasted; and when he expected to have been highly rewarded, the tyrant ordered him to be shut up in his own horrible machine. This story was doubted by Timæus (*Schol. Pind. Pyth.* i. 185), but Diodorus Siculus asserts its truth (xiii. 90, xix. 108). When Agrigentum was taken by the Carthaginians, they carried the bull to Carthage, and when that city was destroyed by Scipio Africanus, B.C. 146, it was presented by him to the Agrigentines. (Cic. *Verr.* iv. 33.) Authors are not agreed as to the mode of his death, but the most probable opinion is, that the Agrigentines, tired of his cruelties, stoned him to death. (*Off.* ii. 7.) We possess a collection of letters under the name of Phalaris, which Charles Boyle, who has edited them, tries to prove the genuine productions of the tyrant; but there can be no doubt that they were written by some of the later sophists, and that Bentley was right in pronouncing them "a fardle of common places." They were published for the first time by Justinopolitanus, at Venice, 1498, in 4to. The best editions are those of Oxford, 1695, 1718, in 8vo, with a Latin translation, notes, and a dissertation of Boyle on the life of Phalaris; that of Groningen, 1777, in 4to, which was begun by Lennep, and finished by Walkenaer; and, above all, that of Schæfer, Leipzig, 1823. The Epistles of Phalaris have been repeatedly translated into Italian, French, and English. (See the Dissertation of Dodwell, *De Ætate Phalaridis;* and the Answer of Bentley.)

PHALGU, or PHALGOO, a river of British India, in the presidency of Bengal, is formed by the confluence of the Mehanee and Lilajun, two mountain streams, in the district of Ramgurh; flows through that and the district of Behar, first N., and then E.; and finally falls into the Ganges, after a course of about 246 miles. During the rainy season it has a great volume of water, which rushes with great velocity; and the numerous branches which it sends out on both sides are filled, and partially inundate the neighbouring country. The name Phalgu is properly applied only to 25 miles of its middle course, where it is considered sacred; the lower portion is known by the name of Mehanee, and the upper by those of Julwara and Kuthor.

PHANTASMAGORIA. See OPTICS, part ix.

PHARISEES (*Gr.* Φαρισᾶιοι, derived from the Hebrew *parash*, to separate), the most celebrated of all the Jewish sects. As their name implies, they were separated from all others by the assumed correctness of their opinions and the holiness of their lives. The precise origin of the sect is not known. That they, however, as well as their natural opponents, the Sadducees, existed in the priesthood of Jonathan,—that is, between 159 and 144 before Christ,—is known from Josephus, who (*Antiq.* xiii. 5) makes mention of them as well as of the sect of the Essenes. The terms he employs warrant the conviction that they were then no novelties, but established religious parties.

The same historian (who was himself a Pharisee, and who says they were "of kin to the sect of Stoics, as the Greeks call them") further describes them in the following terms:—"The Pharisees have delivered to the people a great many observances by succession from their fathers, which are not written in the law of Moses, and for that reason it is that the Sadducees reject them, and say that we are to esteem those observances to be obligatory which are in the written word, but are not to observe what are derived from the tradition of our forefathers. Hence great disputes. The Sadducees are able to persuade none but the rich, and have not the populace obsequious to them, but the Pharisees have the multitude on their side." (Joseph. *Antiq.* xiii. 10.) "The Pharisees live meanly, and despise delicacies in diet; and they follow the conduct of reason, and what that prescribes to them as good they do. They also pay respect to such as are in years; nor are they so bold as to contradict them in anything which they have introduced; and when they determine that all things are done by fate, they do not take away from men the freedom of acting as they think fit, since their notion is, that it hath pleased God to make a constitution of things whereby what He wills is done, but so that the will of man can act virtuously or viciously. They also believe that souls have an immortal vigour in them, and that under the earth there will be rewards or punishments, according as men have lived virtuously or viciously in this life. The latter are to be detained in an everlasting prison; but the former shall have power to revive and live again: on account of which doctrine they are able greatly to persuade the body of the people; and whatsoever is done about divine worship, prayers, and sacrifices, is performed according to their directions, insomuch that the cities gave great attestations to them on account of their entire virtuous conduct." (Joseph. *Antiq.* xviii. 1. 3.) "The Pharisees say that some actions, but not all, are the work of fate (εἱμαρμένη); that some of them are in our own power, and that they are liable to fate, but are not caused by fate" (Joseph. *Antiq.* xiii. 5. 9). "The sect of the Pharisees are supposed to excel others in the accurate knowledge of the laws of their country" (Joseph. *Vita.*, sect. 38). "The Pharisees have so great a power over the multitude, that when they say anything against the king or against the high-priest, they are generally believed" (Joseph. *Antiq.* xiii. 10. 5). "The bodies of all men are mortal, and are created out of corruptible matter; but the soul is ever immortal, and is a portion of the divinity that inhabits our bodies." (*De Bell. Jud.* iii. 8. 5.)

There is another source of our knowledge of the Pharisees—the books of the New Testament. The light in which they here appear varies, of course, with the circumstances to which its origin is due. The Gospels present the character of the Pharisees in a darker hue, inasmuch as here a higher standard of morality is brought into use. Here they are charged continually with the worst forms of pride, hypocrisy, avarice, and sensuality. At an early period they determined in the Sanhedrim to withstand and destroy Jesus, instigated doubtless by the boldness with which he taught the necessity of personal righteousness and pure worship. (Matt. xii. 14.)

Stäudlin, in estimating the character of the Pharisees, has the following remarks:—"The Pharisees held anxiously to the decisions of the holy writings and the older Jewish

teachers. Thus their whole system was built upon authority, and their morality was changed into a casuistry, like that of the Jesuits. To every event that happened they knew how to apply either a passage of the sacred books or an explanation of the same, or a corollary, an inference, an arbitrary extension or restriction. On this account nothing is more pitiable or more ridiculous than their exegetical theology, whence their system of morality became uncertain and unconnected, without general principles, life, and spirit. Thus arbitrariness and ingenuity, instead of reason and solidity, were applied to morals; and to a party which assumed, and by its nature must assume, dominion over the minds of men, the temptation was often too great to accommodate their principles to the passions of men, and to use for the same purpose their casuistry, dependent on authority, which so easily lent itself to this end. The persecutions of Antiochus Epiphanes, the opposition of the Sadducees, bound them only the more to their old precepts and method of teaching, and filled them with an ever-living opposition to every Gentile doctrine and custom. They considered themselves the more as the only genuine and pure Israelitish teachers of religion; they preserved the reverence for the holy books which had been of old widely spread among the people; and, aided by their principles, which were in fact very rigid, they could not fail to gain with the people a reputation for superior holiness. The greater this reputation became, the greater was the temptation to hypocrisy. The more rigorous were their principles, the more difficult was it to act entirely up to them, and the easier were they led to observe that with a holy *appearance* they could attain the power of imposing on the mass of the people and of ruling over them. This dominion of the Pharisees over the minds of the people was nourishment for their pride, and incentive enough to use it for selfish purposes. Like cunning priests and Jesuits, they played with forms and phrases, they seized a place in the hearts and consciences of men, corrupted them even by means of pious instruction, led them whither they would have them go, acquired many a fair prize, and became rulers of an earthly kingdom of darkness. (Staudlin, *Sittenlehre*, i. 431.)

We are not to suppose, however, that there were no individuals in the body free from its prevailing vices. There did not fail to be upright and pure-minded men, who united inward piety to outward correctness of conduct, and were indeed superior to the principles of their sect; such was Nicodemus (John iii. 1); such also Gamaliel may have been (Acts v. 34). Of men of this kind many were led to embrace the Gospel. (Acts. xv. 5.) In the time of our Lord there were two leading parties, that of Hillel and that of Schammai, the former representing a moderate Pharisaism, the latter "the straitest sect," to which Paul had probably belonged. (See *Trium Scriptorum Illust. de tribus Judæorum Sectis Syntagma, in quo R. Serarii, J. Drusii, J. Scaligeri opuscula cum aliis exhibentur*, found in Ugolini's *Thesaurus*, vol. xxii.; also Stäudlin's *Sittenlehre Jesu*, i. 417, sq.; Beer, *Gesch. Lehren in Meinung. aller relig. Sect. der Juden*, Brunn, 1822; and Tholuck, *Comm. de vi quam Græca Philosophia in Theologiam tum Muhamedanor. tum Judæor. exercuerit*, Hamb. 1835–7.)

PHARMACOPŒIA (φάρμακον, *a drug*, and ποιέω, *I make*), a book containing directions for the preparing and compounding of medicines. Such books are usually published under the sanction of the colleges of physicians or surgeons in the different nations of Europe.

PHARMACY (φάρμακον, *a drug*), the art of preparing and compounding substances to be employed for medicinal purposes.

PHARNABAZUS, a Persian satrap, succeeded his father Pharnaces, in the government of the Persian provinces near the Hellespont. He first appears in history as a devoted ally of the Spartans during the Peloponnesian war. His troops assisted them in capturing Abydos and Lampsacus in 411 B.C.; his aid was effectual in sheltering them after their defeat at Cyzicus in 410 B.C.; and for his attachment to their cause his province was ravaged by Alcibiades in 409 B.C. Yet, after a lapse of time, the course of events placed Pharnabazus in hostile opposition to his former friends. In 396 B.C. he defeated an invading Spartan force under Agesilaus II. In the following year he was routed in turn by that monarch. The conflict thickened immediately afterwards, when the Athenian Conon came to his aid. The two leaders in command of a fleet scoured the Ægean, expelling the Lacedæmonians from the maritime towns, until, in 393 B.C., they had overwhelmed all resistance. The rest of the life of Pharnabazus is involved in considerable obscurity. His unsuccessful expedition into Egypt, in conjunction with the Athenian general Iphicrates, in 377 B.C., is the last action of his on record.

PHAROS, a long and narrow rock, lay off the northern coast of Egypt, at the distance of 7 stadia from the ancient town of Alexandria. In early times it was merely occupied by the huts of a few fishermen. Yet no sooner had the adjacent city been founded, in 332 B.C., than the island began to assume importance. Alexander the Great turning it into a breakwater for the harbour of his new capital, connected it with the mainland by the *Heptastadium*, or Seven-Furlong Mole. Ptolemy I. began to build on its N.E. point the lighthouse of Pharos, which became one of the wonders of the ancient world. (See LIGHTHOUSES.) Meanwhile its population was steadily increasing. At length a street of houses extending along the mole formed it into a suburb of Alexandria. Pharos retained some of its importance till the time of Julius Cæsar. After that period it degenerated once more into a mere fishing station.

PHARSALUS (the modern *Férsala*), a city of Thessaly, was situated in the district of Thessaliotis, on the left bank of the Enipeus. Its position was peculiarly favourable. A gradually ascending hill, 600 or 700 feet high, formed its site; a steep precipice guarded it on three sides; numerous springs flowing out of the declivity supplied it with water; and one of the most fertile valleys in Greece lay around its base. Accordingly, from the earliest days of Grecian history, up to the time of the Romans, it was renowned as a seat of military strength. Yet Pharsalus attained its greatest notoriety when, in 48 B.C., the two stars of Cæsar and Pompey came into collision in its neighbourhood, and the fate of the world was decided in the plain below its northern wall.

PHENEUS, an ancient town in the N.E. of Arcadia, stood on an eminence in the middle of a plain which was 7 miles square, and which was inclosed on all sides by the offsets of Mount Cyllene and of the Aroanian chain. It derived its chief celebrity from the neighbouring river Olbius or Aroanius (the modern *Foniatiko*). That stream, after being formed by torrents from the northern mountains, began to flow through the plain in a straggling and undecided course. To collect all its waters into one bed, Hercules, it is said, dug a canal which was 50 stadia in length and 30 feet in breadth. The impatient flood, however, after a lapse of time, broke out of this artificial channel and resumed its former wanderings. At an advanced point of its course, finding its passage blocked up by mountains, it escaped into subterranean channels called *katavothra*, and gurgled under ground until it came upon the bed of the Ladon. Sometimes it happened that these channels became choked. The waters were then dammed up until they swamped the whole plain, and rose to a considerable height within the rocky basin. When at length they forced away the obstruction, they rushed along their former course, flooding the Ladon and the Alphæus to overflowing. Such an inundation occurred so recently as 1821, and continued till 1832. The

remains of Pheneus are still seen near the village of *Fonia.*

PHERECRATES, an eminent writer of the old comedy, was a native of Athens, and contemporary of Plato, Aristophanes, Phrynichus, and Eupolis. According to Suidas, he was a soldier in his youth, but afterwards attached himself to the stage, and became one of the most successful dramatic writers. We know that he exhibited a play entitled "Savages" (Ἄγριοι), B.C. 420 (Plato, *Protag.* 327, d.; Athen. v. 218, d) He invented a species of verse, called from his name Pherecratean, consisting of a spondee and the two last feet of an hexameter line. Suidas attributes seventeen plays to him, referring probably to those only which he considered as genuine, since the titles of twenty are found in Athenæus. The fragments of Pherecrates have been collected by Hertel in *Vetustissimorum Comicorum Sententiæ*, p. 340–57; and by Runkel, Leipzig, 1829. Of all the fragments of Pherecrates, the most remarkable is that entitled "Cheiron," in which he introduces music clad in rags, to which state she says she has been reduced by Melanippides, Phryoris, and Timotheus, the authors of some innovations on that art.

PHERECYDES, a Greek philosopher of the island of Syros, one of the Cyclades, was the son of Badys, and the pupil of the celebrated Pittacus, of Mitylene. The exact date of his birth and death is unknown, but he flourished B.C. 544, being a contemporary of Thales, Anaximenes, Anacreon, and Hipponax. There is some doubt whether he is not the astronomer Pherecydes who constructed a sun-dial at Syros; but as this person is said to have been the master of Thales, it is more likely that there was another of an earlier date. The philosopher was the instructor of Pythagoras, and is said to have foretold earthquakes by observing the movement of water in wells (Cic. *Tus.* i. 16; *Div.* i. 50). There were various accounts respecting his death, but most are agreed that he was devoured by worms and insects like Sylla; and the reason assigned was, that he had offended Apollo, because he said that he lived very happily though he had never sacrificed to the gods. (Ælian. *V. H.* iv. 28.) Pherecydes was the author of a work on Nature and on the Gods, being the first of the Greeks who wrote on this subject. (Diogenes Laertius, *Life of Pherecydes.*) The fragments of Pherecydes have been collected by August Wolf, in the first part of his *Litterarische Analecten*, Berlin, 1817.

PHERECYDES, an historian or logographer of the island of Leros, in the Ægean Sea, is satisfactorily proved by Vossius (*De Hist. Græcis*, p. 444) to be the same who is called an Athenian by some. He flourished B.C. 480, in the reign of Darius Hystaspes, and preceded Heredotus by a few years. He is said to have made a collection of the poems of Orpheus, to have written on the genealogy of the gods (*Theogoneia*) in ten books, on the mythological part of the history of Athens (Ἀυτόχθονες) in ten books, and moral maxims in hexameter verse. The fragments of Pherecydes, along with those of Acusilaüs, have been published by Sturtz, Gera, 1789, 1798, 1824; also by C. and Th. Müller, in *Fragmenta Hist. Græcorum*, with a learned dissertation.

PHIDIAS, was the son of Charmidas, and was born about 490 B.C. The facts regarding his education are few and detached. But knowing the result of his training, we can in a general way infer its character, and thus eke out the scanty narrative. He began to study sculpture under a certain Hippias, supposed by some to be the well-known Hegias; and then under Ageladas of Argos. Nor, while under their instruction, did he content himself with a servile observance of stereotyped rules. His bold and vigorous genius pursued his art into all its relations with other arts and sciences. He acquired an experimental knowledge of painting and pictorial effect. He was not unacquainted with the principles of architecture. There was scarcely a department of general information into which his investigating mind did not wander. At the same time his soul kindled its ardour, and nursed its creative energies, by frequent contact with the great genius of Homer. Under such an invigorating discipline it was natural that new and enlarged views of the sculptor's art should dawn upon the mind of Phidias. Accordingly, he began to repudiate the prevalent custom of taking a common-place figure, and then representing it in an attitude stiff and affected, and with a garment falling into formal geometrical lines. The legitimate subject, he thought, should be one of the most perfect specimens of human nature as viewed by an imaginative mind. The bearing ought to be easy and dignified, and the drapery ought to flow in the free and ever-varying folds of nature. Especially in the statues of the gods was it necessary for the sculptor to rise above the dull level of ordinary life. No dimensions could be too grand and imposing to body forth ineffable power; no materials could be too costly to represent immortal health and beauty; no draperies could be too variegated and elaborate to imitate the gorgeous dresses of the court of heaven. Imagination should rise to its highest efforts in the conception, and art should lavish all its resources in the execution. These elevated and catholic principles Phidias set himself to establish. He carried them into practice in a gold and ivory statue of Minerva at Pellene, in a group of bronze statues at Delphi, and in several other works which he executed. He also inculcated them upon a number of pupils; and thus, in course of time, overturned the old, and established a new school of sculpture.

About 444 B.C., Phidias, in the full maturity of his genius and fame, entered upon the brightest part of his career. It was then that the great Pericles chose him for his coadjutor in the high task of raising Athens to the very climax of beauty and magnificence. Appointed overseer of the public works, the sculptor was employed in superintending the erection of the edifices on the Acropolis. The architects Ictinus and Callicrates, several painters, and many artificers all worked under his inspection. He himself designed the numerous sculptures, assigned them to his pupils and to other sculptors to be executed, and frequently gave them the last polish with his own exquisite chisel. Under the busy hands of so many workmen, the Parthenon rose up perfect in form, and enriched with every kind of decoration and device. To complete the general effect and put the finishing stroke upon this great enterprise, the superintendent himself executed, among other images, two colossal statues of Pallas, the presiding genius of the place. The one, a bronze statue, represented the goddess in her warlike character, and was called, on that account, the *Athene Promachos*. Stationed on a pedestal on the summit of the Acropolis, and rising out from among the surrounding architecture, until she overlooked a great part of Attica, she kept guard over the city in the attitude of a combatant. Her left arm extended a shield, and her right hand brandished a spear, as if ready to hurl destruction at any daring invader. Still more imposing was the statue of the same divinity which stood within the Parthenon. Her height was nearly 40 feet; her nude parts were made of ivory; and her drapery and ornaments were of solid gold. She now appeared in her character of the patron goddess of the city. The excited air of battle had given place to the settled attitude of calm deliberation. Her shield stood by her left side. Her spear stood against her left shoulder. A dragon lay coiled at her feet. With her left hand she leant upon her shield, and with her right hand she extended an image of victory. Nor were the decorations out of harmony with such a noble mien. A golden sphinx in the middle, and a golden gryphon on each side, adorned her helmet; a string of golden serpents formed the fringe of

her ægis; and a golden garment flowed down to her feet. On the outer side of her shield the Amazons fought with the Athenians; on the inner side the gods overcame the giants; and on the base which supported the entire work, Pandora received her graces and fascinations from the assembled divinities. In fact the eye of the spectator, while roaming over the grand statue, and passing from the grand statue to the magnificent expanse and painted and sculptured walls of the temple, could see nothing but what was beautiful and harmonious in the entire scene.

The fame of this great masterpiece was still ringing through Greece, when the Eleians, about 437 B.C., invited Phidias to finish and decorate their temple of Jupiter Olympius. Repairing to the plain of Olympia with his scholars, he set up his studio close beside the wall of the Altis, within hearing of the murmur of the sacred olives. In that quiet retreat he began to execute a gold and ivory statue of Jove 60 feet in height. After the lapse of four years the image was completed, was set up in the temple, and was found to surpass every other work of art that the race of men had ever yet witnessed. It was seen to be a striking embodiment of the Zeus of Homer. There, in awful state, and with the most stupendous proportions, sat the almighty king of the gods. There was the serene dignity of countenance which becomes the sovereign of the skies; there were the dark eye-brows and clustering locks whose motion shakes the spheres; there were the shoulders of strength which move and control the dread artillery of heaven. With his left hand he leant upon the sceptre of the universe, and with his right hand he extended a winged Victory. Nor did the imagination of the artist confine itself to the figure. It also lavished its creations upon the furniture and embellishments of the god. A chaplet of olive crowned his brows. A robe of solid gold, garnished with lilies and other flowers, swathed his limbs. Four golden lions supported his footstool. On the back of the throne, above his head, appeared the Hours and the Graces. At each corner of the throne a Victory danced upon a sphinx that was tearing a Theban youth. The cedar throne itself was bespangled with ebony, ivory, gold, and precious stones; and displayed painted and sculptured representations of the destruction of Niobe's children, the contests of Hercules, and other exploits of the heroic age. On the base which supported the entire fabric appeared sculptured figures of the deities in gold, and the interesting inscription—"Phidias, the Athenian, son of Charmidas, made me." So dazzling and sublime indeed, was the general effect, that the Jupiter Olympius became the wonder of the world. Its almost superhuman magnificence threw all succeeding artists into despair, and absolutely set at defiance all competition. It seemed, according to an old epigrammatist, as if Phidias had either ascended to heaven to see Jove, or Jove had descended to earth to sit to Phidias. Some visitors even felt themselves to be in the real presence-chamber of the Thunderer, and expected to see him rise from his throne, and throw off the roof of the temple with his mighty head and shoulders.

Filled with satisfaction at his unparalleled success, Phidias returned to Athens in 432 B.C., only to meet an end which was fearfully discordant with his peaceful and illustrious career. The aristocratic faction were then indirectly aiming at Pericles by attacking the intimate friends of that democratic leader. The old sculptor, as a notable associate of the great statesman, was immediately doomed to persecution. A certain Menon, who had worked in the capacity of an underling at the Parthenon, accused him of having appropriated the gold intended for the garment of Minerva. Even after this charge had been triumphantly refuted by Phidias, who had taken the precaution of fixing on the drapery of the goddess in such a manner that it could easily be unloosed and weighed, his persecutors did not desist. They arraigned him for having inserted his own portrait and that of Pericles in the representation of the battle between the Athenians and the Amazons on the shield of the same statue. This accusation was sustained, and before the year was closed, the ill-requited Phidias died in prison.

The only extant works which retain any traces of the delicate chisel of Phidias are the sculptures which have been recovered of late years from the ruins of the Parthenon. The finest specimens of these were transferred to England by Lord Elgin in 1803, were deposited in the British Museum in 1816, and are now known by the name of the "Elgin Marbles." (In addition to the ordinary histories of ancient art, see Smith's *Dictionary of Greek and Roman Biography;* and Müller's *De Phidiæ Vita et Operibus*, Gottingen, 1827. Quatremère de Quincy, in his *Jupiter Olympien*, and Flaxman, in his *Lectures on Sculpture*, have attempted, with the aid of the descriptions of ancient authors, to give drawings of the Minerva of the Parthenon and of Jupiter Olympius.)

PHIGALIA, or PHIALIA, an ancient town of Arcadia, stood near the confines of Messenia, on the right bank of the small river Neda (*Buzi*). It is famous in history for several contests in which it maintained its liberties against the Spartans. But its chief celebrity is derived from a temple which stood about 40 stadia N.E. from the city on Mount Cotilium. That temple, a peripteral edifice of the Doric order, was erected by Ictinus, one of the architects of the Parthenon at Athens, and was dedicated to Apollo Epicurius, in gratitude for the cures effected by that god during the Peloponnesian war upon the plague-stricken citizens. The hard yellowish-brown limestone which composed its walls and roof rendered it singularly durable. In the times of Pausanias, it was considered the most perfect, with one exception, of all the temples in the Peloponnesus. It continued to remain entire long after the world had lost all knowledge of its existence. Modern scholars discovered it in a state of good preservation, standing deserted among a few aged oaks on the wild and desolate mountain-side. When the ruins were cleared away in 1812, there were found some fine sculptured representations of the contests between the Centaurs and the Lapithæ, and between the Amazons and the Greeks, which are now in the British Museum.

PHILADELPHIA, the second city in size and importance in the United States, is situated on the west bank of the Delaware river, in the south-eastern part of the state of Pennsylvania, 96 miles from the sea by way of the river and bay of Delaware, 136 miles N.E. of Washington, and 86 miles S.W. of New York. The geographical position of the Old State House, which is nearly in the centre of the city, is 39. 57. N. Lat., and 75. 9. W. Long. The Schuylkill river passes through the western part of the city, and enters the Delaware 6 miles S. of the centre of the city proper.

The closely-built portion occupies an area 4 miles in length N. and S., and from 2½ to 4 miles in width from E. to W., or about 12 square miles. The Delaware front is built along a curved line of 4 miles in length, the north-eastern part of the city lying eastward of the central water front. A line through the city at the narrowest part between the two rivers is a little more than 2 miles, but W. of the Schuylkill at this point nearly a square mile is built up, called West Philadelphia. North-westward the city now extends 3½ miles from the City Hall, and still further in that direction along the Schuylkill is the large suburb of Manayunk, 7 miles from the City Hall. Germantown, still larger, is 6 miles N.N.W., and Frankford 5 miles N.N.E. of the same point. A large number of smaller suburban villages occupy the intermediate space, all of the area embraced by the county of Philadelphia being now within the corporate limits of the city. Before the act of consolidation in 1854, the city proper occupied a space 1 mile in

extent N. and S., and 2 miles E. and W., between the two rivers. The districts of Southwark and Moyamensing at the S., and of Kensington, Spring Garden, Penn Township, and Northern Liberties, at the N., each with a distinct municipal government, completed the organization of the occupied portions. But as all the area was densely and uniformly built upon, the whole was consolidated as the city of Philadelphia in 1854; and the whole county formerly so called, covering 120 square miles, was embraced in the corporate limits. Camden and Gloucester in New Jersey, across the Delaware river, are really part of the city also, and contain 20,000 inhabitants.

The plan of the city, as laid out by Penn, is remarkably regular, 10 streets being laid E. and W., and 25 streets N. and S., crossing the first at right angles. The subsequent extensions of its limits have in most cases been equally regular. The greatest street E. and W. is High or Market Street, 100 feet wide; and Broad Street, N. and S., is 113 feet wide; the remaining principal streets being 50 to 66 feet in width. Five squares, in central positions and equidistant, were reserved for parks in the original plan of the city, to which Independence Square has since been added, near the State-House, and several squares in the newer parts of the city, with pleasure-grounds and parks, are now in preparation.

The surface occupied by the city is remarkably level, rising, however, in the northern suburbs, into hills of 90 to 150 feet above tide. Between the rivers the plain rises regularly about 45 feet above tide; but from most points of view the city and site appear a perfect plain. The Fairmount Reservoir, 100 feet high, and the Girard College Observatory, 160 feet high, afford the best views. In the original condition of the Delaware front, a stream, in which shipping could lie, intruded into the city along the space now built over as Dock Street; and a bluff bank along the Delaware was designed as a broad, open levee. This was densely built upon after Penn's death. The streets are well paved with granite blocks for the principal business streets in the eastern part, and with rubble stone generally; the sidewalks being mostly brick, with some flagging of sandstone. Drainage to both rivers is easy; and the subsoil is gravel, facilitating cleanliness and dryness. No American city has so great an extent of clean, well-paved, and well-kept streets, capable at any moment of being flooded from the water reservoirs, and perfectly drained by the sewers.

The predominating material for building is brick, with, in houses of three and four storeys, marble facings. Within a few years greater variety in styles and material has been introduced; and marble, sandstone, and iron have been largely used. The great business streets—Market, Chesnut, and Walnut Streets—now exhibit very fine buildings for business purposes, erected within ten or fifteen years. These streets are now rapidly becoming occupied, westward from the Delaware, by the finer buildings of this character; while elegant buildings for residences are extending west of Broad Street and in the northern part of the city. Several superior marble structures were erected many years since in the older part of the city. The first United States bank, now the Girard Bank, is of marble, in Corinthian style, erected in 1797. The second United States bank building in Chesnut Street, now the custom-house, is a noble specimen of Doric architecture, which, at the time of its erection, cost L.100,000. The United States Mint, farther west in Chesnut Street, is a fine marble building in the Grecian style. The State-House, mostly of brick, and having no high pretensions to architectural beauty, occupies a central square in Chesnut Street, and is the principal point of interest to strangers, in consequence of its historical association, the provincial Congress having held its sessions here. The national independence was declared here, July 4, 1776, and for the greater portion of the time subsequently to the year 1800, the national government remained here. Most of the buildings are now occupied by the various departments of the city government, the Hall of Independence alone being unused, and kept as a place for the preservation of historical relics. Girard College is a magnificent marble structure of Grecian architecture, about 2 miles N.W. of the City Hall. A colonnade of 34 Corinthian columns, 6 feet in diameter, and 55 feet high, surrounds a cella 169 feet long by 111 feet wide; the whole forming a building 218 feet long by 160 wide, and 97 feet high. The whole, with the roof, is of white marble; and this one building cost at its erection L.200,000. The inclosing wall contains 41 acres, and the embellishments, with the remaining buildings of this great charity, cost L.194,546 more. Among the recent buildings are superb banks, churches, hotels, and mercantile structures, built of marble, granite, sandstone, and iron. The Academy of Music, a new sandstone building, is the largest opera-house in the United States, being 238 by 140 feet. Several fine structures are devoted to charitable and scientific purposes; among them the Pennsylvania Hospital, the Blockley Almshouse, the United States Naval Asylum, the Franklin Institute, the Athenæum, the Philadelphia and Mercantile libraries, &c.

The city is well supplied with water and gas. The Fairmount Water-Works, on the Schuylkill, elevate 1,500,000 gallons in twenty-four hours 92 feet, to reservoirs constructed on a rocky bluff, from which the greater part of the city is supplied. Separate reservoirs, into which water is elevated from the Schuylkill and the Delaware by steam-power, supply the northern part of the city. The Fairmount works cost L.687,500, and the others about L.83,000. Gas is supplied to every part of the city by extensive public works, in one of which there is a gasometer 140 feet in diameter, and in another, one 90 feet high and 160 feet in diameter, with others of less size.

The charitable institutions of the city are, first, the Pennsylvania Hospital, centrally placed, but with a branch for the insane 2 miles distant. Both departments together have relieved 65,000 patients since their foundation in 1752; both occupy extensive buildings, those in the city covering a fine square, and being kept in superior order. Ten medical men are in daily attendance, four of whom are surgeons. There are four dispensaries in the city, the Pennsylvania Institution for the Instruction of the Blind, a lying-in charity, a widows' asylum, an orphans' asylum (a temporary house of great usefulness), the Pennsylvania Deaf-and-Dumb Asylum, a city pest hospital, three Magdalen asylums, a coloured orphans' asylum, a home for friendless children, and a large number of other noble and special charities.

Institutions of learning are numerous: the Girard College for orphans has 7 professors and 500 beneficiaries; the university of Pennsylvania, 12 professors, 129 literary and 450 medical students; Jefferson Medical College has 514 students; Pennsylvania College, 160 students; and several less important colleges exist. The scientific societies embrace the American Philosophical Society, the oldest and most distinguished in the United States, with a large library, and high historical associations; the Academy of Natural Sciences, with a fine building and valuable collections; the Franklin Institute, which has a library and building, and publishes a monthly journal; the Athenæum, and others. The educational system of the city is organized separately from that of the state generally; a system of graduated schools being established, with a high school of collegiate grade at the head, to which all may aspire. There were in 1857, 157 primary, 47 secondary, 45 unclassified, 55 grammar, one normal, and one high school, in this system; a total of 306 schools, with 57,521 pupils, and 78 male and 877 female teachers. In the High School there are

10 professors and 534 pupils, and it has had at an average over 500 pupils since its foundation in 1838. The total cost of this system for 1857 was L.100,963. It is under the direction of a body of comptrollers, 24 in number, one being elected from each ward. There are many private schools of high rank, and a very large number are sustained by religious and other associations.

The manufacturing industry of the city is more extensive than that of any other in the United States, at least one-half its population of 600,000 being so supported. By the census of 1850, there was reported as employed in manufactures as capital, L.7,028,731; and as labourers, 43,296 men, and 15,803 women; yielding products valued at L.13,357,106. Investigations subsequently undertaken by the Board of Trade and others interested in the city, showed that many departments were greatly underrated by this census; and it is concluded that the total production for the year closing with June 1857, cannot be less than L.27,000,000. The leading manufactures are of cotton and woollen cloths and other textile fabrics, for which there are 98 factories within the city limits, working 3000 hand-looms, 7000 power-looms, 150 sets of wool cards, 750 cotton cards, 40,000 woollen spindles, and 135,000 cotton spindles. These establishments employ 8700 work-people, male and female, exclusive of the hand-loom weavers, and others outside the mills. The production of this department of manufacture for the year named was L.4,166,000; and the capital invested is calculated at L.5,800,000. The next in importance is the iron manufacture, which, in all its forms, employed 10,000 workmen within the city, and produced an aggregate value of about L.3,125,000 for the same year. The manufactures next in importance are, books and stationery, chemicals and drugs, manufactures of silver and the precious metals, clothing and hats, paper and paper-hangings, leather and manufactures of leather, malt and distilled liquors, &c., each of which makes up the value of one to two millions sterling annually. Carriages, furniture, glass and glass wares, mirrors and upholstery, &c., are also produced in large quantities. A very considerable amount of grain is here converted into flour for consumption and for exportation.

The commerce of Philadelphia embraces all the foreign commerce of the state, and is represented in the statistics given for PENNSYLVANIA. It has a water front on the Delaware of 4 miles in length, with a depth at the wharf line of 14 to 54 feet, constituting extraordinary capacity for shipping. Valuable wharf accommodation exists in the Schuylkill for more than a mile in length on the western side of the city. The shipping of the port of Philadelphia amounted to the following aggregates of registered and licensed tonnage for the years named:—

Years.	Tons.	Years.	Tons.
1850	206,498	1854	268,746
1851	222,429	1855	294,807
1852	229,443	1856	197,228
1853	252,451	1857	211,381

Lines of steam-ships run to New York, Boston, Savannah, Charleston, and other ports. One to Liverpool, established in 1851, was temporarily discontinued in 1857. A line of superior packet-ships to Liverpool was among the first lines from the United States to Europe, and it is now in the best condition of efficiency. A vast coasting trade is conducted from this port in coal, produce, and domestic goods. In 1852, 9993 vessels with coal left this port for the coasting and foreign trade; and in 1854, 8152 vessels, carrying 1,411,731 tons of coals, loaded at the suburb of Richmond; while 571,081 tons were taken from the Schuylkill wharves. An extensive trade to California exists, the exports thither in 1853 reaching L.461,500. The trade of this port with the West Indies and with South America now constitutes the largest department of its foreign commerce, except the Liverpool trade. Of the total value, L.3,718,880, imported in the year ending with June 1857, the following proportions were mostly tropical:—

Sugar	58,137,504 lb.,	value	L.651,351
Molasses	3,137,011 galls.,	„	164,631
Coffee	18,823,714 lb.,	„	371,410
Salt	1,101,567 bush.,	„	32,537
Tobacco and cigars	...	„	51,817
Indigo	47,037 lb.,	„	7,536
Tropical fruits	...	„	10,406

A very extensive internal trade is carried on by the canals and railroads leading to New York; by the great coal roads and canals reaching the city from the north; by the southern tow-boat and railroad lines; and by the Pennsylvania Central Railroad, and other lines to the west. Much of the import trade of the city enters the custom-house of New York, and the goods are brought over the New Jersey roads and canals without breaking bulk. Very large quantities of domestic exports are sent abroad by the same lines; and the apparent decline in the direct foreign trade and shipping of the port is but a transfer to the port of New York as a more convenient entrepôt. The actual export and import trade of the city of Philadelphia is rapidly increasing. The tonnage transportation of one internal line, the Pennsylvania Railroad, for 1857, was 92,660 tons westward, and 205,500 tons eastward; the first of package and dry goods mainly, and the second of hemp, wool, grain, and other agricultural produce. The great coal roads bring an immense tonnage, both for consumption and for exportation.

The consolidated city of Philadelphia is divided into 24 wards, two or three being mainly suburban, and embracing the area formerly called the county. The government is by a mayor, elected for two years; a select council of 24 members, elected for the same period; and a common council of 72 members, elected annually. The police organization is made up of one chief, 8 high constables, 16 lieutenants, 32 sergeants, 615 regular police, and 37 special officers and reserved corps—a total force of 708. There are 16 aldermen or police magistrates; the remaining judicial organization being that of the state.

The city possesses a very large productive property in water and gas works, real estate in fee and in trust, with stocks and bonds in addition to the value of L.2,190,000, only about half of which is at present fully productive. The aggregate debt of the city is L.4,168,500, for the larger share of which sinking funds are established, leaving but about L.730,000, for the interest on which provision is required to be made by taxation. The sum expended for all city purposes in 1857 was L.868,802; of which L.320,840 was for repayment of loans and for interest; L.87,284 for police; L.85,109 for highways, sewers, and bridges; L.54,916 for the poor; L.90,361 for administration of lighting and water departments; and L.100,872 for the support of the city public schools.

There are in Philadelphia 12 daily newspapers, 39 weekly newspapers, and 48 periodicals published monthly, bi-monthly, and quarterly. There are in the city 17 banks, with an aggregate capital of L.2,357,725, which had, June 1858, in specie, L.1,469,831; in circulating notes, L.497,476; and in loans and discounts, L.4,957,517. There are also 15 saving fund banks not issuing notes; 18 fire insurance companies chartered by the state; 29 fire and marine and fire and life, and 5 marine insurance companies. Most of the coal, iron, and navigation companies of the eastern part of the state have their offices in the city.

A system of city railroads was begun in 1857, which will soon supersede the local conveyance by omnibuses, for which over 600 vehicles were employed in 1857. The level nature of the city facilitates the construction of passenger railways, with cars drawn by horses; and ten distinct com-

panies are now chartered, and are placing railroad tracks along most of the principal streets, by which, at a cost not exceeding five cents, passengers are conveyed, in a low noiseless carriage, any distance within the city.

The population of Philadelphia exceeded that of any other America city previous to 1830. It is now second only to New York. The following were the numbers at the several decennial enumerations:—

1777	21,767	1810	96,287	1840	258,037
1790	42,520	1820	119,325	1850	408,962
1800	70,287	1830	167,325	1858 (calculated)	620,000

The increase in the number of voters and of taxable inhabitants indicates a larger population than that assigned for 1858. In 1850 there were 121,699 persons of foreign birth, of whom 72,312 were born in Ireland, 22,750 in Germany, 17,500 in England, 3291 in Scotland, and 1981 in France. The number of coloured persons was 19,761. At the election for president in 1856, 70,198 votes were cast, and at that for mayor in May 1858, 62,839.

PHILADELPHIA (the modern *Allahsher*), an ancient city in the east of Lydia, owed its origin and its name to Attalus Philadelphus, King of Pergamus. It was situated between the southern bank of the river Cogamus and the north-western side of Mount Tmolus. The city makes no small figure in history. Strabo narrates that it was famous for being frequently shaken by earthquakes. In the Apocalypse it is mentioned as one of the "seven churches of Asia." It was also notable in more modern times for holding out against the Turks till 1390, after all the other cities of Asia Minor had surrendered. The only remarkable remains of the ancient Philadelphia are the ruins of a church.

PHILÆ, an island in the river Nile, celebrated for its ancient ruins. (See EGYPT.)

PHILÆNI (*Φιλαίνοι, lovers, of praise*), two Carthaginian brothers, are celebrated in ancient legends for their patriotism. The following is the account of their exploits, as given by Sallust:—It happened that the Carthaginians and the Cyrenians were involved in a bloody and indecisive war regarding the boundary between their respective territories. At length, when they had nearly exterminated each other, without settling the dispute, they mutually consented to try a simpler mode. They agreed that, at the same moment of time, a pair of deputies should set out from Carthage to Cyrene, and another pair from Cyrene to Carthage, and that the spot where the two pairs should meet should be considered the boundary between the two countries. It was then that the Philæni, being chosen to represent Carthage, appeared in the characters of devoted patriots. Hastening eastward, and panting over the toilsome deserts with deathless ardour, they passed the middle distance, and meeting their opponents at a place far on the other side, claimed that advanced spot as the limit of their country's possessions. An altercation ensued; accusations of having started before their time were brought against them; but they remained immoveable. Their determination at last became so invincible that, rather than bate a step of ground, they consented there and then to be buried alive in the sand, and to make their graves the land-marks between the two nations. The fearful proposal was carried into execution; and long afterwards, two altars erected over their resting-place, and called the "altars of the Philæni," preserved their memory, and formed the boundary of the territories of Carthage.

PHILEMON, a Greek dramatist, who stands next to Menander among the poets of the new comedy, was born at Soli in Cilicia about 360 B.C., and settled in Athens at an early age. His career seems to have been singularly prosperous. The lively wit and practical good sense of his plays soon introduced him to popular favour. In many a dramatic contest, he carried off the palm from his abler rival Menander. He continued to write on, free from the troubles and ills of life, until he had produced ninety-seven comedies, and passed beyond the age of ninety. His sunshine even remained till the last, for he is said to have died laughing at a ludicrous incident. The few extant fragments of Philemon's plays are inserted in all the principal editions of Menander. (See MENANDER.)

PHILEMON, *Epistle to*. That this Epistle was written by the apostle Paul is the constant tradition of the ancient church. It is expressly cited as such by Origen (*Homil. XIX. in Jerom.*, tom. i., p. 185, ed. Huet.); it is referred to as such by Tertullian (*Nov. Marc.* v. 21); and both Eusebius (*Hist. Eccles.* iii. 25) and Jerome (*Proem. in Ep. ad Philem.*, tom. iv., p. 442) attest its universal reception as such in the Christian world. It was most probably written during the apostle's two years' imprisonment at Rome. It was occasioned by his sending back to Philemon his runaway slave Onesimus, who, having found his way to Rome, was there, through the instrumentality of the apostle, converted to Christianity; and after serving Paul for a season, was by him restored to his former master, without whose consent the apostle did not feel at liberty to retain him. This Epistle has been universally admired as a model of graceful, delicate, and manly writing.

Of separate commentaries on this Epistle, the following is nearly a complete list:—Eichhorn's *Einleit. ins N. T.* iii. 300; Henr. Hummel, *Explanatio Ep. Ap. Pauli ad Philem.*, Tiguri, 1670, fol.; Lebr. Ch. Gottlieb Schmid, *Pauli Ap. ad Philem. Ep. Gr. et Lat. Illustr. et ut Exemplum Humanitatis Pauli Proposita*, Lips. 1786, 8vo; Konrad Rudolf Hagenbach, *Pauli Ep. ad Philem. Interpretatus est*, Basil, 1829, 4to; W. Attersol, *Commentary upon the Ep. to Philem.*, Lond. 1633, 4to; and Davidson's *Introduction to the New Testament*, London, 1848.

PHILIP, the name of *five* kings of Macedonia, the most celebrated of whom was Philip II., father of Alexander the Great. (See MACEDONIA.)

PHILIP, the name of *five* kings of Spain, of whom the most noted was Philip II., who projected the conquest of England by means of the *Invincible Armada*, was the son of the Emperor Charles V. and of Isabella of Portugal, and was born at Valladolid on the 21st of May 1527. He became king of Naples aud Sicily on his father's abdication in 1554; succeeded to the Spanish throne on the 17th January 1556; was married in succession to the Princess Mary of Portugal in 1543, to Mary, Queen of England, in 1554, to the Princess Elizabeth of France, daughter of Henry II., in 1559, and to the Archduchess Anne of Austria in 1571. This cruel bigot died at Madrid on the 13th September 1598. (For information respecting his life and career, see SPAIN.)

PHILIPPE, the name of *six* kings of France. (For an account of each, see FRANCE.)

PHILIPPEVILLE, a town of Algeria, in the province of Constantine, stands at the head of the Gulf of Stora, 35 miles W. of Bona. It is quite a modern town, having been built in 1838, and has straight and regular streets, lined with handsome houses. It is defended by a citadel and four forts, built on eminences in the vicinity. It is built in a great measure of the ruins of the ancient *Rusicada*, which occupied the site of Stora, not far off. Philippeville is connected with Constantine by a good road. Pop. (almost entirely Europeans) 8050.

PHILIPPI, a city of Macedonia, was situated eastward of Amphipolis, within the limits of ancient Thrace. (Acts xvi. 12; xx. 6; Phil. i. 1.) It was anciently called Κρηνίδες, from its many fountains; but having been taken and fortified by Philip of Macedon, he named it, after himself, *Philippi*. In the vicinity were mines of gold and silver; and the spot eventually became celebrated for the battle in

which Brutus and Cassius were defeated. Paul made some stay in this place on his first arrival in Greece, and here founded the church to which he afterwards addressed one of his Epistles. It was here that the interesting circumstances related in Acts xvi. occurred; and the city was again visited by the apostle on his departure from Greece. (Acts xx. 6.) In the former passage (xvi. 12) Philippi is called a colony (κολωνία); and this character it had in fact acquired through many of the followers of Antony having been colonized thither by Augustus (Dion. Cass. xlvii. 432). The ruins of Philippi have not been much visited by travellers; but an interesting account of them may be found in the *American Missionary Herald*, by the missionaries Dwight and Schauffler, who were there in 1834. The most prominent of the existing remains is the remainder of a palatial edifice, the architecture of which is grand, and the materials costly.

PHILIPPIANS, Epistle to the. Of this part of the apostle Paul's writings the authenticity has never been questioned. It is referred to formally and expressly by Polycarp, in his *Epistle to the Philippians* (§§ 3, 11), besides being repeatedly quoted by him. It is quoted by the churches at Vienne and Lyons, in their letter to the churches in Asia and Phrygia, preserved by Eusebius (*Hist. Eccles.* v. 2); by Irenæus (*Cont. Hær.* iv. 18, § 4); by Clement of Alexandria (*Pædag.*, lib. i., p. 107; *Strom.* iv., p. 511; *Admon. ad Gentes*, p. 56); by Tertullian (*De Resur. Carnis*, c. 23); by Origen (*Cont. Cels.*, lib. iii., p. 122, ed. Spencer; *et sæpiss.*); by Cyprian (*Lib. Testim.* iii. 39), and by many of the later fathers.

From allusions in the Epistle itself, it is evident that it was written at Rome during the period of the apostle's two years imprisonment in that city, and in all probability towards the close of that period (i. 13, 14, 23, 26; ii. 18, 25). This Epistle is written throughout in a very animated and elevated style. It is full of the most sublime thoughts and the most affectionate exhortations. It resembles more the production of a father addressing his children, than that of an apostle laying down authoritatively what is to be received and followed. The whole of it shows, as Theophylact observes, how very much he loved and estimated those to whom it was addressed. (*Proem. in Ep. ad Phil.*)

The chief commentaries upon this Epistle are the following:—M. H. Schotanus, *Analys. et Comment. in Ep. Pauli ad Phil. cum observationibus et earum usibus*, Franc. 1637, 4to; J. Gottfried Am Ende, *Pauli Ep. ad Phil. Gr. ex recens Griesbachii; Nova vers. Lat et annot. perpet. illust.*, Vitemb. 1798, 8vo; G. F. H. Rheinwald, *Commentar. ub. d Brief Pauli an die Philipp.*, Berlin, 1827, 8vo; Konrad Steph. Matthies, *Erklarung d. Briefes Pauli an d. Phil.*, Greifswold, 1835, 8vo; Hermann Gustav. Holemann, *Comment. in Ep ad Phil.*, Lips. 1839; Wessel Alb von Hengel, *Comment. perpetuus in Ep. Pauli ad Phil.*, Amstel, 1839; A. Rilliet, *Commentaire sur l'Epitre de l'Apôtre Paul aux Phil.*, Geneva, 1841, 8vo. In English the works of Pearce and Ferguson may be mentioned; also an English translation of Neander's *Epistle to the Philippians practically and historically considered*, Edinburgh, 1851; and Olshausen's *Commentary on the Epistle to the Philippians*, translated in "Clark's Foreign Theological Library."

PHILIPPICS is a name applied to the orations of Demosthenes against Philip, King of Macedon. The Philippics are reckoned the masterpieces of that great orator. (See Demosthenes.) This name is likewise applied to the fourteen orations of Cicero against Marc Antony.

PHILIPPINES, The (Span. *Islas Filipinas*), a group of islands in the Pacific Ocean, belonging to the Indian Archipelago. They lie between N. Lat. 5. 32. and 19. 38., E. Long. 117. and 127., being bounded on the N. and E. by the Pacific, S. by the seas of Celebes and Sooloo, and W. by the China Sea. The form of the group is triangular; and the total number of the islands, large and small, is, at the lowest estimate, 1200. Of these the largest and most important are the following:—Luzon (by far the largest of the whole), Mindoro, Panay, Negros, Zebu, Bohol, Leyte, Samar, Masbate, Mindanao, and Palawan. The smaller islands in the centre of the group, between Luzon and Mindanao, are known by the name of the Bisayan Islands. The area of the whole group is estimated at more than 120,000 square miles. The outline of most of the islands is very irregular, as they are generally indented by arms of the sea, which stretch far into the land, and the surface of all is more or less mountainous; some of the heights being very considerable. A chain of volcanoes traverses the group, and dangerous eruptions are frequent. Among the mountains lie valleys and plains of great richness and beauty; while numerous lakes and rivers diversify the face of the land, and facilitate the internal communications. There are also extensive marshes and mosses in these islands. Their structure is throughout volcanic. Many of the mountains abound in metals. Gold is found in the sand of the rivers. Ironstone, containing a large proportion of iron, and copper of an excellent quality, are also obtained. Several of the islands contain coal, limestone, marble, and other minerals; while an almost inexhaustible supply of sulphur may be obtained from the volcanoes. The climate of the Philippines is tropical and very hot; but the heat is tempered by the continual moisture, which contributes very much to the fertility of the soil. Extending, however, as they do, over an extensive region of the earth's surface, it necessarily varies at different parts. The same alternation of seasons prevails here as in other tropical countries, the year being divided into a rainy and a dry season. The former begins with the month of May, and continues till the end of October or beginning of November. During this period the fall of rain is very great, frequently continuing twelve or fourteen days without intermission. In many places the low and marshy regions are laid under water. The northern part of Luzon is subject to the tremendous storms called *typhoons*, which occur between May and December; but they are seldom experienced south of 14. N. Lat. Earthquakes occur frequently, as well as volcanic eruptions; and at times they are very destructive in their effects. The soil is in general extremely rich; and the products of the islands are numerous and varied. The mountains are covered with forests of large trees, which yield timber useful for the building of ships and houses. Sapan-wood (*Cæsalpinia Sapan*), which produces a good red dye; the mastic tree (*Pistacia Lentiscus*), the cocoa and palm (*Cocos nucifera*), the sago palm (*Sagus*), the bread-fruit tree (*Artocarpus incisa*), the banana (*Musa sapientum*), and other trees valuable for their fruits or other productions, grow in the islands with more or less cultivation. Among the crops raised, the most important is rice, which furnishes the chief article of food to the inhabitants. It is grown in large quantities for exportation, as well as for home use; and the marshy nature of a great part of the soil is not unfavourable to its growth. The sugar-cane is grown to a large and increasing extent, and the sugar is of an excellent quality; tobacco, coffee, hemp, cotton, indigo, pepper, cloves, and cassia, as well as maize, wheat, yams, sweet potatoes, and various fruits, are cultivated. Among the animals, one of the most important is the buffalo, which is found in a wild state, and is domesticated and used for ploughing, and as a beast of burden. A breed of small but hardy horses has been introduced by the Spaniards: they are only used for riding. A small number of sheep, numerous goats, pigs, ducks, and other tame fowls, are also reared. The only rapacious animal is the crocodile, which is found in most of the rivers and lakes. Fish are numerous on the coasts; and pearl oysters are obtained in large quantities. The forests and jungles are filled with many species of wild birds,—such as eagles, herons, creepers, and parrots; and the swallow which makes the edible nests used by the Chinese, haunts these islands. Monkeys, wild cats, and small foxes are among the quad-

rupeds of the Philippines. The natives of the islands belong to several tribes, differing considerably from each other. The mountains are occupied by the Negritos, a diminutive Papuan race, who are said to have originally possessed the whole of the islands, but have been displaced and driven to the mountains by the Malays from the adjacent countries. These latter are now the predominant population of the Philippines. They consist chiefly of two classes,—the Tagals in Luzon, and the Bisayans in the other islands. Each of these speak a different language; and there are also several subordinate dialects. These people have for the most part acknowledged the supremacy of the Spaniards, and adopted the Roman Catholic religion, while the inhabitants of the mountains preserve their independence. Besides these races, the islands contain a comparatively small number of Spaniards; of Mestizos, or half-castes, who are largely engaged in commerce; and a considerable number of Chinese, who have recently settled here. The manufactures are not very numerous or important. Various textile fabrics, from the coarsest to the finest materials, are woven by the women; straw hats and cordage are made; and the building of ships and coaches is carried on. The manufacture of cigars and cheroots, for which the islands are famous, is a government monopoly, and at Manilla employs a large number of hands. Commerce is extensively and actively carried on here, although neither encouraged by the Spanish government, nor promoted by Spanish enterprise. Indeed, were it not for the cheapness and excellence of the produce, and the advantageous situation of these colonies, the prohibitions and restraints imposed by the mother country would have quite checked the commercial development of the Philippines. The principal articles exported are sugar, tobacco, cigars, indigo, hemp, coffee, dyewoods, hides, and gold dust; while cotton, woollen, and silk stuffs, agricultural instruments, clocks, watches, jewellery, &c., are imported. The trade is chiefly in the hands of British houses; and in 1856 the value of the imports from Great Britain amounted to L.1,575,000, and that of the exports to L.1,370,000. Next to Great Britain, the United States have the largest trade with the Philippines; and there are commercial relations with France, Spain, Germany, Switzerland, China, the Sandwich Islands, and Chile. The entire amount of the trade export and import of the islands is estimated at L.5,700,000, of which L.3,000,000 belong to Great Britain and its dependencies, and L.1,000,000 to the United States. The supreme authority, civil and military, is in the hands of a governor-general, appointed by the crown, who resides at Manilla, the capital. He is commander-in-chief of the forces, and president of the supreme court of law, and is assisted by a ministry. The islands are divided into provinces, each under a governor appointed by the crown; and these again into *pueblos* or townships, with mayors elected by the people. The revenue is made up by the monopoly of cigars, a poll tax on the people, and duties on exports and imports. The dominions of the governor-general of the Philippines include also the Bashee and Babuyan islands, to the north of Luzon, and the Ladrones, which lie a long distance to the west. The entire population of the group is estimated at 5,000,000.

These islands were discovered in 1521 by Magalhaens, who named them the Archipelago of St Lazarus. In 1565 they were taken possession of by a fleet which was despatched from Mexico, in consequence of orders from Philip II. of Spain, and first stopped at the island of Zebu, which was soon wholly subdued. In 1570 a fleet sailed from the island of Panay for Luzon, and after several engagements with the princes of the country, effected a settlement on the Bay of Manilla. In 1571 the Spanish admiral took possession of the town of Manilla, which he constituted the capital of the Spanish possessions in the Philippines (so named after Philip II.), and proceeded in his reduction of the island under the Spanish authority. Towards the conclusion of the sixteenth century a considerable trade was openly carried on with Japan; and many rich cargoes were brought from that country to Manilla, which had now become an emporium of the trade with China, Java, the coast of Coromandel, and Mexico. In 1590 the island of Sooloo was attacked by the Spaniards, but they were repulsed with great slaughter by the natives; nor could the Spanish maritime force make any impression on the Sooloo pirates, who continued for nearly three centuries the scourge of these seas. In 1762 Manilla was attacked by the British under Admiral Cornish and General Draper, and the place was stormed on the 5th of October. A capitulation was agreed upon next day, when, in order to redeem the city from general plunder, a ransom was agreed upon of one million sterling. Manilla was restored to the Spaniards at the peace of 1763, and has ever since remained in their possession. Besides Manilla and the larger establishments in Luzon, the Spaniards have many smaller settlements scattered over the islands to the southward; but they were long unable to protect them against the attacks of the pirates who infest these seas. In 1851, however, the governor-general sent an expedition against the Sooloo islands with a view to putting a stop to these attacks. In this he proved successful, having destroyed the power of the Sultan of Sooloo, and formed a settlement in the principal island.

PHILIPPOPOLIS (Turkish *Filibe* or *Felibe*), a town of European Turkey, in the province of Rumilia, on the Maritza, 86 miles W.N.W. of Adrianople. It stands in a beautiful and fertile region, producing wine and rice; and contains fine mosques, caravanserais, khans, and numerous public baths. Leather, silk, and cotton fabrics are manufactured here. Philippopolis is the chief place of trade for the northern provinces of Turkey. The Maritza is navigable up to this town. A few remains of antiquity are still to be seen here; and the old church is pointed out in which Paul is said to have preached. The ancient town was founded by Philip, the father of Alexander the Great; but it afterwards fell into the hands of the Thracians, who retained it until the Roman conquest. It was almost destroyed by an earthquake in 1818, and again laid waste by a terrible conflagration in 1846. About half of the inhabitants are Greeks. Pop. 30,000.

PHILIPS, AMBROSE, an English poet of some note in his day, was descended from an old Leicestershire family, and was born about 1671. He was educated at St John's College, Cambridge, where he took his master's degree in 1700, and where, four years before, he printed a copy of English verses on the death of Queen Mary, in the collection published by the university. Little is known of his career till the year 1709, when six pastorals appeared from his pen, published along with Pope's in Tonson's *Miscellany.* During the same year Philips wrote his poetical *Letter from Copenhagen,* addressed to the Duke of Dorset. It appeared in the *Tatler,* with a laudatory criticism from Richard Steele, and Pope spoke of it as the production of a man "who could write very nobly." Meanwhile Philips contrived to support himself by translating the *Persian Tales* from the French for Tonson, and by empitomizing Hacket's *Life of Archbishop Williams.* In 1712 he brought upon the stage his tragedy of the *Distrest Mother,* which, although little more than a translation of Racine's *Andromaque,* yet was received with rapturous applause, particularly from all trusty Whigs. The *Spectator* took an entire number to herald its advent, and after its appearance another *Spectator* was written "to tell what impression it made upon Sir Roger;" and, to crown all, Addison, in the name of Budgell, wrote an epilogue for it, which, according to Johnson, was "the most successful epilogue that was ever yet spoken on the English theatre." (*Lives of Brit.*

Poets.) To have a rival, and a Whig too, thus puffed into fame, was too much for the forbearance of Pope, who, not content with whispering something about "packed audiences" into the ear of his friend Spence, resolved, by an unexampled artifice of irony, to strip Philips of his laurels. A short time before Addison had bestowed high praise on the "admirable pastorals and winter-piece" of Philips both in the *Spectator* and *Guardian*. Pope, under a guise of favourable criticism, put a paper into the hands of the guileless Steele, which he inserted in the fortieth number of the *Guardian*. This piece turned out, however, to be filled with the most subtle irony and covert mockery of Philips' pastorals, while written with the apparent design of magnifying their superiority to Pope's own. The open feud which ensued between the two poets was never healed. Philips, by threatening to cane Pope, kept him out of his way, but the satirist sought his revenge by garnishing the *Art of Sinking in Poetry* with the choicest specimens of his rival's verse. Again, when Philips attempted to cultivate simplicity and ease in neat little verses, with very short lines and rather childish thoughts, Pope joined Henry Carey in calling it "namby-pamby." In 1722 Philips produced the tragedies of *The Briton*, and *Humphrey, Duke of Gloucester*, which are now forgotten. His happiest undertaking was a periodical called the *Free-Thinker*, in which one of his associates was Dr Boulter; who, upon his being made archbishop of Armagh, took Philips with him, and got him a seat in the Irish Parliament. In 1726 he was made secretary to the lord chancellor, and in 1733 had risen to be judge of the Prerogative Court in Ireland. Having resigned in 1748, he returned to London, where he died on the 18th of June 1749.

PHILIPS, *John*, an English poet of some eminence, was born in 1676. He was educated at Winchester and Oxford, where he became acquainted with the works of Milton, whom he studied with great application, and traced in all his successful translations from the ancients. The first poem by which he distinguished himself was his *Splendid Shilling*, which in the *Tatler* is styled the "finest burlesque poem in the English language." His next was entitled *Blenheim*, which was written at the request of the Earl of Oxford and Mr Henry St John, afterwards Lord Bolingbroke, on the victory obtained by the Duke of Marlborough in the year 1704. It was published in 1705; and the year after, he finished another poem upon *Cider*, the first book of which had been written at Oxford. It is on the model of Virgil's *Georgics*, and is thought a very excellent piece. We have no more of Philips' writings except a Latin ode to Mr Henry St John, which is esteemed a masterpiece. He was meditating a poem on the *Last Day*, when he was cut off by consumption on the 15th of February 1708.

PHILISTINES (Heb. *Philistim*), a tribe which gave its name to the country known as Palestine, though it occupied only a portion of the southern coast, namely, that which was bounded on the E. by the hill country of Ephraim and Judah, and on the W. extended from Joppa to the borders of Egypt, thus touching on the Israelite tribes Dan, Simeon, and Judah. Indeed the portions of Simeon and Dan covered a large part of Philistia; but its possession by the Israelites was disputed, and was never entirely achieved. This country was originally held by the Avims, who were destroyed and their land seized by the Caphtorims, coming forth out of Caphtor (Deut. ii. 23). Caphtor has been thought to be Cappadocia; so is it rendered by the Targums, as well as by the Syriac and Vulgate translations ("Palæsthinos reliquias insulæ Cappadociæ"). Bertheau, however, decides that Caphtor is Crete, on several grounds (Bertheau, *Zur Geschichte der Israeliten*, 1842; see also *Die Phönizier*, von Movers, 1841; and *Kanáan*, von C. von Lengerke, 1844). Since the appearance of Lakemacher's *Observat. Philol.* (ii. 11, sq.), and Calmet's *Biblical Researches*, the word Kreti has been considered to prove that the Philistines were wanderers from Crete, which recent scholars have confirmed. Greeks and Romans support this view. Tacitus (*Hist.* v. 2) relates that inhabitants of Palestine came thither from Crete. Stephen of Byzantium, under the word Gaza, states that this city was properly called Minoa, from Minos, King of Crete, who came to Gaza with his brothers Acakos and Rhadamanthus, and named the place after himself (comp. *Kreta*, von Karl Hoeck, ii. 368). The same writer adds that the Cretan Jupiter was honoured in Gaza. (See PALESTINE.)

The Philistines are represented in the Old Testament as foreign immigrants. The ordinary translation of their name in the Septuagint is Ἀλλόφυλοι, *men of another tribe*. The root פלש, whence Philistine, denotes *a wanderer, one from a foreign land*, and was probably given by the Hebrews to the foreign immigrants who called themselves Cretans. The names of their cities and their proper names are of Shemitic origin. In their intercourse with the Israelites there are many intimations that the two used a common language. How is this, if they were immigrants in Palestine? This difficulty is removed by supposing that originally they were in Palestine, went westward, but afterwards returned eastward, back from Crete to Palestine; so that in Amos ix. 7, it is to be understood that God brought them up to Palestine, as He brought the Israelites out of Egypt—back to their home. (Movers, *Die Phönizier*, pp. 19, 29, 35.) Greek writers, however, give evidence of a wide diffusion of the Shemitic race over the islands of the Mediterranean. (See Thucydides, i. 8; Herodotus, i 173; and Homer, *Od.* ix. 174; comp. Strabo, p. 475.) Many proofs offer themselves that, before the spread of the Hellenes, these islands were inhabited by Shemitic races. The worship observed in them at this time shows a Shemitic origin. The Shemitics gave place to the Hellenics; a change which dates from the time of Minos, who drove them out of the islands, giving the dominion to his son. The expelled population settled on the Asiatic coast. This evidence, derived from heathen sources, gives a representation which agrees with the Scriptural account of the origin, the westerly wandering, and return eastwards of the Philistines.

If now we follow the Biblical accounts, we find the history of the Philistines to be in brief as follows:—They had established themselves in their land as early as the time of Abraham, when they had founded a kingdom at Gerar. (Gen. xxi. 32; xxvi. 1.) When the Israelites left Egypt, they were deterred by fear of the power of the Philistines from returning by the shortest road—that which the caravans still take—because it lay through the country of the Philistines. (Exod. xiii. 17.) Joshua appears to have thought it prudent to attempt nothing for their dispossession. The days of the Judges, however, brought conflicts between the Israelites and the Philistines, which were destined to continue during the entire history of the Hebrew monarchy.

In the Maccabæan period the Philistines were Syrian subjects, and had at times to suffer at the hands of the Jews (1 Macc. x. 86; xi. 60, sq.) King Alexander (*Balas*) gave Jonathan part of their territory, Accaron, with the borders thereof in possession (1 Macc. x. 89). The Jewish monarch, Alexander Jannæus, overcame and destroyed Gaza (Joseph. *Antiq.* xiii. 3. 3; *De Bell. Jud.* i. 4. 2). By Pompey Azotus, Jamnia and Gaza were united to the Roman province of Syria (*Antiq.* xiv. 4. 4); but Gaza was given by Augustus to King Herod (*Antiq.* xv. 7. 3).

The cities of the Philistines were greatly distinguished. The chief were Gaza, Ashdod, Askalon, Gath, and Ekron (Josh. xiii. 3; Judg. iii. 3). The greatness of these cities was mainly owing to commerce, for the coast of Palestine was in the earliest ages exclusively in possession of the trade which for many ages was carried on between Europe and

Asia. Besides a great transit trade, they had internal sources of wealth, being given to agriculture, &c. Their religion was not essentially different from that of the Phœnicians. The idol which they most reverenced was Astarte. Priests and soothsayers were numerous (1 Sam. vi. 2). Their magicians were in repute (Isa. ii. 6); and the oracle of Baalzebub at Ekron was consulted by foreigners (2 Kings i. 2). They had the custom of carrying with them in war the images of their gods (2 Sam. v. 21). Tradition makes the Philistines the inventors of the bow and arrow.

PHILISTUS, a celebrated Syracusan, was the son of Archonides or Archomenides, and was born about 435 B.C. His chief fame in ancient times was derived from his character as a historian. In this capacity his conduct was that of an inveterate time-server. He aided Dionysius the Elder in seizing the chief power at Syracuse, and afterwards became one of the most devoted supporters of the tyranny. Nor when the ungrateful despot banished him to Adria was his spirit cured of its servility. He gave vent to the most beseeching complaints in order to move the pity of his former patron. He sought to regain favour by giving, in the History of his country which he was then writing, a virtuous colouring to all the tyrant's unprincipled deeds. When all these devices had failed, and Dionysius the Elder had died in 367 B.C. without pardoning him, he assumed the same cringing attitude towards Dionysius the Younger. The interest of his friends at court was employed to procure his recall. No sooner had that object been attained, than he insinuated himself into the highest place in the young tyrant's confidence. He was continuing to hold that position by pandering to his master's vices, when the revolt of Dion in 356 B.C. brought about his overthrow. The defeat of the naval armament under his command drove him to commit suicide. The fragments of the works, and the facts of the biography of Philistus, are given in an appendix to Göller's *De Situ et Origine Syracusarum*, 8vo, Leipsic, 1818; and in Didot's *Fragmenta Historicorum Græcorum*, Paris, 1841.

PHILLIPS, RICHARD, an eminent mineralogical and pharmaceutical chemist, was born in London in the year 1778. He spent the earlier part of his career as a chemist and druggist; and in 1805 he first attracted the attention of the scientific world by his "Analyses of the Bath Waters," followed by analyses of our mineral waters generally, and of minerals of a rare kind. These papers were published for the first time in the *Annals of Philosophy*, a journal partially conducted by Phillips both before and after its subsequent incorporation with the *Philosophical Magazine* in 1827. He was appointed lecturer on chemistry to the London Hospital in 1817; and about the same period he was elected by government professor of chemistry at the Military College, Sandhurst, and became lecturer on chemistry at Grainger's School of Medicine in Southwark. It is, however, in the character of editor and translator of the *London Pharmacopœia* that Richard Phillips is best known. In 1816 he produced a review, consisting of an *Experimental Examination of the Last Edition of the Pharmacopœia Londinensis*, which established his name as a scientific critic, and raised his reputation as a chemist. During the same year he wrote another *brochure* entitled *Remarks on the Editio Altera of the Pharmacopœia Londinensis.* These pungent criticisms had the effect of drawing upon their author the notice of the College of Physicians; and Phillips was accordingly induced to come forward with his first official translation of the *Pharmacopœia* in 1824. From that period down to the time of his death Phillips took a lively interest in the improvement of this important publication, and much of its present excellence is mainly due to his industry and skill. In 1822 he was made a fellow of the Royal Society; in 1832 he became lecturer on chemistry at St Thomas's Hospital; in 1839 he was appointed chemist and curator of the Museum of Practical Geology; and in 1849 he was chosen president of the Chemical Society, a position which he continued to occupy till his death, which happened on the 11th of May 1851.

The numerous and valuable contributions to science which Richard Phillips left behind him are to be found scattered throughout the *Transactions of the Royal Society*, the *Philosophical Magazine*, and the *Pharmaceutical Journal.* He likewise contributed the principal articles on chemistry and mineralogy in the *Penny Cyclopædia.* "Of modern British analytical chemists," said Dr Thomas Thomson in his *History of Chemistry*, published in 1831, "undoubtedly the first is Mr Richard Phillips, to whom we are indebted for not a few analyses conducted with great chemical skill, and performed with accuracy."

Richard Phillips was younger brother of William Phillips, the mineralogist, who will be found noticed in a subsequent article.

PHILLIPS, *Samuel*, an industrious and successful litterateur, was the son of a Jewish tradesman in Regent Street, London, and was born in 1815. A somewhat precocious talent for mimicry and recitation had disposed his parents to train him for the stage; but they were afterwards induced, through the advice of the Duke of Sussex, to send the lad to the London University. After remaining a year at that institution, Phillips proceeded to the university of Göttingen. Having renounced the Jewish faith, he returned shortly afterwards to England, and entered Sidney Sussex College, Cambridge, with the design of taking orders. His father's death, however, altered his plans; and after an unsuccessful attempt, in conjunction with his brother, to carry on his father's business, he, in 1841, took to literature as a profession. His first work, the novel of *Caleb Stukely*, appeared originally in the pages of *Blackwood's Magazine;* and he subsequently contributed other anonymous tales to that and to other periodicals. In 1845 he began, through the interest of Lord Stanley, to write political leaders for the *Morning Herald;* and about the same time he obtained an appointment on the staff of the *Times* as literary critic for that journal. In the following year he purchased the *John Bull* newspaper, which he edited for a year; but finding his strength, which was slowly wasting under the influence of confirmed consumption, quite unequal to such laborious work, he was constrained to abandon the undertaking. From that period till his death Phillips worked cheerfully and courageously as literary critic for the *Times*, and also wrote an occasional review for the *Literary Gazette.* Two anonymous volumes of *Essays from the Times* were published by him in 1852 and 1854. They are written in a light, dashing, picturesque style, sometimes eloquent, frequently bitter, and with a tolerable show of fairness. Phillips took an active part in the formation of the Crystal Palace Company. He was appointed their literary director; he wrote their *Guide to the Crystal Palace and Park*, and the *Portrait Gallery of the Crystal Palace.* In 1852 the university of Gottingen conferred upon him the honorary degree of LL.D. But while success attended his industry, and honours came thick upon him, the fell disease with which he had long struggled at length brought his career to a close. He died at Brighton on the 14th October 1854, leaving behind him a widow and five children, for whom he had made a comfortable provision.

PHILLIPS, *Thomas*, an eminent portrait-painter, was born at Dudley in Warwickshire in 1770. Having acquired the art of glass-painting at Birmingham, he visited London in 1790 with an introduction to Benjamin West, who found him employment on the glass-paintings in St George's chapel at Windsor. In 1792 Phillips painted a "View of Windsor Castle," and ere the two succeeding years had passed, he exhibited "The Death of Talbot, Earl of Shrewsbury, at the Battle of Cassillon," "Ruth and Naomi,"

"Elijah restoring the Widow's Son," "Cupid disarmed by Euphrosyne," and other pictures of that class. From the year 1796, however, he seems to have mainly confined himself to portrait-painting; and it was in this walk he was destined to acquire his reputation as an artist. It was not long before he became the chosen painter of men of genius and talent, notwithstanding the rivalry of such distinguished artists as Koppner, Owen, Jackson, and Lawrence. He has left behind him, accordingly, portraits of nearly all the illustrious characters of his day, which will serve to justify the laudatory epithet of "the English Vandyck" bestowed upon him by the eminent foreign artist Nicaise de Keyser. In 1824 Phillips suceeeded Fuseli as professor of painting to the Royal Academy, an office which he held till 1832. During this period he delivered ten *Lectures on the History and Principles of Painting*, which were published in 1833. He likewise wrote a large number of the articles on the fine arts in Rees's *Cyclopædia.* He died on the 20th of April 1845.

Phillips, *William*, an industrious mineralogist and geologist, was born in London on the 10th of May 1773. In conjunction with his brother Richard Phillips, already noticed, and eight other young men, chiefly of the Society of Friends, he founded the Askesian Society, to which he contributed his first paper in 1801, "On the *Virgula Divinatoria*, or Divining-Rod," afterwards published in the *Philosophical Magazine*. The principal objects of Phillips' early studies were mineralogy and geology; and few men of his time contributed more to the diffusion of general information on these sciences. He was among the very first to turn to good account the reflective goniometer of Wollaston in the measurement of crystals; and in the use of that instrument, says Dr Whewell (*Hist. of Ind Sciences*), "No one was more laborious and successful than William Phillips, whose power of apprehending the most complex forms with steadiness and clearness led Wollaston to say that he had a 'geometrical sense.'" His *Elementary Introduction to the Knowledge of Mineralogy*, first published in 1816, and made the basis in 1852 of Brooke and Miller's *Introduction to Mineralogy*, is pronounced by the same writer to be "an extraordinary treasure of crystallographic facts." This work had been an expansion of his *Outlines of Mineralogy and Geology*, published some years previously for the use of the young. In 1818 he published *An Outline of the Geology of England and Wales*, which he afterwards expanded into his more famous *Outlines of the Geology of England and Wales.* William Phillips likewise contributed elaborate communications on subjects connected with his favourite sciences of mineralogy and geology to the first series of *Transactions of the Geological Society*. He also wrote some minor papers for the *Annals of Philosophy* and the *Philosophical Magazine*. He was chosen a fellow of the Royal Society a year before his death, which took place in the spring of 1828.

PHILO JUDÆUS, or *Philo the Jew*, an ancient Greek writer, descended of a noble family amongst the Jews, flourished at Alexandria during the reign of Caligula. He was the chief of an embassy sent to Rome about the year 42 A.D., to plead the cause of the Jews against Apion, who had been sent by the Alexandrians to charge them with neglecting the honours due to Cæsar. He afterwards went to Rome in the reign of Claudius, and both Eusebius and Jerome inform us that he became acquainted with St Peter, with whom he lived on terms of friendship. At a later period, it is said, his son Tiberius Alexander married Bernice, the daughter of King Agrippa.

Philo was educated at Alexandria, and made very great progress in eloquence and in philosophy. After the fashion of the time, he cultivated, like many of his nation and faith, the philosophy of Plato, whose principles he so thoroughly imbibed, and whose manner he so well imitated, that it became a common saying, *Aut Plato philonizat, aut Philo platonizat.* Josephus describes him as a man "eminent on all accounts;" and Eusebius represents him as "copious in speech, rich in sentiment, and sublime in the knowledge of Holy Writ." He was, however, so much immersed in philosophy, particularly the Platonic, that he neglected the Hebrew language, and also the rites and customs of his own people. Scaliger, Grotius, and Cudworth declare that, though a Jew by nation, he was yet very ignorant of Jewish literature and of Jewish customs. But Fabricius and Mangey think differently. In his works, however, there are certainly many excellent things. Though he is continually platonizing and allegorizing the Scriptures, he abounds with fine sentiments and lessons of morality; and his morals are rather the morals of a Christian than those of a Jew. History, as well as his own writings, give us every reason to believe that he was a man of great prudence, constancy, and virtue.

His works were first published in Greek by Turnebus, at Paris, 1552; and to these a Latin translation, executed by Gelenius, was afterwards added. The best editions are those of Paris, 1640; Dr Mangey, London, 2 vols. folio, 1742, of which the text is considered to be the best; Richter, 8 vols. 8vo, 1828–30, with additions not before published. The works of Philo Judæus have been translated into English by C. D. Yonge, forming 4 vols. of Bohn's "Ecclesiastical Library," 1854.

Philo, a celebrated writer on mechanics, was a native of Byzantium, and flourished in the year 160, being the contemporary of Ctesibius and Hero. He was the author of a work, entitled Πολιορκητικά, on the method of attacking and defending towns, of which the fourth and fifth books have been preserved. The first treats of the manner of preparing arrows, balistæ, catapultæ, and other warlike engines. Amongst other inventions, he mentions a machine of Ctesibius which discharged weapons by means of compressed air, upon the same principle, no doubt, as our air-gun. In the second book he treats of the manner of fortifying and provisioning cities, and, amongst other things, recommends that the provisions and water be poisoned if there be danger of the place falling into the hands of an enemy. This work has been published, with a Latin translation, in a collection entitled *Veterum Mathematicorum Opera*, Par. 1693. The invention of the air-gun has been treated of by Alb.-Louis Meister, *De Catapulta polybola Commentatio qua locus Philonis Mechanici, in libro iv. de telorum constructione extans illustratur*, Göttingen, 1768. There is another little work attributed to Philo, entitled Περὶ τῶν ἑπτὰ θεαμάτων (*On the Seven Wonders of the World*), part of the sixth chapter of which, and the whole of the seventh, are lost. It has been published, with a Latin translation and many learned notes, by J. C. Orelli, Leipsic, 1816, 8vo.

PHILOLAUS, a distinguished Pythagorean philosopher, born, according to some, at Crotona, according to others, at Tarentum, some time during the latter half of the fifth century B.C. He was instructed in philosophy by Aresas, and had for his disciples Simmias, Cebes, and Archytas, the friend of Plato, whom he taught at Thebes in Bœotia. Philolaus was the first who published a book on the Pythagorean doctrines, a treatise which Plato is said to have made use of in the composition of his *Timæus.* This work of the Pythagorean seems to have consisted of three books:—1. Containing a general account of the Origin and Arrangement of the Universe; 2. An Exposition of the Nature of Numbers; 3. On the Nature of the Soul. (See Fabricius' *Bibliotheca Græca.*) There is an edition of the fragments of Philolaus, by Böckh, 8vo, Berlin, 1819.

PHILOLOGY.

Definition.

PHILOLOGY, in the usual and generally correct acceptation of the term, is a branch of study of which the object is some language and literature fixed in a permanent, if not unalterable form. The application, however, of the original word by the Greeks themselves is much wider and more general than this definition would imply; and modern scholars have endeavoured to claim for philology a distinct and important place among the highest and most systematic sciences. As common Greek terms, φιλόλογος and φιλολογία denote merely a fondness for literature and literary discussion. In more than one passage Plato makes Socrates describe himself as φιλόλογος (*Phædr.*, p. 236 E.; *Lach.*, p. 188 C.; *Theætet.*, 161 A., cf. 146 A.), meaning by this that he delighted not only in hearing speeches, but also in the dialectical argumentation which formed his chief employment; and the same great writer describes Athens in general as both φιλόλογος ("loving discourses"), and πολύλογος ("full of talk"), in contradistinction to Lacedæmon and Crete, which cultivated reflection rather than conversation. (*Legg.*, p. 641 E.) A little later, a distinction was made between the more general sense in which philology could be predicated of all the Athenians as a national characteristic, and a more special application of the term; and Zenon contrasted those who were mere lovers of conversation with those who cultivated literature and philosophy as liberal studies, by calling the latter φιλόλογοι, but the former λογόφιλοι. (Stobæus, *Serm.* 36, 26, vol. ii., p. 40, Meineke; *Ecl.*, vol. ii., p. 214, Heeren.) When philology had thus fixed itself as a word denoting liberal study, it soon became applicable to studies of a particular kind. And as philosophy denoted the whole compass of ancient learning,—that is, not only the investigation of nature and thought, but also the study of transmitted opinions and of the books by which they were conveyed,—philology was understood to signify the second part only of philosophy,—namely, all that referred to literature, language, and history. (See Wyttenbach on Plutarch *de audiend. poët.*, p. 22 C., p. 226.) The first person who was called a philologer (φιλόλογος) in this sense was the great Eratosthenes (Sueton. *de illustr. Gramm.*, c. 10), who, however, did not by any means relinquish the name or the functions of a philosopher, but laid claim especially to a combination of various departments of learning (*multiplex variaque doctrina*), which made him the "admirable Crichton" of his age. The same name, for the same reason, was bestowed upon Atteius (Sueton., *u. s.*) and Demetrius of Scepsis (Diog. Laërt. v., § 84). And all these, with many others, regarded the possession of book-learning, which made man a philologer and polyhistor (πολυΐστωρ; Vit. Arat. *Phæn.*, p. 268, 11), or more generally a student (*studiosus*, Plin. *Epist.* iii. 3), as merely an adjunct to other accomplishments, or rather as a department of philosophy. In process of time, however, philosophy was limited to the investigation and discovery of physical and psychological facts; and then philology assumed a sort of antagonistic position in regard to that which was originally esteemed as merely a branch or department of the same manifestation of intellectual activity. Hence it was that Plotinus, whose literary qualifications were of a very humble order, described his eminent contemporary Longinus, who was emphatically a learned man (Eunapius, *Porphyr.*, p. 13), and had written a book called *The Philologers* (οἱ φιλόλογοι: see Ruhnken, *Diss. de Long.*, § 10), as a philologer indeed, but in no sense a philosopher (Porphyry, *Vit. Plotini*, c. 14, p. lxiv., Creuzer). This opposition has been either accepted by those in modern times who have wished to claim for philology the most extensive province and the most exalted functions; or, allowing physiology and philology to be still the two main branches of philosophy, they have assigned to the latter the duty of surveying all knowledge which is already placed on record; so that all human study is divided into two great departments,—the retrospective and the prospective, the known and the unknown. "It appears to me," says the enthusiastic disciple of W. von Humboldt (*De Pronomine Relativo Commentatio Philosophico-Philologica*, scripsit H. Steinthal, Berolini, 1847, pp. 4, 5), "that it is the business of the human understanding, or of literature in general, to comprehend those simple and absolute laws which appear in the *world* or in *nature* on the one hand, and in *the history of the human race* on the other hand. As, therefore, there are two forms of literature,—one, the *history of nature*, or *physiology;* the other, the *history of the human mind*,—philologers undertake the examination of all that the λόγος, or human reason, has produced. Now, whatever the human reason produces is some idea, something recognised and discerned by the mind, although it may be clothed in some outward form, whether it be a form of government constituted by human society: or some monument of hewn stone: or some type of mythology and religion: or some demonstrative result of philosophical acuteness: or some outpouring of poetical genius or oratorical eloquence. So that even the history of philology belongs to philology, with this limitation, that, *e.g.*, the history of classical philology is the specialty of those who consider modern life from a philological point of view. Accordingly, the only true definition is Böckh's, that *philology* is the *teaching and learning of that which is already discovered* (*philologiam esse cogniti cognitionem*); which is not to be understood, as though philologers were always doing over again the work done to their hands; but all the products of the human mind which remain as recorded facts have to be submitted afresh to the crucible of human thought, to the end that, being recognised, not as the arbitrary acts of individuals, but as sprung from the necessary laws of minds individually free, they may be regarded as a mirror or picture of the human reason in general." This sweeping generalization, by claiming for philology a sovereignty over all that has received a literary expression,—everything, in fact, except the new discoveries which inductive science may make in the domain of visible nature,—virtually deprives the philologer of any definite functions, and almost makes his name co-extensive with that of studious and thinking man. Still, it contains the germs of the true definition of philology—a definition quite consistent with the popular acceptation of the term. For the opposition between discovery (*inventio*) and learning (*cognitio*), on which it rests, is really that which, in his own proper department, distinguishes the philologer from all others who claim the possession of a particular science,—namely, some branch of knowledge methodized and reduced to general laws and principles. The fact is, that philology always presumes, as the basis of its operations, some fixed form of language and literature. By the nature of the case, it deals with that which has been completed in the past, and is no longer liable to fluctuation and change. Living and contemporary literature may be criticised, but it cannot be a proper object of philology. No fixed conclusions can be drawn from that which is still in a state of transition. It follows therefore, that, as far as language and literature are concerned, philology is most truly defined as the science of investigating and learning that which is already before the world as an accomplished result of human intellect. And the Romans actually used this distinction to describe the contrast between the Greeks, who had furnished them with models of rhetoric and philosophy, and themselves, as the

Ancient Philology.

intelligent inheritors of that transmitted wealth,—"Illis enim," says Quintilian (*Inst. Orat.* xii. 11. § 22), "hæc *invenienda* fuerunt, nobis *cognoscenda* sunt." The essential distinction, that philology deals only with a fixed and completed form of language and literature, leads to another limitation by which its province is more accurately defined It not only does not deal with modern and living literature, but it does not even concern itself with those departments of criticism which are equally applicable to all forms of literature, whether modern or ancient. This removes from the province of philology many branches of study which the ancient φιλόλογος claimed as his own, such as rhetoric, poetry, and the theory of taste. The philologer, in the full sense of the term, deals with ancient literature for the sake of language in general, which the fixed forms of an ancient idiom enable him to analyse according to methodical and scientific principles. With the literature itself the philologer, as such, is concerned chiefly as a verbal critic and interpreter. He undertakes to furnish the means by which the true reading may be ascertained and the intended signification elicited; and although a knowledge of many collateral subjects may be necessary to enable him to do this effectually, he regards these particulars as auxiliary matters only, and does not concern himself with the literary or philosophical results of his own criticisms so far as the subject-matter of his author is concerned. Taking all the circumstances into consideration, we are disposed to define philology as, in itself, the general name for a scientific inquiry into the principles of language. It deals at once with the theory of the origin and formation of words, and with the method of language, which treats of the formation of sentences. But whether we consider the origin of philology,—*i.e.*, the circumstances under which such a branch of study has assumed a systematic form,—or the procedure by which it tests its conclusions and extends its field of research, we must consider it as dealing with some branch of literature, national or classic, which is no longer vague or floating; so that it includes all the higher applications of grammar, criticism, and exegesis. Again, when we regard the intimate connection between the mind of man and his spoken language, we cannot fail to see, that the highest philology must involve an investigation of the laws of thought, and so trench on the boundaries of psychology. Lastly, when we remember that language is the most ancient and the most trustworthy of pre-historical records, we shall not be surprised to find that philology constitutes one of the main ingredients in the new science of ethnography, or the history of the varieties of the human race, and that it has led to special investigations into the primitive condition and primitive religious belief of families of men long since divided by the inevitable process of emigration. In the following pages it is not our object to treat methodically of any branch or application of philology. It is sufficient that we should show how this science of language gradually developed itself; what it has achieved; and what it is still doing. With this view, we propose to discuss, in order, the establishment of a methodical and minute study of language on the basis of classical and sacred criticism, and the subsequent growth of comparative grammar, with its adjuncts—comparative history and mythology. The following will be the most convenient divisions of our subject:—(1.) Ancient Philology; (2.) Philology during the Middle Ages; (3.) Classical and Sacred Philology, after the revival of literature; (4.) Comparative Philology, with its various developments and applications in the present century.

I.—ANCIENT PHILOLOGY.

The science of philology, like the name, is of Greek origin. Its first faint beginnings may be discerned in the age when the Pisistratidæ at Athens undertook the collection and editorship of the scattered poems attributed to Homer. (See the important Scholium on Plautus, Ritschl. *Alexandr. Biblioth.*, p. 4.) In the classical period which followed, the great epic poems were more and more regarded as a text-book for study and elucidation; and to such an extent did the text of Homer serve as the foundation of all Greek training, that Plato, in his *Republic*, feels himself obliged to discuss formally how far such an influence should be encouraged in his model commonwealth. At the same time, the Sophists, or literary men by profession, who were the earliest students of language on its own account, began to investigate the elements of grammar and criticism with an immediate reference to the text of the old poems. Protagoras, one of the most eminent of this class of public teachers, was the first to treat of the inflections of his own language; and he noticed with due attention the machinery used for the modal distinctions of the verb, and for the genders of the noun. The first principles of syntax, namely, the relation of the subject to the predicate, and the distinction between the substantive verb as a mere copula and its use as a means of predicating existence, were perhaps not stated distinctly before the publication of Plato's *Sophistes*. And Aristotle from this developed his theory of the method of language, which has since held its place as the best exposition of the subject. These, however, were but the beginnings of philology, scattered over a hundred years, and appearing only as incidental hints at a time when the productive genius of Greek literature was in full vigour, and when the age of writers had not yet given place to the age of commentators. Philology, as a study furnishing a main occupation to those who embraced it, came into active operation at the end of the fourth or at the beginning of the third century B.C., when the Greek dynasty settled in Egypt established at Alexandria a museum or college and a library on a large scale, and invited to that city all the men of letters who were willing to devote themselves to a life of book-learning. As far as any one man can claim the distinction of having initiated this school of learning, the honour must be conceded to Demetrius the Phalerian, who, having come to Egypt as an exile from Athens, induced Ptolemy Soter to lay the foundation of the library, and to undertake methodically the revision of the more ancient writers, especially Homer. The undertaking thus started was carried on with increasing vigour by a series of eminent men who filled the office of chief of the museum at Alexandria, and who, besides their special employments as literary men in different fields, were critics and commentators by profession. The first six of these librarians were Zenodotus, the great Homeric editor; Callimachus; Eratosthenes; Apollonius of Rhodes; Aristophanes of Byzantium; and Aristarchus of Samothrace. By their exertions, and those of their contemporaries among the grammarians of Pergamus and the Stoics of Athens, all the details of editorial criticism were put into a systematic form. The Greek language was analysed; the parts of speech were classified; cases and other inflections received their names, and their usage was defined; the divisions of the sentence were marked by a system of punctuation; and the pronunciation was registered by the simple but ingenious contrivance of accentual marks. At the same time, the texts of the great poets, especially Homer, were settled by a most careful revision of all the materials.

Origin of classic Philology in Greece.

The Sophists.

Plato and Aristotle.

The school of Alexandria.

From the establishment, then, of the Alexandrian school we date the origin of classical philology, or at least of a methodical and critical study of the Greek language, resting on a revision of its oldest literary remains. The period marked by the labours of the first six librarians at Alexandria also saw the first beginnings of sacred philology, which may, indeed, be regarded as an offshoot from the studies of the Alexandrian scholars. The Jews had begun to make

Beginnings of sacred philology.

Ancient Philology.

a collection of their sacred books as early as B.C. 446, when they were restored to their own country; and those of the nation who were settled at Alexandria were already in possession of the Pentateuch, at all events, when Demetrius the Phalerian persuaded Ptolemy Soter either to procure a translation of these books, or to add to his library the Greek version of them already in use by his Jewish subjects, which, however, he had revised and sanctioned by the Sanhedrim at Jerusalem; and the name of the version (that of the Seventy, *Septuaginta*), is derived from the number of that council. As other books were added to the canon at Jerusalem, they were from time to time translated at Alexandria; and when the collection was completed, sometime about B.C. 130, the whole series was divided into twenty-four parts, in accordance with the number of letters in the *Greek* alphabet, and in imitation of the same division adopted by Aristarchus for the two great Homeric poems. As the division into twenty-two parts, according to the number of letters in the *Hebrew* alphabet, was not adopted till afterwards (see Beveridge's *Works*, vii., p. 202, *sqq.*), it is clear that in this important matter the procedure of the classical school established at Alexandria re-acted on the Jewish Masorets; so that classical and sacred criticism may really be traced back to one and the same origin.

Philology at Rome.

The philology of Rome was merely an offshoot or application of that which had established itself in the schools of Greece. Not only was the later Roman literature entirely built up on the foundations of the Greek, but the later Greek literature was itself domesticated at Rome; and rhetoricians, grammarians, commentators, and lexicographers wrote or compiled for the benefit of the accomplished Romans no less than for the literary public still furnished by their own countrymen. Among the Romans themselves, or those who wrote in Latin, the most eminent philologers were M. Terentius Varro, the contemporary of Cicero; Atteius Philologus, the friend of Sallust and Pollio, who wrote an enormous miscellany in 800 books, called Ὕλη, or "Materials;" Verrius Flaccus, the tutor of the grandsons of Augustus, whose invaluable treatise *De Verborum Significatione* has come down to us only in the mutilated abridgment of Festus; Quintilian, the great rhetorician, who flourished under the Flavian emperors; Aulus Gellius, who was a contemporary of Hadrian and the Antonines; Macrobius, the author of the *Saturnalia*, and his contemporary Servius, the learned commentator on Virgil, who are referred to the age of Honorius and Theodosius; and Martianus Capella, who is usually placed at the end of the fifth century A.D. These writers treated the classical authors of Greece and Rome in the manner and spirit which the Alexandrian grammarians had exhibited in their commentaries on the older Hellenic literature; and many of them do not differ in any essential respect from the commentators who have appeared since the revival of learning in the fifteenth century.

Philology in India.

Quite unconnected with any of the manifestations of philology which we have hitherto noticed, but destined at a distant period to exercise no slight influence on the science of language in general, a school of grammarians sprung up in India, and applied to their own sacred or classical literature methods virtually identical with those which had been adopted by the classical philologers. It cannot be determined at what particular date the northern tribe of the worshippers of Brahma effected the conquest of the district which they called the Arian land (*Arya-ávartah*), lying between the Himalayan and Vindhyan chains of mountains. From the internal evidence of the oldest writings, it is concluded that their movement from the north-west did not commence until after B.C. 1400. There can be no doubt, however, that these conquerors introduced into India their own language, the Sanscrit, or grammatically perfect idiom, and with it their sacred literature; and that the latter, represented by the Vêdas, dates as far back as the fourteenth century before Christ. On the basis of this revelation (for the Vêdas, by their very name, claim to be a direct communication from the Supreme Being) was built up a copious literature, partly poetical and partly scientific. In process of time, the Sanscrit language, in which this literature, or the more solemn parts of it, was composed, and even the Prâcrit dialect, which represented a more vulgar and popular type of the sacred dialect, became dead languages; and the literature was studied only by the learned men of the upper classes. (See Lassen, *Indische Alterthumsk.* ii., pp. 1153, sqq.) In India, then, as at Alexandria, a school of philology arose; and connected as their grammatical studies were with the intellectual activity of the highest functionaries in the religious and secular bodies, it is not surprising that the learned and able grammarian obtained a rank little less sacred than that of the writers whose works he expounded. The full establishment of the grammatical system in northern India is referred to the reign of King Vicramâditya, who rescued the north-western provinces of India from the Sacæ, and reigned as absolute sovereign from the Punjâb to the Ganges. The beginning of his epoch is fixed at B.C. 58. (Ideler, quoted by Lepsius, *Chronologie der Ægypter*, i., p. 4.) How long before this time the philological element had existed in Sanscrit literature cannot be determined; for the grammarians of Vicramâditya's court at Oujein were, like the Masorets of the Jews, the sole editors of the sacred or classical books, and may have introduced into the texts the grammatical allusions which we find here and there. For example, we cannot but regard it as an interpolation when Krishna is made to say in the Bhagavad-Gita, an episode of the Mahâ-Bhârata:—"I am the A of letters, and the copula which connects the elements of the compound word" (aksharânâm-a-kâras asmi; dvandvas sâmâsikasya-cha, *Bhag. Git.* x. 33). The first of the Sanscrit grammarians, Pânini, is referred to a fabulous antiquity. "Pânini," says Colebrooke (*Miscellaneous Essays*, ii., p. 4) "lived in so remote an age that he ranks among those ancient sages whose fabulous history occupies a conspicuous place in the *Paranas*, or Indian theogonies. The name is a patronymic indicating his descent from *Panin;* but ascending to the *Paurânica* legends, he was grandson of *Dêvala*, an inspired legislator." The probability is, that the Indian scribes, like those in other countries, claimed as the author of their own theories some great personage veiled in the mist of ages, and endeavoured to exalt their own science by referring it to a sacred origin. The same attempt to give undue antiquity to a philological work is apparent in the reference of the vocabulary of Amara-Sinha to an older age. It is pretty clear that this lexicographer flourished under Vicramâditya, and was one of the nine gems of his court—a phrase which reminds us of the Alexandrian Pleiad; and it is at least probable that the *Sutras* attributed to Pânini were not much more ancient. The latter, at all events, found a commentator in the person of Bhartrihari, a brother of King Vicramâditya, whose *Kâri-kâ*, or metrical aphorisms of grammar, and the *Vârttikas*, or annotations of the inspired saint and legislator Kâtyâyana,[1] have nearly the same authority as the work of Pânini itself.

Parallel between philology in India and among the Greeks and Jews.

Those who are interested in every additional proof of the axiom, that the same causes produce the same effects, will be gratified by observing how exactly similar the growth of philology has been not only in the Greek and Jewish schools, which had a certain connection with each other, but also in the Indian school, which, though long subsequent, must have been nearly independent of any western influences. In Central Hindostan, where Vicra-

Ancient Philology.

mâditya reigned, no less than in Egypt under the Ptolemies, and in Palestine after the return from Babylon, these critical and grammatical labours were stimulated by the wish to preserve an accurate knowledge of an idiom which was becoming less vernacular every day, and which contained the key to a literature regarded as classical at Alexandria, sacred at Jerusalem, and both classical and sacred at Oujein. The process in all these cases was precisely the same. The first care was to settle the texts of the most ancient and precious books. What Zenodotus, Aristophanes, and Aristarchus attempted at Alexandria, was the object of Ezra and his followers in Judea, and of the priestly or princely scholars who illustrated the glories of King Vicramâditya. The different editions of the text of Homer, and the varieties indicated by the Septuagint, as compared with the Hebrew texts of the Hebrew books, are paralleled by similar phenomena in India. For example, the great epic poem called the *Râmâyana*, which describes, under the mythical form of the adventures of *Râma*, an incarnate deity, the conquest of Southern India and Ceylon by the Brahminical race, appears in two distinct recensions, one of which is called the edition of the commentators, and is supposed to have been settled at Benares; the other, which belongs to the Bengal school, and is called *Gaudana*, from *Gauda*, the ancient name of the central region of Bengal, and of its capital, now destroyed.[1] The commentaries and paraphrases of the Alexandrian scholiasts and the Jewish Talmudists are more than paralleled by the similar efforts of the Indian pundits; and while the latter are rivalled by the Greeks only in their lexicography, neither Greeks nor Jews can vie with them in the minute and artificial accuracy of their grammatical system.

Greek philology during the decline of the Roman Empire.

Under the Roman emperors Greek philology, which had domesticated itself in Italy from the time when the Greeks first fell under the paramount influence of the Romans, was represented by an unbroken series of rhetoricians and grammarians. Flourishing schools existed not only at Rome, Athens, and Alexandria, but in outlying places like Marseilles, Rhodes, Apollonia, and Tarsus. In the reign of Vespasian distinct provision was made for the due remuneration of the Greek teachers settled at Rome (Suet. *Vesp.*, c. 18). Hadrian directed his efforts to the re-establishment of Athens as the principal university in the empire, and the steps which he initiated were carried out by M. Aurelius in the second century. In the school of Athens the chief professor was the occupant of the chair of rhetoric; and that his functions implied that he was the greatest philologer or scholar of the day is clear, not only from his title as "leader of the youth of Athens," but also from the fact that Julius Pollux, who held this office under Commodus, had been the tutor of that prince, and has left us an *Onomasticon*, or lexicon of classical terms, corresponding in effect to the *Amara-Cosha* of the Indian grammarians. Other rhetoricians or grammarians of the same age drew up glossaries or treatises on grammar and metres, which exhibit a thoroughly philological spirit, and have been found very useful by modern scholars. Among the most eminent of these were Apollonius Dyscolus, who first reduced Greek grammar to something like a systematic form, and his son Herodian, whose writings treated of many departments of minute criticism. We see the influence of the philological studies of the second century in some of the writings of the great satirist Lucian, who was not only an eminent verbal critic, but contrived, by a careful study of the best authors, to pass from the semi-barbarous Hellenism of his native place (Samosata, on the Euphrates) to a style more purely Attic than has ever been attained by an imitator. Philology of the same kind was cultivated by many other learned Greeks, most of them being, like Lucian, of oriental origin. As scholars, the most eminent of these were the contemporary writers of the third century,—Longinus, who, as we have seen, wrote a book called *The Philologers*; Porphyry, who was called "the most grammatical of philosophers" (Wyttenb. *ad Eunap.*, p. 7, ed. Boissonade); and Origen, the Christian father, who may be said to have founded the modern school of sacred hermeneutics. A taste for philological investigation was exhibited by many writers in the fourth and fifth centuries; and Athens, Alexandria, and Constantinople abounded in philosophers and rhetoricians, both Christian and pagan, who made the illustration of the classical authors one of the main objects of their labours. Such were Themistius and Libanius, Synesius, Theon and his daughter Hypatia, Olympiodorus and Simplicius, and, above all, Proclus, the last of the Neo-Platonists. Orus and Orion wrote on the details of the language; Stephanus of Byzantium collected the traditions of geographical knowledge; and perhaps at this time John of Stobi preserved, by a series of extracts, some records of the ancient philosophical systems.

Philology during the Middle Ages.

II.—PHILOLOGY DURING THE MIDDLE AGES.

Commencement of the middle ages fixed by two nearly contemporaneous events

The *middle*, or, as they are sometimes called, the *dark* ages, may be said to have commenced with two nearly contemporaneous events in the eastern and western divisions of the Roman empire. In 529 A.D. the school at Athens was closed by Justinian, and the living literature of Greece received a blow from which it never entirely recovered. Heathen philosophy took refuge for a while in the uncongenial hospitality of Persia; and the intermitting patronage of the Byzantine emperors never gave it an opportunity of really reviving in the regions where the Greek language was still vernacular. In 524 A.D. Boëthius died in prison; and his *Consolation of Philosophy* was the last dying swan-note of classical culture in the districts where the Latin language was still spoken and written according to the forms of the better ages. For some nine centuries after these events, philological studies were prosecuted, if at all, in a very partial and imperfect manner. According to the definition of the term from which we have started, there was no true philology in the dark ages. For though something was done for the illustration of the ancient writers, and something more for their preservation, the classical languages were not viewed with any proper regard to their structure and significance, and the higher kind of verbal criticism was simply non-existent.

How far philology existed during the middle ages.

As far as philology existed at all during these nine centuries, it may be said to have presented itself under four distinct forms of activity, —that which appeared in the general cultivation of Greek literature at Constantinople; that which was represented by the biblical studies of the Jews, especially at Tiberias in Palestine, and at Babylon; that which manifested itself in the intelligent curiosity of Arabic scholars at the two extremities of the Mohammedan conquests,—Baghdad and Seville; and that which is implied in the scholastic learning of Northern and Western Europe.

a. Philology at Byzantium.

At Constantinople, in the long interval between the reigns of Justinian and Constantine Palæologus, the cultivation of Greek literature went through many phases of neglect and revival. And from the time of Photius the Patriarch, in the latter half of the ninth century, down to the fourteenth and fifteenth centuries, when wandering Greeks appeared as the teachers of their own language in Italy and other parts of Europe, Byzantine literature contained some strong ingredients of a philological nature. Lexicons, like the well-known compilations known by the

[1] See Gorresio's Preface to his edition of the *Râmâyana*. Lassen thinks that there were three recensions, all amplifications of a common nucleus. (*Ind. Alterthumsk.* ii., p. 500.)

Philology during the Middle Ages.

names of Hesychius and Suidas, or by the title of *Etymologicum Magnum;* commentaries, like those of Eustathius on Homer; treatises on grammar and dialects, like those of Thomas Magister, Georgius Lecapenus, and Gregory of Corinth, at least furnished the materials for those who, a little later, and in a different part of Europe, were destined to bring a more accurate and searching criticism to the same department of study.

b. Philology among the Jews.

The attention which the Jews had paid to the texts of their sacred books from the time of their restoration, and especially after they had come into contact with the Greek learning of Alexandria, was in the strictest sense philological; though, from their one-sidedness and natural prejudice, they were not likely to bring any comprehensive or philosophical views to bear on the study of their own language and literature. The Masora or traditionary school, which dates from the days of Ezra, continued to exist in Palestine for many centuries. Even after the destruction of Jerusalem it had its seats of learning at Jabneh, Tsiphoriah, Cæsarea and Tiberias. In the last of these places the Rabbi Jehudah was famous about A.D. 230; and after his death Babylon became the chief abode of Jewish learning, having been in fact the birthplace of the studies which Ezra and Nehemiah had imported into their native land, and having been the second home of the Israelites from the time of their exile under Nebucadnezzar. (See Fuerst, *Kultur und Literaturgeschichte der Juden in Asien*, i., p. 3.) In the time before this establishment of Jewish learning in Babylon as its metropolis, three epochs are distinguished,—that from 585 to 300 B.C., when the canon was in the process of formation; that from 300 to 32 B.C., when tradition and Jewish theology were establishing themselves on an independent basis of speculation; and that from 32 B.C. to 188 A.D., when the Mischna was in the process of formation. But although Babylon became the chief seat of Jewish learning after the death of the Rabbi Jehudah, the school of Tiberias still retained its authority; and it was here, in A.D. 506, that the Masora of the law was first committed to writing, its last compiler and editor being Ben Asher, who lived at a somewhat later period. The school of Babylon flourished till the year 1037 A.D., and from this proceeded the thriving branches of Jewish literature which were transplanted to Italy, Barbary, and Spain about the year 900 A.D. These learned Jews not only devised an elaborate system of grammar, which still holds its ground, to the great detriment of comparative philology, but they endeavoured to fix the pronunciation of the sacred language by a system of vowel-points, which came into use between the sixth and eighth centuries A.D.; and while they seem to have dealt rather arbitrarily with the text itself, they sought to fix its interpretation by an elaborate contrivance of points and accents.

c. Arabic learning.

While the Jews, though denationalized and dispersed in foreign lands, were exhibiting this activity in the philological study of their sacred literature, another branch of the Semitic family had succeeded in carrying their living language from the Indian Ocean to the Atlantic. The establishment of the religion of Mahomet, and the proselytizing conquests of his successors, had made Arabic the court language in more than one populous and civilized region; and it was the policy of the khalifs to encourage the cultivation of a native literature among their subjects. It was under the Abbassidæ, and especially under Haroun-al-Rashid, in A.D. 786–808, that this Alexandrian period of Arabic learning attained its greatest lustre. Translations were made from Greek, Syriac, Persian, and Pehlevi writings; and this love of foreign learning was carried so far by Al-Mamun, who reigned in 813–833, that he offered the Byzantine emperor a large sum of money and favourable terms of peace for the services of Leo the philosopher. Under this khalif schools were established at Baghdad, Bosra, Bokhara, and Kufa, and great libraries collected at the capital and in other places. The Moorish dynasty of the Omayids in Spain vied in this patronage of learning with the Abbassidæ at Baghdad; and Cordova became one of the chief seats of Arabic culture, especially in the tenth century. Besides Cordova, Spain possessed 14 universities and many lower schools in which Arabic studies were prosecuted; and the influence of these Semitic teachers on the education of Europe in general is shown by the universal substitution of the Arabic for the Roman numerical signs, and by the adoption from the Arabic of a great many technical terms, such as *alcohol, algebra, alkali, azimuth, zenith, nadir*, &c. The extent to which these Arabic scholars studied the classical writings of the ancients, at a time when they were almost unknown in Europe, is indicated by the importance attached, on the revival of letters, to the translations and commentaries on Aristotle published by Averroes (*Ibn-Roschd*) of Cordova in the twelfth century, and rendered into Latin for the benefit of the European schoolmen.

d. Scholastic learning in Northern and Western Europe.

In Northern and Western Europe the clergy for a long time monopolized the little learning which still struggled for existence. The prejudice which the church had entertained against heathen culture from the fourth century, prevented the priests themselves from engaging with much interest in the study of the best writers. Greek was an unknown tongue to the Latin Christians; and the language of Cicero and Virgil was gradually breaking up into the Romance dialects, which are its representatives in Italy, France, and Spain. The Latin was indeed retained as the language of religion and law; and the necessity imposed upon the clergy of studying the vulgate translation of the Scriptures and the standard books of canon law, which were written in the classical idiom, maintained the practice of grammatical training even on the part of those who had no taste for a pure and accurate style. And if the classical writers were not much studied, they were at all events preserved from a wider destruction than has befallen them by the monks of the Benedictine order, whose rules obliged them to read and copy manuscripts, and who exercised this rule not unfrequently on behalf of the best Latin authors. Individual instances occurred in which a desire for better learning was manifested. In England, in particular, an Asiatic Greek, named Theodore, who became primate in 668 A.D., introduced a knowledge of Greek and Latin; and in the following century Bede, and a little later Alcuin, exhibited a respectable amount of philological attainments. The intellectual excitement occasioned by the first Crusade, and the glimpses of eastern civilization and refinement which this pilgrimage of warriors and priests opened to the ruder nations of the West, seem to have led to the development of universities in the twelfth century. It is generally supposed that the university of Paris was the earliest of these institutions; but it was followed speedily by similar establishments in England and Italy. In all these universities the faculty of arts or philosophy was the original department; and of the seven liberal arts of which the course of study consisted, the first three, or grammar, logic, and rhetoric, attracted the greatest attention. And as all these consist more or less in the study of language for its own sake, it may be said with truth that the universities of Western Europe had at once grappled with no inconsiderable part of philology.

Foundation of universities.

The scholastic philosophy.

Almost contemporary with this beginning of university education was the establishment of the scholastic philosophy; that is, of a system of grammar and logic derived ultimately from the Stoics, and applied to the solution of the most difficult questions in metaphysics and theology. The founder of this school-philosophy was Roscelin of Compiègne, who flourished in the early part of the twelfth century, and adopted the tenets generally known as *nominalism.* He was, therefore, the first to inaugurate a

Classical and Sacred Philology.

mode of dealing with language, which in the fourteenth century, under the able guidance of our countryman, William of Ockham, was destined to pave the way at once for a reformation of theology, and a revival of literary criticism. The schoolmen, however, dealt only with the method of language, or with the structure of the sentence; and though they occasionally speculated on the meaning of terms, they had no linguistic knowledge; and if the universities had been left to the training which they encouraged and exemplified, there would have been no restoration of the better kind of learning. But while they were wrangling on questions of divinity at Paris, Oxford, and Salamanca, and while Bologna was prosecuting the study of the civil law, eminent literary men in Tuscany had been led by their own good taste to make themselves acquainted with the great writers of ancient Greece and Rome, and to acquire the classical idioms in which they had composed their works. Dante, who wrote his *Divina Commedia* at the very beginning of the fourteenth century, takes Virgil for his guide through the gloomy regions of future punishment, admitting that he had derived all the graces of his style from a careful study of that great poet. Petrarch was induced to devote his special attention to Virgil and Cicero, and recommended them by his warm eulogiums to the notice of his contemporaries. But the traditions of classical Latin had never been entirely lost; and Petrarch aimed at a more important acquisition when he endeavoured, with the aid of the Calabrian Barlaam, to gain some knowledge of Greek in 1342. In this effort he was not successful; but the achievement was effected by Boccaccio a few years later, when he was fortunate enough to obtain the assistance of Leontius Pilatus, the last of those who, in Greece itself, were supposed to understand the text of Homer. These, however, were isolated instances; and no public teacher of Greek was established in Italy before the year 1395, when Emmanuel Chrysoloras gave lectures at Florence, and became the founder of a school of Italian Hellenists. Guarini of Verona had been his pupil at Constantinople, and became his fellow-labourer in spreading a knowledge of Greek. Numerous manuscripts of the best authors were imported by Aurispa and others; and nothing was wanted but formal and public patronage to establish in Italy the renewed study of classical antiquity. The accordance of that patronage in the fifteenth century, combined with the invention of printing in Germany or the Netherlands, and other concurrent causes, gave rise to the revival of learning in Europe, and led to the foundation of modern philology as a main ingredient in liberal education.

Classical studies revived in Italy in the 14th century.

III.—CLASSICAL AND SACRED PHILOLOGY AFTER THE REVIVAL OF LITERATURE.

Patronage of ancient learning in the 15th century.

It was about the same period that printed books began to appear in the Low Countries and in Germany that the conquests of the Turks drove the most learned Greeks from their own country, and obliged them to seek an asylum in Italy; and that Alfonso, King of Naples, the Pope Eugenius IV., and, above all, Cosmo de' Medici, encouraged learning by a direct countenance of its professors. While the first of these contemporary circumstances paved the way for a general circulation of books, the active patronage of the leading men in Italy enabled native or foreign scholars, like Poggio Bracciolini, Laurentius Valla, Theodore Gaza, John Bessarion, Filelfus, Gemistus Pletho, and others, to place the study of the classical writers on a footing of recognised importance. In tracing briefly the history and development of philological studies from this period, which was not only in one sense a revival of what had previously existed among the Greeks and Romans, but also, in another sense, the beginning of critical scholarship and linguistic science in the modern acceptation of these terms, it will be most convenient to consider separately and in succession the different countries which made important contributions to the methodical investigation of the classical languages in the fifteenth and sixteenth centuries.

Italian scholarship.

We must begin with Italy, which, while it may claim the honour of inaugurating modern learning, has perhaps contributed less than any other country in Europe towards the improvement of scientific philology. At the time of their greatest activity,—namely, in the first hundred years after the revival of letters,—the Italian scholars were chiefly occupied with printing Greek and Latin books, and furnishing the former with Latin versions. An eager desire to know the contents of the books written in Greek, which so few had adequately mastered, made the work of translator very popular and remunerative. Poliziano's version of Herodian passed through three editions in 1493, the year of its publication; and the versions of Plato and Plotinus, which Marsilius Ficinus executed from the Greek manuscripts, were for a long time the only sources of knowledge for those who studied the Platonic and Neo-Platonic philosophy. Laurentius Valla, who had begun at an earlier period to translate the historians and epic poets, was the first of these Italian scholars who attempted to deal philologically with the Latin language. His six books on the elegancies of Latin, which were first published before the invention of printing, laid the foundation of modern researches in syntax and the distinctions of synonyms. And he also set the first example of writing critical notes on the text of the New Testament. The first specimen of more general criticism was supplied by the *Miscellanies* of Poliziano, which appeared in 1489, and contained illustrations of one hundred passages, taken at random from the best Latin authors. He entered into questions sometimes involving the minutest accuracy. For example, he was the first to prove what all scholars admit, though few adopt that spelling, that the name of Virgil was really *Vergilius.* With all this, however, the book contains at the end the following curious admission and demonstration of the author's disregard of orthography:—"Impressit ex archetypo Antonius Miscominus. Familiares quidam Politiani recognovere. Politianus ipse nec *Horthographiam* se ait nec omnino alienam præstare culpam." In the same year with the *Miscellanies* of Poliziano appeared the *Cornucopia* of Nicolas Perotti, which was mainly a commentary on Martial; and the same scholar compiled a Latin Grammar, which was used as a text-book by the learners of that age. Philippo Beroaldo did good service as an editor of Latin works; and Hermolaus Barbarus, a noble Venetian, who enjoyed a reputation not inferior to that of Poliziano, boasted that he had introduced some 5000 emendations into the text of Pliny's *Historia Naturalis.* Meanwhile the press of Aldus was in full activity, and before the end of the fifteenth century it had put forth nearly twenty editions of Greek authors, beginning with the elegant but comparatively recent poem of Musæus. The Greek text of Plato, whose writings had excited so much attention at Florence, where they were known in the Latin translation of Ficinus, appeared for the first time from the press of Aldus in 1513, under the editorship of Musurus, who prefixed some Greek elegiac verses of his own, perhaps the last specimen of such a composition from the pen of a native Greek.

German scholarship—Reuchlin.

The heavy ecclesiastical atmosphere, which hung over Italy, did not allow that country to see the full development of the scholarship which it had inaugurated. It was reserved to Germany and the Netherlands, which had introduced the art of printing, to produce also the first beginnings of a free and enlightened criticism, which rescued classicalism from the trammels of sacerdotalism, and paved the way for intellectual liberty in all departments of literature. The founder of modern scholarship in Germany, and the pioneer of the Reformation, which sprung, in part at least, from the establishment of a better kind of learning in

that country, was John Reuchlin, whose name, according to the pedantic fashion of the age, was Græcized into *Capnio.* Born at Pforzheim in 1455, and having received his early education in Germany, he was enabled to extend his opportunities of acquiring knowledge by visits to France and Italy; and while in the latter country in the suite of Eberhard of Wurtemberg, he excited the admiration of Joannes Argyropulus by the accuracy with which he translated Thucydides, and elicited the exclamation that the banished learning of Greece had taken refuge beyond the Alps. His studies were not confined to Greek and Latin. He was also an oriental scholar, and had paid particular attention to the later Hebrew literature.

Melancthon.

His mantle descended to Melanchthon, whom he recommended as his substitute when invited to Wittemberg; and he died in 1522, after having laid the foundation of the philology which has become the inalienable inheritance of his country.

Scholarship in the Netherlands—Erasmus.

In the Low Countries, Desiderius Erasmus of Rotterdam, who was born in 1467, and died in 1536, pursued a course which tended to the same object as that of Reuchlin, though he was less frank and open in the avowal of his convictions. He, too, had visited Italy, and became a doctor at Bologna. And he had made his appearance in England before the end of the fifteenth century, and not only stimulated the learned activity which was commencing in this country, but actually held a professorship in the university of Cambridge, and wrote a book on Latin style for the use of his friend Dean Colet's newly-founded school of St Paul's.

Progress of philology in France—Budæus.

Although the greatest normal influence is thus attributable to Germany and Holland, it was in France that the earliest philological works of the new school made their appearance. William Budé (Budæus), who was born in the same year as Erasmus, by the publication of his two great works, *De Asse et Partibus Ejus* in 1514, and his *Commentarii Linguæ Græcæ* in 1519, opened a new era in philological research. The latter, in particular, must be regarded as the foundation of all modern Greek lexicography; and though the first book of its kind, it is still an excellent authority in some of its departments, especially in the explanation of the orators; insomuch that Porson, the greatest critical scholar of the present century, at one time contemplated a republication of the work. We owe to Frenchmen of the sixteenth century not only this, the earliest specimen of a really scholarlike explanation of Greek words, but also the first beginnings of Latin and Greek lexicography in the ordinary acceptation of the term. The Dictionaries of Calepio and others were completely superseded by the appearance of the

Robert and Henry Stephens.

Latin Thesaurus of Robert Stephens (Etienne) in 1535; and Henry, the son and successor of that eminent scholar and printer, by the publication of his complete Greek Thesaurus in 1572, not only took the place of the Lexicon published ten years previously by his countryman Robert Constantin, but has furnished the groundwork of all future labours of the same kind; and his great Dictionary has been republished twice in the present century, with all the aids and appliances of modern erudition. Besides these eminent men, and the two greatest scholars of the end of the sixteenth and the early part of the seventeenth centuries, Isaac Casaubon, the son-in-law of Henry Stephens, and Joseph Justus Scaliger, the founder of philology in Leyden, when the university was established there in 1575, as a reward for the heroic valour of the citizens, France contributed to Italy, in the fifteenth century, the most learned of those who wrote on philology in that country,—M. A.

Muretus.

Muretus, who, to considerable erudition and critical acumen, added the rare accomplishment of writing Latin in a style which any Roman but Cicero might have envied.

The scholarship of England in the sixteenth century was not only stimulated by the direct influence of foreigners established in the country as teachers, such as Erasmus, P. Martyn, and M. Bucer, and by the intercourse between the leaders of the Reformation on this side of the Channel, and men like Melancthon, who represented at once the revived learning and Protestant feelings of Northern Germany, but also by the labours of Englishmen high in the state—such as Sir T. Smith, who taught Greek at Cambridge in 1533, and was ultimately secretary of state to Queen Elizabeth; Sir John Cheks, who, after being regius professor of Greek and public orator in the university of Cambridge, was tutor, privy councillor, and secretary of state to Edward VI.; and Roger Ascham, who was private tutor and Latin secretary to Queen Elizabeth. The foundation of a number of grammar schools in the latter half of the sixteenth century did a great deal towards confirming the study of philology as the chief branch of a liberal education; and not only the clergy and gentry, but even the ladies of England, attained to a familiarity with Greek and Latin literature which was not common on the Continent. Grammars of both languages were compiled; and in a series of editions, beginning from the year 1548, Thomas Cooper, afterwards bishop of Lincoln and Winchester, so improved Sir T. Elyot's Latin and English Dictionary, that classical students in this country possessed, with explanations in their own mother tongue, a very adequate substitute for the Thesaurus of Robert Stephens.

Classical learning in England.

Philology established in Europe at the end of the 16th century.

By the end of the sixteenth century, classical philology, in its modern sense, was fully established, and the publication of various editions of the New Testament, an active study of Hebrew, especially in Germany and England, and various contributions to the interpretation of Scripture, had placed sacred philology on a parallel footing in the countries which professed Protestantism. Even the remote kingdom of Scotland had felt the influence of this revived study of antiquity; and George Buchanan, who was born in 1506, and died in 1582, obtained a place, at any rate in Latin scholarship, equal to that of his most celebrated contemporaries.—Οὐ Σκότος ἦν, said his pedantic eulogist, ἀλλὰ φάος Σκοτίης. After the commencement of the seventeenth century, it is no longer necessary to consider the progress of philology with reference to the different countries which contributed to it. The republic of letters was of no country; and while scholars formed a sort of confraternity which kept up a friendly intercourse by means of Latin, the universal language, sometimes publishing in one country what had been written in another, the successive epochs in the development of linguistic science were due rather to the eminent talents of individuals than to anything peculiar to the training or circumstances of their respective nations.

Buchanan.

Isaac Casaubon.

J. J. Scaliger.

As we have already intimated, two great French scholars form the link between the creative efforts of the sixteenth and the completed scholarship of the seventeenth century: Isaac Casaubon, who was born at Geneva, where his parents had taken refuge in 1559, and who died as prebendary of Westminster and Canterbury in 1614, being as nearly as possible the contemporary of Shakspeare; and Joseph Justus Scaliger, who was born at Agen in 1540, and died at Leyden in 1609. The latter of these celebrated men constitutes an epoch in the history of philology; and, encouraged as he was by the communications of Casaubon, he laid the foundation of the science of learned chronology. "Scaliger," says Niebuhr (*Hist. of Rome*, i., note 660), "stood at the summit of universal solid philological learning in a degree that no one has reached since; and so high in every branch of science, that from the resources of his own mind he could comprehend, apply, and decide on whatever came in his way." It was not only by his great work *De Emendatione Temporum*, and his numerous contributions to the elucidation and criticism of the ancient authors (see the list given by J. Bernays in his biography of Scali-

ger, Berlin, 1855, pp. 269–316), but also by his labours in oriental learning, that Scaliger deserves to be regarded as the epochal scholar of his age. It was he who, without any dictionary or grammar, engaged first in the study of Arabic; and though he published nothing on the subject, the notes which he had drawn up served as the basis of Rapheleng's Arabic Dictionary, and laid the foundation for the grammatical and lexicographical labours of Erpenius and Golius, who were successively professors at Leyden in the middle of the seventeenth century. The revised translation of the Bible, which appeared in 1611, was a proof of the deep root which philology had struck in this country; and there were many book-learned men of first-rate eminence in England, France, and Holland during the period, which was rendered unhappy by the wars of political or religious opinion in those countries. But the mode of study adopted by these scholars, eminent as they were, did not differ from that of their predecessors. Bellenden, Andrews, Selden, Usher, Pearson, and Gataker, can hardly claim anything as peculiar to themselves, unless we should make an exception in favour of the Latin orthography adopted by the last-named of these writers.

R Bentley.

It was towards the end of the seventeenth century that another new epoch in philology was marked by the appearance of Richard Bentley. Born in January 1662, and educated at Cambridge, he was led by a sort of accident to investigate the genuineness of some epistles written by a sophist, probably in the second century A.D., and attributed to Phalaris, who flourished some six centuries B.C. The absolute demonstration at which Bentley arrived, that these epistles were the ingenious forgeries of an age long subsequent to their pretended date, opened the way for an application of philology as new as it was important. Up to that time it was usual to accept the title-pages of ancient books as conclusive evidence of their authorship. But the matchless learning which Bentley, stimulated by personal controversy, brought to bear on the worthless production of some rhetorician of the age of the Antonines, suggested to scholars of kindred genius similar efforts in the cause of truth where works of greater antiquity and importance came to be cross-examined in the court of philological judgment; and Bentley has been regarded by all the greatest of the scholars who have succeeded him as the author and founder of historical criticism. One of his most active opponents in the squabbles with his college, which occupied too large a portion of his life, Dr Conyers Middleton, was one of the first to enter on this delicate field. To Bentley, also, is due the first beginning of a new form of sacred criticism. He undertook an edition of the New Testament resting on a full collation of all the manuscripts; and though he did not live to carry out his plan, it has produced much fruit in the hands of those who, for a hundred years after his death, laboured according to a similar procedure. In regard to the details of classical scholarship, Bentley was distinguished above all his predecessors and contemporaries by his faculty of conjectural emendation, by his keen observation of the facts of language and the forms of words, and by an attention to the details of the ancient metres, which was quite new at that time. In these particulars he found worthy successors among his own countrymen; and the accurate discipline of the public schools in England placed our scholars generally in a better position at starting than most of their brethren on the Continent. Bentley died in 1742; and in the remaining part of the eighteenth century, the English scholars Dawes, Markland, Toup, Tyrwhitt, and, above all, Porson, had brought minute verbal scholarship to its highest point of accuracy and refinement.

Bentley's successors in England.

Meanwhile Germany and Holland, with which Bentley had kept up uninterrupted intercourse, were contributing largely to the materials at least of philological learning. J. G. Grævius and J. F. Gronovius, the contemporaries of Bentley, were Latinists of first-rate eminence in Holland. Similar studies were pursued at Hamburg by J. A. Fabricius, who was born in 1688, and died in 1736; at Gottingen by J. M. Gesner, who was born in 1691, and died in 1761; and at Leipsic by J. A. Ernesti, who was born in 1707, and died in 1781, and who combined with his classical attainments some amount of theological learning.

German and Dutch scholars.

The Latinism of the university of Leyden was developed into a combination of Latin with Greek, and a devoted study of the latter, by Tiberius Hemsterhuis, whose early labours were both stimulated and guided by Bentley. He was followed by David Ruhnken, who united to a refined accuracy of Greek scholarship, worthy of the English school, a practical skill as a Latinist, in which he was surpassed only by Muretus; by L. C. Valckenaer, who was the first to pay that attention to the remains of the Greek drama which has been a characteristic of more recent scholarship, and who was also an eminent expositor of the New Testament; and by Dan. Wyttenbach, who vied with Ruhnken as a Latinist, and, for the first time, brought accurate scholarship to bear on the study of the best Greek philosophers.

New phase of philology in Germany.

A new phase in the development of philology was marked by the rise of modern German scholarship at the end of the eighteenth century. Up to this time German philology had been little more than an offshoot of that which flourished in Holland; and some of the ablest German scholars, such as Grævius, Alberti, Drakenborch, Ruhnken, and Wyttenbach, had established themselves at Leyden.

Lessing and Winckelmann.

But German literature in general was placed on a new footing by the genius of Lessing, who shook off the overruling influence of the French school; and at the same time Winckelmann laid the foundations of the archæology of art. The peculiar genius of the Teutonic mind seemed to rise at once from its slumbers, like a giant refreshed with necessary repose. Besides the great efforts of original thought in the departments of theology, philosophy, and general literature, which have proceeded from the pens of German writers since the period of the Seven Years' War, the same spirit was soon seen in classical philology.

Heyne.

Here the epochal man was Christian Gottlob Heyne, and the scene of his activity was the university of Gottingen, founded by our King George II. in 1739. Heyne was the son of a poor weaver, born in 1729 at Chemnitz in Upper Saxony, and brought up in the most abject poverty. He contrived to get educated as a starving student under Ernesti at Leipsic; and his editions of Tibullus and Epictetus, which he published in 1754 and 1756, having attracted Ruhnken's notice, he was, on the recommendation of that scholar, in which Hemsterhuis concurred, appointed to succeed J. M. Gesner, and settled at Göttingen in 1763. The difference between Heyne and all preceding scholars consisted in the spirit of general literature which he brought to his philological labours, and the thoroughly modern enlightenment with which he illustrated the objects of erudite speculation. To him politics and art, and all the subjects of the day, fell within the range of a lively and searching interest; and it was to this that he owed the instincts which guided him to some of his discoveries. For instance, a consideration of the socialistic doctrines preached by the leaders of the French revolution probably led him to the inquiries which enabled him to explain, for the first time, the true nature of a Roman agrarian law,—namely, that it dealt with "the pastures of the common land, which were of common right," and not with the private property of the more opulent classes. Heyne did not excel as a verbal critic; and the application of the more reasoning and philosophical spirit, which he exhibited in his own department, to the ancient languages themselves, was due to other scholars.

Reiz.

A beginning in this important field was made by Fr. Wolfgang Reiz (born in 1733, died in 1790), who first started a rational method of dealing with

Classical and Sacred Philology.

grammar and criticism opposed to the mere empiricism which had previously been considered sufficient for all practical purposes. The chief works of Reiz were his treatise *De Temporibus et Modis Verbi Græci et Latini* (Leips. 1766), and his essay *De Prosodiæ Græcæ Accentus Inclinatione* (published after his death, by F. A. Wolf); but whatever influence he may have produced on the learned world by these treatises, a more important effect resulted from his training of the mind of Godfrey Hermann (born 28th November 1772, died on the last day of 1848). The first edition of Buttman's Greek Grammar had been published in 1782, but without evincing any of the marked features of the work as we now have it. In 1801 appeared

G. Hermann.

Hermann's Essay *De Emendanda Ratione Græcæ Grammaticæ*, which took a truly philosophical view of the subject, and applied to the traditionary system of the Greeks principles derived from the general theory of language. The historical criticism, which had been founded by Bentley, and to which Heyne had made some approximations, was revived in a very striking manner by a pupil of the latter,

F. A. Wolf.

Fr. Augustus Wolf, who, following up a theory which had been ventilated in 1725 by an eccentric Italian, Giambattista Vico, perhaps also acting on the hints thrown out by Wood in 1772 (*On the Original Genius of Homer*), and certainly guided in some degree by the Venetian Scholia published by Villoison in 1788, undertook to prove in 1795 that the poems attributed to Homer were not the work of one poet, but were collections of lays reduced to an outward coherence and consistency by the editorial labours, first of the Pisistratidæ at Athens, and afterwards of the Alexandrian grammarians; that, in fact, they were not originally committed to writing, but had gradually assumed in the hands of the rhapsodists the form in which they were thus submitted to the diligence of successive remodellers. Wolf's *Prolegomena ad Homerum*, supplemented in 1797 by his *Briefe an Hrn. Hofrath Heyne, eine Beilage zu den neuesten Untersuchungen über Homer*, produced an effect not unlike that of Bentley's *Dissertation on Phalaris;* and though his views have not found more than a partial acceptance in his own country, and have been warmly combated by some of the best scholars in England, Wolf is accepted, by the chief promoters of historical criticism in the present century, as their great model and immediate forerunner. This was directly admitted by Barthold

Niebuhr.

George Niebuhr (born at Copenhagen 26th August 1776, died at Bonn 2d January 1831), whose *History of Rome* is the most remarkable example of destructive and reconstructive criticism that modern philology has produced. The study of the classical writers in that connection with the taste of modern literature which the old pedantic scholars (Ruhnken's *Doctores Umbratici*) had formally repudiated, and which Heyne had done so much to esta-

Schleiermacher.

blish,[1] found a great supporter in Fr. Schleiermacher, an eminent philosopher and divine, who applied to his examination of Plato's Dialogues a system of interpretation resting on a comprehensive view of the connection of thought in the collected works of his author; and his method was avowedly adopted by Augustus Böckh and Ludolf Dessen. Perhaps the summit of excellence in this application of

K. O. Müller.

classical philology was attained by Karl Otfried Müller, the favourite pupil of Böckh, who pursued with success the paths opened by Heyne, Bockh, Niebuhr, and Winckelmann, and brought his own genial spirit to the aid of his multifarious researches in fields already occupied by other labourers. Views of mythology not confined to the old limits of clas-

Lobeck and Creuzer.

sical erudition were put forth by Lobeck and Creuzer; and when Niebuhr's discovery of the manuscript of Gaius had given a new impulse to the study of civil law, Savigny and

Savigny.

others improved the occasion with such zeal that, in Germany at least, there is a complete union between classical philology and jurisprudence.

Comparison of German and English philology.

The full effects of this new school of German philology were not felt in England until after the general pacification of Europe in 1815. From that time to the present we have gradually extended our acquaintance with the labours of our contemporaries on the Continent; and it may now be said that, according to the definition of those terms on which we have elsewhere insisted (*Classical Scholarship and Classical Learning*, Cambridge, 1856, pp. 149, *sqq.*), philological students in this country have adequately combined the *learning* which is the special characteristic of German classicalism, with the *scholarship* which has been hitherto regarded as the most solid basis of a liberal education in England. The great problem has been, to harmonize the practical skill, the finished mastery over the resources of the Greek and Latin languages, which the habit of composition in prose and verse, in our great schools and older universities, has produced, perhaps in superabundant measure, and in which the Germans are conspicuously deficient, with a more general possession of that knowledge of facts and books, that comprehensive erudition, which the numerous philological professors scattered over Germany are generally found to possess. That such a combination is possible,—that it is sometimes effected in a most remarkable manner,—will not be denied by any one who is aware that the financial affairs of this great commercial country have been administered in succession by two statesmen of nearly the same age, both educated with singular distinction at Eton and Christ Church, Oxford; and that, while one of these has, among other learned works, produced the most profound and critical treatise on the early history of Rome that has appeared since Niebuhr, the other has submitted to an elaborate review, only too much diversified by the flights of an enthusiastic imagination, the various questions connected with the philological analysis of the Homeric poems. We refer of course to Sir G. C. Lewis and Mr W. E. Gladstone.

Completeness of modern classical philology.

Rather more than four centuries have elapsed since the revival of literature, and the commencement of a period when modern scholars proposed to themselves the task of recovering philologically the knowledge of the classical languages which had been lost in Italy and Greece. It is now a long time since the more accomplished scholars of the northern universities have been qualified to expound Thucydides at Athens, and to explain Virgil at Rome; since they could write Greek iambic verse with a correctness not attainable by Gregory of Nazianzus, and could translate their vernacular poetry into Latin elegiacs which Claudian might have acknowledged as equal to his own best efforts. And especially during the last forty years the principles of philological science have attained to such fixedness and maturity, that it does not seem very probable that any very important modifications will be introduced into the method of study which has been established in Germany and England. We cannot therefore conclude the brief survey which we have taken of the history of classical and sacred philology since the middle of the fifteenth century without stating the results which have been secured, and the resources which have been collected for the use of philologers of the present and future ages.

Departments of classical and sacred philology.

The domain of classical and sacred philology has been mapped out, with various degrees of minute detail and refined subdivision, by the most recent writers on the subject (see especially F. A. Wolf, *Vorlesung über die Encyclopädie der Alterthumswissenschaft*, published by Gürtler, Leipsic, 1831; G. Bernhardy, *Grundlinien zur Encyclopädie der*

[1] Compare what Ruhnken says (*De Doctore Umbratico*, p. 120), with the admission of Bockh (*Orat.* A. 1826, *habita*), "qui non videam homines Græcam Latinamque grammaticam imprimis tenentes ceteris mortalibus animo bene conformato longe præstare."

Classical and Sacred Philology.

Philologie, Halle, 1832; A. Matthiä, *Encyklopadie und Methodologie der Philologie*, Leipsic, 1855; Haase, art. "Philologie," in Ersch and Gruber's *Allgemeine Encyclopadie*, part 33, Leipsic, 1847, pp. 392, *sqq.*). It does not appear necessary, at least for our present purpose, that we should go beyond the simple and general classification suggested by Böckh,—namely, that philology falls into two great masses, the *formal* and the *material*, or the doctrine of words (*verbal philology*), and the knowledge of things (*real philology*). To the first (I.) belong exegesis and criticism, including (*a*) grammar, (*b*) lexicography, and (*c*) the constitution and interpretation of the classical and sacred texts; to the second (II.) belong (*a*) political history, with chronology and geography, (*b*) public and private antiquities, (*c*) mythology and the archæology of art, and (*d*) the history of ancient literature and science. In all these departments the labours of the last four hundred years, and especially the methodical efforts of the last half century, have made such progress that it is not reasonable to expect from those who come after us much more than a gradual improvement in the details.

I. (*a*.) Grammars.

I. (*a*.) The grammars of the Greek, Latin, and Hebrew languages have been subjected to the most searching and accurate scrutiny; and both the origin of the word-forms and the structure of the sentences have been expounded according to principles of scientific criticism altogether beyond the reach of Apollonius, Priscian, or the Jewish rabbis. The author of these pages is of course prevented from speaking of what he has attempted to do for the improvement of Greek and Latin grammar; but it is right to mention, as works which have produced a marked influence on the classical scholarship of the present century, the contributions of Buttmann and Lobeck to the establishment of an accurate acquaintance with the forms of words (*Formenlehre*) in the Greek language, and the exposition of Greek syntax by Buttmann, Matthiä, Madvig, and Rost; the metrical researches of Porson, Gaisford, Hermann, and Böckh, have left little to be desired in that department; K. L. Schneider's collections of the forms and inflexions of Latin words exhaust the subject as far as he has gone; and the numerous editions of Zumpt's Latin Grammar, combined with the independent researches of Madvig, have given a lucid and accurate view of Latin syntax. The improvement of Hebrew grammar, and of that of the Aramæan and cognate dialects, is due to Gesenius, Ewald, Fuerst, and Hoffmann.

I. (*b*.) Lexicography.

I. (*b*.) The department of lexicography attained to a complete and lasting development much earlier than that of grammar. We have already mentioned that the great French printers of the sixteenth century, Robert Stephens and his son Henry, drew up respectively complete Dictionaries of the Latin and Greek languages. The Greek Thesaurus of Henry Stephens, which was arranged, as far as the knowledge of those days allowed, in etymological order, was reproduced in the same form, but with very copious additions, by the English printer A. J. Valpy (London 1816–26); and a new edition, with the words arranged alphabetically, has been in the course of publication at Paris since the year 1830, under the conjoint or successive editorship of C. B. Hase, G. B. L. Sinner, T. Fix, L. and W. Dindorf,—all German scholars; and the work, thus remodelled and enlarged, must remain the most copious repertorium of information respecting the facts of the Greek language. A more methodical arrangement of the significations is exhibited in the Greek Lexicons with vernacular interpretations, of which the first specimens were put forth by the German scholar J. G. Schneider, and his editor and abridger F. Passow. After more than one unsuccessful attempt, Greek and English lexicography was placed on a satisfactory footing by Messrs Liddell and Scott of Oxford, whose labours were professedly based on those of Passow. The improvement, however, of the German Dictionary by its more recent editors, Rost and Palm, will probably give rise to a corresponding effort on the part of English scholars. The Latin Thesaurus of Henry Stephens and its successor, Faber's Lexicon (first published in 1571), assumed their best form under the editorship of J. M. Gesner. But the honour of drawing up a Latin Dictionary which should rank with the Greek Thesaurus of Henry Stephens, was reserved for an Italian scholar, Egidio Forcellini of Padua, who, after forty years' labour expended on his task, published his great work in 1771, in 4 vols. folio. His countryman, Furnaletti, enriched the work with a valuable appendix; and the Lexicon has appeared in the best form which it can be expected to attain in the English edition by Mr Bailey (London, 1826). Some Latin and German Dictionaries, especially that by Scheller, have merits of their own; but although the Lexicon of Forcellini, with all its copiousness, is occasionally imperfect, it will ever remain the greatest monument of honest labour bestowed upon the Latin language. Of Latin and English Lexicons, the best representative of the scholarship of the day is undoubtedly that of Dr W. Smith. With regard to the Hebrew language, the Buxtorfs, Pagninus, and others, had adequately conveyed the traditionary interpretation of Hebrew phraseology; but a new era in Hebrew lexicography was opened by the Thesaurus of W. Gesenius, and the elaborate Concordance of Julius Fuerst, and his Dictionary, which is in the course of publication, will leave the student of this language nothing to desire.

I. (*c*.) Criticism and exegesis of texts.

I. (*c*.) The constitution and interpretation of the classical and sacred texts presented the first and most necessary object to the scholars of Europe on the revival of letters; but it has required a long probation in grammatical and metrical criticism to bring this department to its present state of methodical perfection. It can hardly be doubted that the great English scholars have done more than any of their brethren on the Continent to establish the laws of language and metre, and the principles of criticism, which are of constant application in dealing with the texts of authors deformed by the transmitted blunders of ignorant copyists. With regard to the sacred texts, the peculiar feelings with which they are regarded have induced editors to rely as far as possible on manuscript authority, and the most laborious collations have been made with this view. It has been shown, however, that conjectural emendations may be safely introduced into the Hebrew text of the Old Testament, which has often been arbitrarily altered by the Scribes and Talmudists; and Lachmann, one of the most recent, and at the same time most careful editors of the New Testament, has asserted and exemplified the occasional necessity of having recourse to the unaided sagacity of the critic in certain cases of difficulty. (Tom. ii, præf., p. v., *sqq.*) In the classical authors, and especially in the poets, a scrupulous regard for the manuscripts is seldom entertained by any one who has mastered the details of the Greek and Latin languages, and who knows that he has rarely before him a manuscript authority of older date than the later centuries of Byzantine literature. The obvious errors found in the papyri of the newly-discovered fragments of Hypereides, and even in some inscriptions, show that the most ancient copyists were not more immaculate than modern printers; and the chances of error are infinitely multiplied when we have to deal with the last results of many centuries of transcription. The confidence of the verbal critic in conjectural emendation has often been confirmed by the subsequent discovery that the alteration which he felt to be necessary to the grammar or metre is actually preserved in some older copy, or in some citation from the author by an ancient grammarian. The perfection of modern grammar and lexicography, and the great ability which has been brought to the study of the ancient texts,

Comparative Philology.

have left us very few authors, and indeed very few inscriptions or coins, which still require the care of a competent editor.

II. (*a*.) History, chronology, and geography.

II. (*a*.) In history, chronology, and geography, English scholarship has placed the results of philological research in their most complete and perhaps final condition. Although the great German writers, especially Niebuhr and O. Müller, have done very much to investigate the early and obscure periods of Roman and Greek history, the classical period of the former is most adequately narrated by Arnold, Liddell, and Merivale; Gibbon will always remain the master-work for the period of the decline and fall; and Sir G. C. Lewis has investigated even the early history in a new spirit of learned scepticism. In regard to Greek history, the labours of Thirlwall and Grote, coming close in succession, have challenged an incontestible superiority to all previous or contemporary labours. The *Fasti* of the late Mr Clinton are the standard work on chronology. And in geography, the learned investigations of Leake and others are most satisfactorily exhibited in the valuable Dictionary edited by Dr W. Smith.

II (*b*.) Antiquities.

II. (*b*.) For the collection of facts illustrative of the public and private life of the ancients we are chiefly indebted to the laborious erudition of the Germans in the present century, among whom Bockh, Becker, Wachsmuth, Schömann, and K. F. Hermann, occupy a distinguished place.

II (*c*.) Mythology.

II. (*c*.) In mythology, also, no other scholars can vie with the philologers of Germany. From different points of view, Creuzer, O. Müller, and Lobeck have treated the subject with great acuteness and exhaustive learning. The archæology of art, since Winckelmann's time, has been prosecuted with eminent success by German scholars. The Archæological Society of Rome is chiefly sustained by students of this nation; and the late O. Müller's *Manual* is the best text-book on artistic antiquities.

II. (*d*.) Literary history.

II. (*d*.) The history of ancient literature is no longer confined to the learned collections of J. A. Fabricius. Not to speak of the valuable articles contained in the Dictionaries of Pauly and W. Smith, in the various Encylopædias, and in the Prolegomena to elaborate editions of the ancient writers, many books have appeared, or are in the course of publication, which treat elaborately of the history of ancient literature and science. The history of Greek literature, in particular, was undertaken by O. Müller, whose book has been recently completed; and a similar review has been commenced on a much larger scale by Mr Mure, of whose valuable work five volumes have already appeared. Dr Whewell's *History of the Inductive Sciences* contains all that need be said of the progress of physical knowledge in ancient times; and the *Kosmos* of A. von Humboldt is not less remarkable for the learning with which he has collected the reports of more ancient observers of nature, than for the genial sentiment and graphic power with which he has stated the results of modern investigations.

IV.—COMPARATIVE PHILOLOGY.

Distinctions between classical and comparative philology.

Up to the beginning of the present century the great fabric of classical and sacred philology, which had received a gradual increase of solidity or dimensions from the contemporary or successive labours of scholars during the preceding 350 years, stood by itself in a sort of solitary magnificence. Since then there has risen by its side a method of linguistic study, which, though it serves in many respects as a most important auxiliary to the older form of philology, and, conversely, derives from classical learning some of its best materials and safest principles, nevertheless presents many features of contrast to its predecessor, and has not yet been able to effect the intimate and cordial alliance which is necessary for the best possible prosecution of both. This is *comparative philology*, or the comparative study of languages, with an immediate reference to the discovery of the laws which regulate human speech in general, and with an ulterior application to palæological researches respecting the origin of the human race and its various branches, the pre-historical condition, abodes, and civilization of the different tribes of men, and the derivation of those forms of religious belief which seem traceable to some early but not otherwise discoverable contact of nations now geographically distant from one another. The differences between classical and comparative philology seem at first sight sufficiently pronounced. While the student of classical and sacred philology bestows a minute, searching, and critical attention on the grammars of two or three ancient languages, with a professed and special reference to the literature to which they serve as the key; while, if we except the educational results of his grammatical training, we find that the real object of his pursuit is often not so much the words as the things recorded in writing; the comparative philologer, on the other hand, does not confine himself to the classical, or even to the most ancient languages, for every variety of human speech which is fixed in a permanent form furnishes him with inductions for his science, and is alike interesting to him; and he does not concern himself with any literature, whether ancient or modern, except so far as it enables him the better to investigate the structure of language, and so to establish scientifically his views respecting the nature and laws of human speech. Thus, while the classical or sacred philologer studies two or three languages, mainly, or at least professedly, for the sake of their literature, the comparative philologer studies not only all languages, but all literature, for the sake of language in general, and what results from the affinities of particular languages. But though there is this opposition between the two different departments of philology, and though one-sided students in either province have been disposed to regard their fellow-labourers with distrust or superciliousness, philologers of more comprehensive views have recognised the fact, that a prolonged and critical study of some ancient language and literature is the most satisfactory basis for the comparative investigation of all languages with a general object, and that no ancient language and literature can be studied in the best manner by those who ignore the processes and results of comparative philology. And if we speak of a philologer in the fullest and strictest sense of the term, we must not at the present day concede this name to any one who has not ascended from classicalism to comparative grammar, and who cannot extract scientific truth from an examination of the structure and history of language in general.

Rise of comparative philology.

It has been already intimated that comparative philology did not establish itself as a recognised science until after the commencement of the present century. Indeed, its origin may be dated from the time when Sanscrit grammar began to be studied in a proper manner by European scholars; and if a particular year may be fixed as that of its birth, we could hardly select any other than 1808, that of the death of our great verbal scholar, R. Porson; when the publication of Colebrooke's edition of the *Amara-Côsha* at Serampore, paved the way for a more convenient form of Sanscrit and English lexicography; when Wilkins' Sanscrit Grammar, and the notice of the book in the *Edinburgh Review* (vol. xiii.), directed the attention of English scholars to the affinities of Sanscrit with the other Indo-Germanic languages; when F. Schlegel's book *On the Language and Wisdom of the Indians* awakened a similar interest in Germany; and when Prichard's *Inaugural Dissertation on the Varieties of the Human Race* laid the foundation of the modern science of ethnography. But long before this time, gradual and imperfect approximations had been made to a comparative analysis of ancient languages. The first beginnings were

The year 1808.

Comparative Philology.

Earlier approximations to a comparative study of language

due to the fruitless search among existing languages for the primitive form of human speech; and as various idioms were selected as having the highest claim to this distinction, the affiliation of other languages was attempted by the most violent and precarious etymologies. Sometimes the Celtic, in one case the low Dutch, more frequently the Semitic languages, especially the Hebrew, were favoured with this recognition of priority; but the process was in every case the same, the assumptions equally inadmissible, and the conclusions equally unsatisfactory. The true affinity between Persian, German, and Greek was perceived by Lipsius (in 1599), by Salmasius (in 1643), and by D. Wilkins (in 1715); but as they had no fixed principles of philology, no results flowed from the observation of the facts. The progress of missionary labour led to the translation of the Lord's Prayer into a variety of languages, and a collection of these versions was made by Gesner, whose *Mithridates* appeared in 1555, and led to the collection by Wilkins and Chamberlayne in 1715, and ultimately to the more extended work by Adelung and Vater. The first, however, who prosecuted the comparative study of language on sound principles, and saw its possible application to ethnography was the illustrious Leibnitz. His comprehensive genius anticipated many of the future results of linguistic science, and it was he who recommended the formation of comparative lists of words designating common objects, which would be a basis for the inductions of the general grammarian. The first elaborate attempt to carry out this recommendation was made by the Jesuit Hervas in the last twenty years of the eighteenth century, his various works being published between 1784 and 1787; and about the same time appeared the collections made by the naturalist Pallas, under the direction of the Empress Catherine II. The publication of the first volume of Adelung's *Mithridates* in 1806, brings us close upon the period which we have indicated as the true birth-tide of comparative philology, and completes the previous epoch of preparatory labours. Before we discuss the rapid progress of comparative grammar subsequently to the year 1808, it will be desirable to notice what had been done before, or was doing at that time, or has been done since then, for the critical study of the three main branches of language which are spoken by the great Christian nations of Europe,—the Romance, the Teutonic, and the Sclavonian.

Leibnitz.

Hervas.

Pallas.

Adelung.

Study of the Romance languages.

It might have been expected that the obvious resemblances of the Romance languages, and their known derivation from a common origin, and not from any one of themselves, would have attracted attention at an early period, and led to a recognition on these data of the general principles of comparative philology. For if any scholar had merely written down in parallel columns the substantive verb in the Italian, French, Spanish, Portuguese, Rhœto-Romance, and Wallachian languages, he could not have failed to see that the inflexions were but six variations of a common type; and a very small acquaintance with history would have taught the inquirer that this common type was to be found in the old Latin; so that the Romance languages were all sisters, the daughters of one mother. This conclusion, extended to all the members of the Indo-Germanic family, is the primary result of comparative philology in general. But though scholars to whom these languages were vernacular had, from the time of Dante, noted many peculiarities common to them, and though even the Byzantine Greek, Laonicus Chalcondyles, had remarked in the fifteenth century the affinity of the French and Italian (p. 89, ed. Bonn.), nothing was done for the methodical philology of the Romance languages before the time of Raynonard, who was born in 1761, but did not publish the first volume of his *Choix des Poésies Originales des Troubadours* till 1816. His best predecessors—Menage, in the seventeenth, and St Palaye, in the eighteenth century—had only entered on the confines of the subject. But his Grammar and Lexicon, and the abundant examples which he collected, have placed Romance philology on a scientific footing, and enabled his successors, especially Diez, to deal on the principles of comparative grammar with all the languages which derive their origin from the Latin.

Raynonard.

The Teutonic languages—Hicks.

The founder of the comparative philology of the Teutonic languages was an English non-juror, George Hickes, whose *Thesaurus Grammatico-Criticus et Archæologicus Linguarum veterum Septentrionalium*, published in 1715, indicated, however imperfectly, the results which might be obtained from an examination of the affinities of the German and Scandinavian languages. He had no doubt derived great advantage from the Mæso-Gothic studies of Francis Junius, a German settled in England, who died in 1677; and the increasing attention which was subsequently paid to the venerable remains of Ulfilas, the Sanscrit of the Teutonic family, and to Anglo-Saxon literature, contributed to pave the way for the establishment of a scientific school of German philology. The application to this work of a comprehensive and original mind is due to Rasmus Christian Rask, a native of Denmark, who commenced in 1807, while still a young man (he was born in 1787), a series of labours which have placed him in the highest class of linguistic discoverers; and it has been well observed (*Edinb. Rev.*, vol. 94, p. 317), that "Rask's works on the classification and comparison of languages are the best specimens of what could be accomplished in comparative philology without the aid of Sanscrit." In the years 1807–1812 he occupied himself with writing Grammars of most of the Germanic, Scandinavian, Sclavonian, and Romance languages—making references occasionally to the Indian idioms. In 1812 he travelled to Sweden, and laid the foundation of his knowledge of the Finnish dialects. In 1813 he went to Iceland, where he spent three years; and in 1814 appeared his prize essay *On the Origin of the Old Norse or Icelandish Language*. His perception of the affinities of the German and Asiatic languages led him to undertake, in 1820, an overland journey to Persia and India; and the fruit of his linguistic studies in the East appeared in his essay *On the Age of the Zend Language, and the Genuineness of the Zendavesta*, published by Hagen in 1826. On his return to his native country in 1823, he engaged in a long series of linguistic labours; and he died in November 1832. For Teutonic philology he did more than any of his predecessors and contemporaries, and may really claim the honour of having first noticed the law of the permutations of consonants, which is generally connected with the name of James Lewis Grimm. This distinguished philologer, born two years before Rask, may be said to have completed the edifice of which that great linguist laid the foundations. His German Grammar (1819–1840) has subjected the whole range of the Teutonic dialects to a comparative analysis, and in the first volume he has established, by a copious induction, to which, however, there are some exceptions not yet fully explained, the laws for the regular interchange of the mutes, which Rask had less completely indicated. His subsequent works, *The Legal Antiquities of Germany* (1840–1842), his *German Mythology* (1835–1844), his *History of the German Language* (1848), and his German Dictionary, now in the course of publication, have brought all the resources of philology to bear on his Teutonic researches. In this department, however, we must not forget to mention the valuable labours of our own countrymen, the late Mr J. M. Kemble, who not only revived among us, but prosecuted with eminent success, the study of Anglo-Saxon; Dr R. G. Latham, who, in addition to more general labours in comparative philology, has for the first time expounded the principles of English grammar, and investigated the ethnography of the British Islands, in accordance with the results of modern science; and the late Mr Richard Cleasby, who devoted his life, during a

long residence at Copenhagen, to the compilation of a Dictionary of the old Norse or Icelandic language, and whose great posthumous work is about to appear at Oxford, under the competent editorship of Dr G. W. Dasent.

Sclavonic philology—Dobrowsky.

The Sclavonic languages, spoken by a hundred millions of Christians in the east of Europe, have not failed to claim their share in the general interest of philologers. The father of Sclavonic philology was Joseph Dobrowsky, born at Gyermet, near Raab, in 1753. Of his numerous works, in which he penetrated for the first time into the peculiar structure of the Sclavonic idioms, the most important was his *Institutiones Linguæ Sclavicæ Dialecti Veteris*, Vienna, 1822. In the path which he opened Dobrowsky was successfully followed by Paul Joseph Schafarik, who was born at Kobeljarowo in Hungary in 1795, and whose *History of the Sclavonic Language and Literature* (Ofen, 1828) is the classical work on the subject. The great Polish Lexicon of Samuel Gottlieb Linde, born at Thorn in 1771, is a complete treasure-house for the comparison of the Sclavonic languages. It appeared at Warsaw in the years 1807–1814. The Lithuanian, Lettish, and Old Prussian, which have many features in common with the Sclavonian, and have made most important contributions to the materials of comparative grammar, have been habilitated in this domain by C. G. von Arndt (1818), J. S. Vater (1821), and A. F. Pott (1837).

Schafarik.

Study of Sanscrit.

But these detached labours bestowed on the different languages of Europe would not have produced, even in connection with the old classical philology, the necessary unity of results, if they had not been assisted and guided by the critical and grammatical study of the old language of the Brahmins. The striking resemblance between the Sanscrit, Persian, Greek, and Latin languages had been incidentally noticed by Mr Halhed as early as 1776, when he edited the code of Gentoo laws, and afterwards in 1778, when he published his Bengali Grammar at Hoogly; and Sir William Jones, and the German missionary John Philip Werdin, had—the latter with very slight knowledge of the subject—carried their observations a little further. In order that satisfactory progress should be made, it was necessary that Sanscrit, and the books written in it, should be really known; and for this the world is indebted to the abilities and industry of certain Englishmen, especially Mr Colebrooke, Sir Charles Wilkins, and Professor Horace Hayman Wilson. When this safe foundation had been secured, it was easy to use it in building up the superstructure of comparative philology; and labouring in the same field with Rask and Grimm, who, in one sense, led the way in the new science of comparative philology, Edward Francis Bopp (born in 1791), and Augustus William Schlegel (born in 1767, died in 1845), were the first who applied Sanscrit scholarship, as a branch of European study, to a general analysis of the structure of human speech. In his *Conjugations-system der Sanskritsprache* (Frankfurt, 1816), which appeared four years afterwards in an English form (*Annals of Oriental Literature*, Lond. 1820), Bopp gave the first specimen of that elaborate and exact scrutiny of grammatical forms, which has made him the chief authority in all that relates to the comparative philology of the Indo-Germanic languages. The works which contain his linguistic discoveries are, besides the early treatise which has just been mentioned, his Essays *On Certain Demonstrative Roots* (1830), and *On the Influence of the Pronouns* (1832); and above all, his *Comparative Grammar of the Sanscrit, Zend, Greek, Latin, Lithuanian, Old Slavonic, Gothic, and German* (1833–1852), which fully established the original identity of the pronominal words and inflexions in all those languages. Schlegel, in a journal called the *Indische Bibliothek*, of which the first part appeared in 1820, did a great deal both to stimulate the study and extend the knowledge of Sanscrit among his countrymen; and a long series of

Colebrooke, Wilkins, and Wilson.

Bopp and A. W. Schlegel.

Grammars and Lexicons, together with editions and translations of Sanscrit texts, have appeared from the pens of German scholars who for the most part have never travelled in India. It is true that these home-students have occasionally fallen into errors (see, for examples, Gildemeister's tract entitled *Die falsche Sanscritphilologie aus dem Beispiel des Herrn Dr Hoefer*, Bonn, 1840); and that they have often engaged in comparative philology without a competent knowledge of Sanscrit. Others, again, have limited their acquirements to the Indian languages, and have seen Sanscrit names and Sanscrit ideas in domains to which they could not have penetrated. But there are instances, on the contrary, where this learning of the German universities, when directed by competent talent and sagacity, has produced fruits equal to those which have ripened on the soil of India itself; and Christian Lassen, in particular, a Norwegian settled at Bonn (born at Bergen in 1800), has either anticipated, or made good by important additions, the discoveries of Rawlinson at Baghdad and of James Prinsep at Calcutta. It is to be remarked, however, that the best edition and translation of a Sanscrit classic that has appeared in Europe, at least the most extensive labour of this kind, is the *Râmâyana* from the Gaudana recension, published at Paris by the Italian scholar G. Gorresio. The best Sanscrit grammars are those by Wilson and Monier Williams; and the same two scholars have produced as yet unrivalled Dictionaries—the former in Sanscrit and English, and the latter in English and Sanscrit. In one important department of Sanscrit learning, the study of the oldest religious books of the Brahmins, the publication of the *Rig-Vêda*, the most ancient and important of these books, has been undertaken by this country; but the editorship has been intrusted to an able and learned German, Dr Max Muller, who is established as Taylorian professor at Oxford. He has thus completed the work commenced by his countryman, the late Professor F. Rosen, of University College, London.

Study of Zend or old Persian.

While Sanscrit scholarship was connecting itself thus intimately with the development of comparative philology, collateral aid of the most important kind was derived from an improved knowledge of another Arian language still spoken in the original abode of the Indo-Germanic race. This was the oldest form of the Medo-Persic idiom. In the middle of the eighteenth century, Anquetil du Perron had introduced into Europe a knowledge of the old languages of Persia, the Zend and the Pehlevi or Huzvaresh, the former deriving its name from "the book" (*Zend*, Sanscrit *Ch'handas*), which contained "the text" (*Avestâ*) of the Zoroastrian religion; and the latter from the heroic race (*pahlau*, "hero;" *hu-zvaresh*, "good heroism") who spoke it. But the most inconsistent and erroneous opinions were entertained respecting the nature and relations of these languages, until Rask, after his journey to the East, both established the genuineness of the Zend language and explained its true nature as an ancient type of the modern Persian. The complete establishment, however, of Zend as an important ingredient in Indo-Germanic philology is due to Eugéne Burnouf (born in 1775, died in 1856), who, in his *Commentaire sur le Yaçna* (Paris, 1835), submitted the Zend texts to a critical analysis, and arrived at philological results strictly analogous to those obtained by Grimm in German, and by Bopp in Sanscrit grammar. He has been followed by Spiegel and Westergaard; and it is now agreed that the Zend language represents a phase of the Arian speech very similar to the Sanscrit of the Vêdas, and that the *Avestâ*, in its original form, was drawn up probably in the north-eastern provinces of Persia—those on the borders of Sogdiana and Bactria—at some period anterior to the establishment of the South Persian dynasty of the Achæmenidæ. The language of South Persia under these kings has been recovered from the cuneiform in-

Du Perron.

Cuneiform inscriptions. Rawlinson.

scriptions of the first Darius, which have been completely deciphered and interpreted by the perseverance and sagacity of Sir H. Rawlinson, assisted by the previous labours of Grotefend, Burnouf, and Lassen. The language of the Sassanian dynasty, the Pehlevi or Huzvaresh, though Indo-Germanic in its grammatical structure, is, like modern Persian, only of secondary importance to the comparative philologer.

Study of Pâli.

Another collateral aid to the study of Sanscrit, as a main ingredient in comparative grammar, has been furnished by the researches of scholars in the field of Pâli records. In the sixth century B.C. Buddhism arose in India; and it is supposed with reason that the Pâli, which is the language of the Buddhist books in Ceylon, and which has many points of affinity with the Prâkrit, or popular language of India, as represented by the dramas of the first century B.C., was the ordinary dialect of the Hindus at the time when Buddha preached. A language very like this has been traced in the inscriptions of the great Buddhist king Asoka, calling himself Piyadasi, who reigned from B.C. 260 to 220, and the interpretation of whose edicts is the glory of our countryman James Prinsep. For, as Mr Prinsep justly observed, "The Buddhists, like all sects who have appealed to the common-sense of the people against the learning and priestcraft of the schools, made use of the vernacular dialect." That the Pâli was a language corrupted by oral and perhaps provincial use is shown by many significant peculiarities, such as the omission of the liquid *r*, which is almost regular; thus the Sanscrit *kritvâ*, "having made," becomes *katvâ* in Pâli; *drishtvâ*, "having seen," becomes *disvâ; srutvâ*, "having heard," becomes *sutvâ;* and so on. In fact, its relation to the Sanscrit is that of the Romance languages to the Latin; and on this account, among others, it is an object of interest to the comparative philologer. It owes most to the researches of Burnouf and Lassen, who have done so much for the study of old Persian.

Prinsep.

Armenian philology.

Armenia, as the traditionary cradle of the human race, naturally invited the attention of comparative philologers as soon as their science had gained an adequate amount of fixity. But although the Armenian is exhibited in a copious literature, these works are not more ancient than the fourth century A.D., and the spoken language is much corrupted by an infusion of Turkish ingredients. The grammar, however, is still decidedly Indo-Germanic; and by a philological analysis of its forms, such as that undertaken by Petermann, Windischmann, and Diefenbach, its affinities to the other members of the Arian family have been established in a very striking manner. These conclusions have been strengthened by a reference to the ancient traditions of Armenian mythology, which to a certain extent identify themselves with those of the Persians. Some valuable inferences may be derived from the statement of Herodotus (vii. 73), that the Armenians were colonists of the Phrygians—a statement which merely implies a recognition of affinity, and might be understood conversely. It can also be shown that the Armenians were related to the Cappadocians on the one hand, and to the Sauromatæ on the other. Striking affinities between the Armenian and the languages of Albania and Dalmatia have been pointed out. And it is not unlikely that the original ingredients of the Armenian language represent in a very ancient form the speech which was common to the oldest Arian settlers in Europe. (See Windischmann's *Grundlage des Armenischen im Arischen Sprachstamme*, Abhandl. d. Bayr. Akad. iv. Bd. Abth. ii.; Diefenbach's Review of Petermann's Grammar, *Jahrbucher d. Wissensch. Kritik*, 1843, Nos. 56, 57; Bötticher, *Arica;* Gosche, *De Ariana Linguæ gentisque Armeniacæ indole;* Ellis, *Contributions to the Ethnography of Italy and Greece.*)

Petermann, Windischmann, and Diefenbach.

In the valleys of the Caucasus, to the north of Armenia, an isolated branch of the Indo-Germanic family of languages has attracted the notice of philologers. This is the Ossetian, from the name *Os*, given by the Georgians to the people, who call themselves *Iron.* Their own traditions point to a time anterior to the thirteenth century, when their territory extended from the Caucasus to the Don; and there can be little doubt that they are an outlying branch of the old Sarmatian stock. Klaproth first called attention to the linguistic importance of their idiom, which is not represented by any literature; and the Royal Academy of Berlin sent Dr George Rosen (a brother of the late Dr F. Rosen) to the Caucasus to learn the Ossetian language from the lips of the Ossetians. The philological results of this expedition, which Rosen has published with the co-operation of Bopp, are an important addition to the materials of comparative grammar.

Celtic philology.

The earlier attempts to deal philologically with the Celtic languages were marked by the usual defects of conjectural etymology. The credit of having brought these banished, and in some of their last homes already obsolete idioms, within the domain of comparative grammar, is due to Dr Prichard, the founder of ethnography, whose book on *The Eastern Origin of the Celtic Nations* appeared in 1831; and to his reviewer, the late Mr Richard Garnett, one of the most original and accomplished philologers whom this century has produced. Mr Garnett's contributions to Celtic and general philology, we are happy to say, are about to be republished in a collected form. On the Continent Dr Prichard has been followed by Bopp, Pictet, Diefenbach, and others. The results of their researches were made known by Dr Charles Meyer in the *Report of the British Association for* 1847; and he added the fruits of his own studies, which he had prosecuted with great diligence in the countries where Celtic is still spoken. The *Grammatica Celtica* of J. C. Zeuss (Leips. 1853) has entered fully into the antiquities of the Celtic languages, and has exhibited scientifically the relations of the different dialects with regard to the laws of sound and the development of the inflexions; and some important contributions to Celtic philology are contained in the *Ethnographie Gauloise* (Paris, 1858) of the Baron de Belloguet.

General results of Indo-Germanic philology established in 1833.

Independently, however, of the more recent investigations into the nature of the various Asiatic and European branches of the Indo-Germanic family of languages, the affinity and mutual relations of these modifications of human speech were fully and finally established more than twenty years ago. At any rate, since the year 1833, when the first part of Bopp's *Comparative Grammar* and the first volume of Pott's *Etymological Researches* appeared together, there has been no doubt that, from the Ganges and the ridges of the Vindhya Mountains to the shores of the Baltic, the Mediterranean, and the Atlantic, one great mother tongue is spoken, or preserved in writing; and that, although the different Arian or Indo-Germanic races are no longer able to understand one another,—though, in fact, long and earnest study is required before the more distant members of the family can interchange oral communications, and though a similar effort is required to pass from the living to the dead forms of the same language,—yet there must have been a time when the original representatives of these widely-separated tribes were united on the table-land of Irân, bound by ties of brotherhood, and speaking the common speech, which may almost be reproduced by a comparison of the different forms of its living children or of their direct progenitors, embalmed in classical and sacred literature. In this great family it is now seen that there are six main branches—I. The Indian; II. The Medo-Persic, including the Armenian, Ossetian, and perhaps the Albanian; III. The Sclavonic, comprising the Lithuanian; IV. The Teutonic, embracing the Scandinavian languages; V. The Celtic; VI. The Græco-Latin, including the old classical languages, with all their dialects,

Branches of the Arian family of languages.

Comparative Philology.

and their modern offspring the Romance languages, namely, the Provençal and French, the Italian, the Spanish and Portuguese, the Rhætian, and the Wallachian. The Indo-Germanic family, then, comprehends, besides some of the most important Asiatic languages, all the languages of Europe, except the Turanian idioms spoken by the Finns, Laplanders, Hungarians, Bulgravians, and Turks, and the isolated Basque or Euskarian language still vernacular in the north-west of Spain. In all these Arian languages, not only are a vast number of the most common and necessary words traccable to an identity by the application of certain established laws for the permutations of consonants, but it can be seen that their system of inflexions, and all the machinery of their grammar, either now works, or must at one time have worked, according to the same organization. The results are as certain as those of any other department of inductive science; and there is little room either for felicitous conjecture or ingenious blundering.

Arian philology—illustrations.

It may be worth while to show, by a few specimens, the nature of the induction on which Arian philology depends. We shall therefore exhibit some of the most important resemblances of the Indo-Germanic idioms, in those words which belong to the inherited treasures of every language, and in the elementary forms of the nouns and verbs.

To show that these languages, exhibiting such marks of affinity, need not, on that account, claim any one of their number as the parent-stock, but may all have sprung from one common source, it is only necessary to make a similar comparison in the case of the Romance languages, which we know may be derived from their common mother, the classical Latin. Let us take, for instance, the substantive verb in six of these languages, and we shall see that the form in each bears a relation to *sum*, different from that which this latter does to any of the five forms with which we have compared it above:—

Latin.	Italian.	French.	Spanish.	Portuguese.	Wallachian.	Rhœtian.
sum	sono	suis	soy	son	sum	sunt.
es	sei	es	eres	es	es	eis.
est	e	est	es	he	e	ei
sumus	siamo	sommes	somos	somos	suntemu	essen.
estes	siete	êtes	sois	sois	sunteh	esses.
sunt	sono	sont	son	são	sunt	eân.

It is clear, on the most cursory inspection, that all these forms are derivatives from *sum;* and we shall be still farther convinced of their secondary condition if we find, as we do on farther examination, that the substantive verb in the Romance languages generally borrows some of its tenses from the Latin *stare*, "to stand;" that all Romance verbs of the regular type form their future by annexing the present term of *habere*, "to have," in its corrupted state, *avere*, *haber*, *aver*, or *avoir*, to the infinitive mood of each verb, which in the Provençal is often separated by the interposition of another word; and that although the French alone forms its infinitive from *stare* (for *être* is the modern form of *ester*, from *estar*), while all the other Romance languages have their infinitives formed from *esse* (Ital. *essere*, Prov. *esser*, Span. *ser*), yet the future *ser-ai* of the French substantive verb proves that they must once have agreed in this point also. While, then, the resemblances of these forms among themselves are analogous to those of the substantive verb as it appears in the older Indo-Germanic languages, including the Latin, we are able to trace their derivation from this idiom, just as we can derive the Prâkrit from the Sanscrit; but we cannot thus deduce any of the older Arian languages from another of the same class. We see the same marks of resemblance among the dialects themselves, combined with still more striking proofs of derivation from a common original, in those cases in which a tendency to abbreviation, already observable in Latin, has been consistently carried out in the principal Roman languages. Take, for example, the habit of dropping the letter *d* when it is flanked by two vowels. That this took place in ancient Latin is clear, not only from the old pronunciation, as indicated by the exigencies of the comic meters, but even by a few instances in which this letter is omitted in writing. Thus, while we see that *pater* and *quidem* were often monosyllables, we remark that the *d* is absolutely dropped in writing in such forms as *es* for *edis*, *est* for *edit*, and perhaps *item* for *itidem*. This tendency, which is only indicated in Latin, becomes uniformly phenomenal in the Romance languages, and not only *d*, but *t*, disappear in most of the words which have passed, without direct borrowing at a later period, from Latin into French or Italian. If we compare the old words *Noel* and *naif* with the forms *natal* and *native*, which have been taken from the Latin since the French became a fixed language (Schlegel, *Observations sur la Langue et la Littérature Provençales*, p. 44), we shall see that this omission of the *t* must have prevailed among the Roman provincials themselves, and was not caused by anything peculiar to the French articulation. Sometimes this dropping of the dental is accompanied by other absorptions, which reduce the original word to a bare residuum. Thus the pronominal adjective *même*, signifying identity in general, Spanish *mismo*, Portuguese *mesmo*, although the dental is retained in the Italian *medesimo*, is quite a disguised representative of the original *memet ipsissimum*. To extend these comparisons is not our present duty. The few samples which we have given will suffice to show the nature of the evidence on which the comparative philologer has to rely.

Comparative Philology.

Extensions of Arian philology

The scientific certainty, attained by these researches of comparative philology in the domain of the Arian or Indo-Germanic languages, has not unnaturally led to the wish on the part of those who have prosecuted them, that they might, on the one hand, be connected with the results of the older classical and sacred criticism, and, on the other hand, that they might be extended so as to embrace *primarily* the Semitic languages, which are connected by their literature rather than their idiomatic texture with those of the Arian race, and one of which holds a place by the side of Greek among the studies of the older school of philology; and so as to reach *ultimately* to a classification of human speech in general, and thus to form a basis for the collateral science of ethnology.

Comparative grammar combined with the old classical philology.

A combination of the results of comparative grammar with those of the older classical philology was sure to take place sooner or later, and sooner rather than later. Just about the time when the study of Sanscrit literature was beginning to establish itself in Europe, several scholars, who had not yet made acquaintance with this guide to the analysis of organic inflexions, exhibited a tendency to seek for etymologies in the classical languages by a more rational system of comparison with other tongues than had previously been attempted. For example, Buttmann showed, by the various articles collected in his *Mythologus*, some of which date as far back as the end of the last century, by his *Lexilogus*, of which the first volume appeared in 1818, and by his paper on the *Electron*, which was read in the same year, that he was in spirit a comparative philologer, and would have made an ample use of his opportunities if he had lived a few years longer, or had been born a few years later. The German language, in particular, was brought into direct comparison with Greek and Latin, not always scientifically, but sometimes quite correctly, by Drs Jamieson, Hunter, and Carson in Scotland, and by Jaekell and Rainshorn in Germany. In the year 1828, the establishment of Dr F. Rosen as professor of Sanscrit in University College, London, awakened the attention of classical teachers and students in that institution to a sense of the important results which might be obtained by a combinatian of Greek and Latin philology with the methods which had resulted from the comparative study of Sanscrit grammar. In 1836, only three years after the appearance of the first part of Bopp's grammar, one of the most eminent philologers of the old school, K. O. Muller, expressed himself in the following decided language (*Kleine Schriften*, i., p. 12):—"It has now indeed come to this, that philology must either renounce altogether any historical knowledge about the growth of language, and all etymological researches into the form of roots and the organism of grammatical structures, or trust herself in these matters entirely to the guidance and counsels of the comparative study of language." It is true that some of those who had obtained eminence in classical criticism, and their immediate disciples, regarded comparative philology with much suspicion and distrust. For example, Godfrey Hermann, in the paper which suggested Müller's remarks, had spoken with some contempt of those "who sought light from a sort of aurora borealis, reflecting the gleams of eastern illumination, and who, betaking themselves to the Brahmins and Ulfilas, endeavoured to explain Greek and Latin by the help of languages which they only half understood." Another eminent verbal scholar, K. A. Lobeck, in his *Aglaophamus* (published in 1829), in his *Paralipomena* (published in 1837), and in his *Pathologia* (published in 1843), indicated how little confidence he had in Sanscrit as a help to the Greek grammarian. And the same protest against the claims of Sanscritism was made in 1835 by F. Ellendt, a pupil of Lobeck, in the Preface to his *Lexicon Sophocleum*. In January 1837 the Imperial Academy of Sciences at St Petersburg published a scheme for a prize essay on the Greek dialects from which all consideration of Sanscrit was to be excluded. It was about the time when these opposite opinions were entertained respecting the propriety of an intimate alliance between the old and new philology, that the writer of these pages, who had been indirectly brought within the reach of Rosen's influence in 1829–30, undertook to prove that, by making the classical languages, and especially the Greek, the basis of a scientific method of comparative grammar, not only would the general results be more definite and important than those which had been obtained by starting from the Indian or Teutonic members of the Arian family, but that very great advantages would redound to the improvement of Greek and Latin philology in particular. The first product of these studies appeared in February 1839, the second in 1844; and the author's labours have been continued in this field down to the present time, either in successive editions of these original works, or in auxiliary labours having the same object in view. There are still strong prejudices in favour of the old-fashioned methods of teaching Greek and Latin grammar, arising chiefly from a conventional and conservative bias in favour of established traditions; but it is to be hoped that the stream of philological speculation has finally turned its course into the right direction, and that those who undertake to reason on the grammar and word-forms of the classical languages will from henceforth seek their rules and principles in the method which has been confirmed by the comparative study of the Arian family as a whole.

Comparative philology extended to the Semitic languages.

From the comparison of the Indo-Germanic idioms with one another, the general philologer's next step was to consider the relationship between the different families of languages; and his attention would be arrested primarily by the Semitic group, one of which had connected itself with the special studies of the older school of criticism. The general result of the philological analysis, in the case of the Arian languages, was to show that all words were ultimately reducible to monosyllabic roots, which were, so to speak, set in a framework of significant prefixes and affixes. On the other hand, the Semitic languages presented, both in their nouns and verbs, a basis of triliteral or bisyllabic roots, beyond which the analysis of the grammarian did not attempt to penetrate. As early as the seventeenth century it had been suggested that these triliteral roots may have been primarily biliteral. Michaelis was prepared, in the latter part of his life, to relinquish the triliteral system (see Adelung, *Mithridates*, i., p. 302); the great critical Hebraists of the present century, Gesenius and Ewald, had admitted that, by recognising monosyllabic roots in Hebrew, we might compare that language with the various members of the Indo-Germanic family; and Klaproth, in 1828, plainly asserted that the Hebrew roots were originally and properly monosyllabic. ("Observations sur les Racines des Langues Sémitiques," in Merian's *Principes de l'Etude Comparative des Langues*, pp. 212, sq.) A more formal and systematic attempt to establish the original monosyllabism of the Semitic languages, and especially of the Aramaic branch, was made by Julius Fürst in his *Lehrgebäude der Aramaischen Idiome, mit Bezug auf die Indo-Germanischen Sprachen* (Leipsic, 1835); and in his *Veteris Testamenti Concordantiæ* (completed in 1840). The procedure of Fürst was recommended in an enthusiastic and somewhat extravagant manner by his pupil, F. Delitzsch, in his *Jesurun* (*Isagoge in Grammaticam et Lexicographiam Linguæ Hebraicæ contra G. Gesenium et H. Ewaldum*), which appeared as an Introduction to Fürst's *Concordance* in 1838. Meantime Æmilius Rödiger, who, like Delitzsch, belonged to Halle, and has succeeded Gesenius in that university, was prosecuting similar researches with regard to the structure of the oldest form of Arabic; and a young scholar, Charles Richard Lepsius, who had enjoyed the advantage of direct intercourse with the best

philologers at Leipsic, Göttingen, and Berlin, and was pursuing his researches at Paris in the domain of the old Egyptian and Coptic languages, published some essays indicating the most remarkable genius for philology, and tending to establish the affinity not only between the Indo-Germanic and Semitic languages, but also between both of these and the old language of Egypt. (*Palaographie als Mittel fur die Sprachforschung zunächst aus Sanskrit nachgewiesen*, Berlin, 1834; *Zwei Sprachvergleichende Abhandlungen*, ib. 1836) In the last of these essays Lepsius quite established the affinities of the Egyptian, Semitic, and Indo-Germanic languages, in regard to the numerals and some of the most important of the pronominal elements.

Deciphering of hieroglyphics.

And here the discovery of the clue to the Egyptian hieroglyphics (see articles EGYPT, HIEROGLYPHICS, CHAMPOLLION), produced an immense influence on the determination of the problems to be solved by those who would establish the affinities between the two central families of languages. As the hieroglyphic, hieratic, and demotic inscriptions have been partially deciphered, as the grammatical forms have been established, and the interpretation of particular words ascertained and the virtual identity of the Coptic with the language of the Pharaohs placed beyond doubt, the newly-acquired knowledge has been pressed into the service of comparative philology, and elaborate works have been written, not merely for the purpose of exhibiting the relationship between the Semitic and the old Egyptian (as in Benfey's treatise *Über das Verhaltniss der Ägyptischen Sprache zum Semitischen Sprachstamm*, Leipsic, 1844), or of analysing the structure of the Coptic language with reference to the principles of Indo-Germanic philology in general (as in M. G. Schwartze's great work, *Das Alte Ægypten*, Leipsic, 1843, of which he lived to write only the Introduction, in more than 2000 closely-printed quarto pages!), but still more, in order to make Egyptology a sort of elevated standing-point, from which all the realms of ethnography and philology might be surveyed, and the most distant and isolated points brought within the range of view. This undertaking has been attempted chiefly by Bunsen, who has completed in five volumes his work entitled *Ægypten's Stelle in der Weltgeschichte* ("Egypt's Place in Universal History," Hamburg, 1845–1857), and has discussed some of the same subjects in a more general and miscellaneous book, or collection of treatises, called *Christianity and Mankind, their Beginnings and Prospects* (London, 1854). It is Bunsen's theory that "the Egyptian language is the point in universal history at which the creative energy of language still shows its original form, just before it raises its pinions aloft, and assumes in the world-ruling nations an entirely different and more spiritual form, while in the other races, according to laws not yet explored, it sinks into the atomic and mechanical, or at best deflects into subordinate ramifications." (*Ægypten*, i., p. 338.) Looking back over a period of more than 20,000 years, this philological speculator recognises a time when the as yet undivided families of Japhet and Shem lived together in a civilized state in Northern Asia. From this undivided Asiatic stock Egypt, according to Bunsen, must be a colony, gradually degenerated into the African type, for the old Egyptian language claims affinity at once with the Aramaic idioms in immediate contact with it, and with the Indo-Germanic tongues, with which it has no direct commerce. (*Report of the Brit. Assoc.*, 1847, p. 280; *Ægypten*, iv., Pref., p. 10.) It must be owned that these sweeping conclusions do not rest upon philological inductions of the most accurate kind, and are supported by arguments which are sometimes as arbitrary as they are precarious.

Benfey.

Schwartze.

Bunsen.

Meanwhile the comparative philology of the Semitic languages has been assisted by other palæographical discoveries scarcely less important than that of the hieroglyphic syllabarium. At the beginning of the present century, Professor G. T. Grotefend (born in 1775) made a first attempt to explain the cuneiform or arrow-headed writing of the old Persian inscriptions. His discovery was announced in the *Gottingen Literary Gazette* of 1802; but a full account of it did not appear till 1815, when it was given in the appendix to the third edition of Heeren's *Ideen*. The subject was pursued without any important results by M. Saint Martin, whose Memoir was read at Paris in 1823. More valuable verifications were secured by Rask's identifications in 1826 of the signs of M and N in the name *Achæmenes*. In 1836 appeared Burnouf's Memoir on the cuneiform inscriptions of Hamadân, which contained some interesting discoveries; and in the same year Lassen published his work on the *Old Persian Cuneiform Inscription of Persepolis*, which supplied an identification of at least twelve characters mistaken by his predecessors, and which secures for him perhaps the most honourable place in this band of decipherers. Meanwhile, however, an able British officer was prosecuting in the East, and with complete success, the cuneiform studies which the learning and ingenuity of these European scholars had already advanced so far. In 1835, Major (now Colonel Sir H. C.) Rawlinson, being posted at Kermanshah, on the western frontier of Persia, began to direct his attention to the cuneiform alphabet, and the inscriptions written in it. With the exception of Grotefend, none of the other labourers in this field were known to Rawlinson. He did not receive Burnouf's Memoir till 1838, the year after he had sent to the Asiatic Society his translation of the first two paragraphs of the Behistun inscription; and it was only in 1839 that Lassen sent him a *précis* of his improved system of interpretation. By this time, chiefly by the aid of Burnouf's *Yaçna*, he had completed a literal translation of some 200 lines of cuneiform writing, and by the year 1846 this was augmented by more than 400 lines, and the Persian portion of the Behistun inscriptions of Darius I. was no longer a sealed book to scholars. That inscription, however, like others of the same age, was trilingual. Besides the Persian recital of the deeds of Darius, which Rawlinson had mastered, there was a Semitic or Aramaic version for the conquered inhabitants of Assyria and Babylonia; and one in a Tataric or Turanian dialect, for the benefit of the Scythian tribes beyond the Oxus. As early as 1845 Rawlinson had recognised the Semitic character of the second, or, as it stands on the monument, the third of these inscriptions, and had begun to examine the proper names in it; he had also surmised that the other inscription was Turanian, and not, as some inferred, Median; and the soundness of this opinion has since been established by Mr E. Norris. Rawlinson prosecuted his investigations respecting the Assyrian inscriptions, comparing the Behistun monument with the bricks and other excavated memorials from Nineveh and elsewhere, till, in 1849, he was enabled to decipher and interpret some of these ancient records, and to ascertain the nature of the language in which they were written; and his views have been confirmed in many points by the contemporary and independent labours of Dr E. Hincks, who has done a good deal towards exhibiting the grammatical structure of this old form of the Semitic languages. The result of these inquiries has been to show that the language spoken at Nineveh in the days of Sennacherib and his predecessors was a very ancient type of the language which is recognised as the basis of Arabic and Hebrew.

The oldest form of Arabic is that which is still spoken in the south of Arabia. Its primitive type is exhibited in the Himyaric inscriptions which have been fully investigated since 1830 by Fresnel, Gesenius, Rödiger, and Ewald. Linguistic affinities show that the Ethiopic or Abyssinian, which

Ancient Arabic—the Himyaric inscriptions.

Comparative Philology.

is called Gheez by the people who speak it, is an offshoot from the ancient Himyaric.

Sinaitic inscriptions Beer.

Another ancient form of the Semitic, approaching to the Arabic in many points, has been learned from the inscriptions in the peninsula of Sinai. Although these inscriptions had been known for many hundred years, they were not deciphered till Dr E. Beer of Leipsic published his account of the alphabet in 1840–1843 (*Inscriptiones veteres Litteris huc usque incognitis ad Montem Sinai servatæ*); and his views have been carried out with complete success by Professor Tuch (*Zeitschrift d. Deutsch. Morgenl. Gesellsch.*, 1849, pp. 129–215). It is concluded, with much probability, that the language of these inscriptions is that of the ancient Amalekites and other Bedouins of the Sinaitic peninsula.

Tuch.

Classification of the Semitic languages.

These palæographical investigations, combined with a more rational system of grammatical criticism, have enabled scholars to settle the mutual relations of the Semitic languages, and to determine the area occupied by them and the distinctive peculiarities of their structure. The best classification of this group of languages seems to be the following:—I. The old Babylonian or Assyrian, established in the primitive abodes of the Semitic race between the Tigris and the western borders of Irân. From this the Aramaic dialects—the Chaldee and Syriac—derive their origin. II. The old Canaanitish, of which the Hebrew and Phœnician were important dialects. III. The old Arabic, of which the Ethiopic and Abyssinian are offshoots, and which is represented by the modern Arabic in all its literary and geographical developments. IV. The old Egyptian, which is a deposit of some ante-historical Semitic idiom, disorganized by certain local influences. It is represented in a modern form by the Coptic. V. The Berber dialects scattered over the whole north of Africa, from Egypt to the Atlantic Ocean, and still distinct from the cognate Arabic of the Mohammedan conquerors.

Contacts of the Arian and Semitic families to be sought in the Sclavonian.

In seeking a point of contact between these languages and those of the Indo-Germanic class, it has seemed most reasonable to the writer of these pages to look to the district where one of the oldest, if not the very oldest, of the Semitic tribes appears to have been geographically conterminous with a very old Indo-Germanic people,—namely, the district that was occupied by the ancient Assyrians and Babylonians, in close contact with the old Sauromatæ or Sclavonians. He has developed the following argument in a special essay on the subject ("On two Unsolved Problems in Indo-German Philology," *Report of the British Association for* 1851, pp. 143, sqq.) The Sclavonians may be identified with that branch of the great Iranian family which occupied Media, and therefore in their original home stand in close contact with the Assyrians of the adjoining plain. Now, these Assyrians, according to Rawlinson's investigations, spoke a very old form of the Semitic language. But, according to a general agreement among scholars, the Chaldeans, who conquered the plains of Mesopotamia in the eighth century B.C., were an Indo-Germanic tribe, whom some identify with the Sclavonians, while others called them Medo-Persic, which is much the same thing. Consequently, Semitic and Indo-German tribes were in close contact, if not intermingled with one another, on the banks of the Tigris. When, therefore, we find that although the Sclavonian and Semitic tongues stand in direct antithesis or contrast so far as their state or condition is concerned,—the former being marked by the fulness of the etymological forms, and the absence of syntactical machinery, and the latter by a triliteral uniformity and a pervading syntactical mechanism, — they nevertheless present, both in words and forms, the most remarkable indications of original affinity, we are bound to conclude that the inference from their geographical contiguity is philologically also valid and satisfactory.

Outlying groups of languages.

Even if the relationship between the two great central families of language—the Indo-Germanic and the Semitic—were fully ascertained and established, the comparative philologer would not have completed his examination of the affinities of human speech. For (to say nothing of the languages of America and Central and Southern Africa) the idioms spoken by the Finns, Hungarians, and Turks in Europe, and by the tribes scattered over the whole of Northern and Eastern Asia, together with the dialects of the aboriginal inhabitants of Southern India, constitute a class of linguistic phenomena, which differ in the most striking manner from the Arian and Aramaic types. An attempt, however, has been made to classify these languages, and to group them together in accordance with certain peculiarities which they have in common. These languages are called by the general name *Turanian*, a word derived from the root *tur*, signifying "to be swift," "to roam about;" and therefore indicating generally the nomadic character of the tribes which are distinguished by these varieties of human speech. The first beginning of the scientific classification of the different members of the Turanian family was made by John Sainovics, who, in 1770, published at Copenhagen his *Demonstratio Idioma Hungaricum et Lapponicum idem esse*. He was an Austrian astronomer of Hungarian extraction, and had noticed these affinities when sent with Kell to Lapland in 1764. The same position was maintained by Ihre-Oehrling (*De Convenientia Linguæ Lapponicæ cum Hungarica*, Upsal, 1777); and Hager (*Neuen Beweisen der Verwandtschaft der Ungarn mit den Laplandern*, Vienna, 1794). But the most complete work on the subject was Dr Samuel Gyarmathi's *Affinitas Linguæ Hungaricæ cum Linguis Finnicæ Originis grammatice demonstrata* (Gottingen, 1799). This work proves the identity of the Hungarian with all three of the Chudic dialects, the Finnish, the Esthonian, and the Lappish; and adopts in the proof a truly philological method. A comparison of the Asiatic branches of the Turanian family was first attempted by Klaproth (*Reise in den Kaukasus*, 1814); and the whole of the un-Arian and un-Semitic races were boldly grouped together by the great philologer Rask (*Über die Thrakische Sprachklasse*, 1818; *Zend-Sprache*, 1826), under the general name of Scythian. He found in the language of Greenland a link of connection between the idioms of Asia, Europe, and America; and divided the great Scythian race into four main classes,—the North Asiatic, the North American, the Tatar, and the Mongol-Tungusian. The details of the subject were prosecuted with great success by William Schott, who, after stating the case in his Essays on the Tatars and Finns, published in 1836 and 1847, went fully into the linguistic proofs in his valuable paper *Über das Altai'sche oder Finnisch-Tatarische Sprachengeschlecht* (Berlin, 1849). At the same time, Alexander Castrén of Helsingfors, by his travels and the various treatises in which he expounded the results of his inquiries, beginning with his *Elementa Grammatices Syrjænæ*, published in 1844, and ending with his *Reise-Erinnerungen*, published in 1853, completely established the general principles of Turanian philology. Some of these views, especially those of Schott, have been controverted by Bœhtlingk (*Uber die Sprache der Jakuten*, 1851); but the general features of resemblance have been undoubtedly recognised: the peculiar system of vocalization, the process of agglutination by which the naked roots are formed into words, the identities in certain primitive terms, such as the numerals, which in such widely scattered tribes could not have been borrowed by mutual intercourse in the historical ages,—all this, and much else that might be mentioned, would render it considerably more difficult to establish the total independence and diversity of the Turanian tribes than to seek in the peculiar circumstances of their dispersed and nomadic condition for a natural ex-

Turanian family. Sainovics. Ihre-Oehrling. Hager. Gyarmathi. Klaproth. Rask. Schott. Castrén. Bœhtlingk.

Comparative Philology.

planation of the heterogeneous elements in this wide-spread manifestation of human speech. The subject has been so well discussed in English by Dr Max Muller, that we need only refer to what he has written on the subject in the first volume of Bunsen's *Outlines of the Philosophy of Universal History* (London, 1854), or in his own little work *On the Languages of the Seat of War in the East* (second edition, London, 1855). The classification of the Turanian languages, according to the most recent researches, is the following :—I. The Finnic, including the Hungarian, Bulgarian, Chudic, &c. II. The Samoiedic, divided into the northern and eastern branches. III. The Turkish or Tataric, including the Usbeks, Turcomans, Baskirs, Yakuts, Rumelians, and Anatolians. IV. The Mongolic, including the Eastern or Proper Mongols, the Western Mongols, such as the Kalmucks, and the Northern Mongols, such as the Buriats. V. The Tungusic, divided into the western and eastern branches. To these must be added, according to the researches of Max Müller, the Tamulic, Bhotiya, Tai, and Malay languages of the aboriginal tribes inhabiting the Deccan, the sub-Himalayan plains, the trans-Gangetic empires of Siam and Assam, and the Polynesia. There are many striking resemblances between this last group of Turanian languages and the Chinese; and we are strongly inclined to think that the latter is merely a form of the Turanian variety of human speech brought into a different state or condition, by the change from the nomadic to the city life.

Max Müller.

Classification of the Turanian languages.

American family.

The languages of America, to the south of that Turanian fringe which is occupied by the Esquimaux, have not yet been brought into recognised relationship with those of the older continent. Among themselves, however, they fall into distinguishable groups, and both their traditions, and certain peculiarities in the laws which regulate their word-formations, point to the north-east of Asia as the origin of their race, and to the Turanian languages as the parent-stock of their idioms. If this shall ever be established on evidence which the philologer can admit as scientifically valid, diversities of language will oppose no obstacle to the traditionary belief of the unity of the human race, a belief confirmed by the invariable testimony of history, that man has ever occupied new and vacant regions by migration, and by the same process which is still in full activity. So far as it is allowed to anticipate by conjecture the results which comparative philology, in its widest range, may one day hope to realize, the following will be the ultimatum of linguistic ethnography:—Mankind was divided in the ante-historical period into two great connected families, from which all the rest of the world's population has been derived. From the Semitic, occupying primarily the regions of Mesopotamia, Syria, Asia Minor, and Arabia, was derived the population of all Africa. From the Indo-Germanic, primarily settled on the great table-land of Irân, was derived an unbroken series of connected tribes extending into India to the south-east, and spreading to the north and west over the whole of Europe. Of these tribes, the oldest, it seems, were the Celtic emigrants. Next in antiquity, or in the date at which they left their home in Asia, were the Sclavonic nations, including the Lithuanian; and the last or newest immigration into Europe was that of the Teutonic tribes, beginning with those which we call the Low Germans. About the time when these Low Germans left the north-eastern frontier of Irân, it is probable that the Arians began their descent from Bokhara in the direction of the Punjâb; and it is calculated roughly that this must have been about 1400 B.C.; so that the Hindu-Arians are among the youngest members of the family in reference to the period at which they settled in their new abodes, though, being among the last to leave their native seats, they have retained more completely perhaps than any of the sister tribes the original characteristics of the language once common to them all. The traces of Indo-Germanic affinity, which are still perceivable in the Turanian idioms, render it probable that these nomad races broke away from Irân at various periods of undefinable antiquity, or in hordes or clans inconsiderable in number; and that, being kept apart by the very circumstances of their pastoral and wandering life, they lost more and more the original type of their language, and fell into a mode of speaking suited to their detached and deteriorated condition. Where geographical advantages led to re-centralization, as in China, these disintegrated languages assumed new forms, passed, according to one proposed subdivision, from the *nomad* to the *state* or *political* type (Max Muller in Bunsen's *Outlines of the Philosophy of Universal History*, i., p. 282), and connected themselves with literary developments, which again influenced their structure. In accordance with this general view of the population of the world, spreading from a common origin and a common home over the whole face of the globe,—a view which rests on the oldest records of the human race, and is supported by the inductions of philology, as far as the comparison of languages has been carried up to this time,—we have proposed the following classification of the varieties of human speech (*New Cratylus*, § 69):—Languages are either (A) Central or (B) Sporadic. In the first of these classes there are two main subdivisions,—(1.) The Indo-Germanic or Arian; (2.) The Semitic or Syro-Arabian. In the second we place all the African and Turanian languages, adding to them, without, as yet, any accurate means of approximation, the varieties of speech found in America and the Pacific Ocean. And the Sporadic languages also apportion themselves in two groups to the two subdivisions of the central class, the African languages belonging to the Semitic, and the Turanian claiming, however faintly, some affiliation to the Arian stock.

Original unity of the human race.

Process of dispersion from the common home.

Testimonies of Prichard and A. V. Humboldt.

Such are the results, obtained or probable, by which comparative philology has fortified the conclusions of the new science of ethnography. The founder of that science, Dr J. C. Prichard, concluded a general survey of the subject with the following words (*Report of the British Association for* 1847, p. 253):—"I may venture to remark, that with the increase of knowledge in every direction, we find continually less and less reason for believing that the diversified races of men are separated from each other by insurmountable barriers." And A. von Humboldt, to whom he refers with gratification at having arrived at the same ultimate conviction, has thus expressed his sense of the achievements of philological science:—"Languages," he says (*Kosmos*, ii., p. 142), "when compared together and considered as objects of the natural history of the mind, and when separated into families according to the analogies existing in their internal structure, have become a rich source of historical knowledge; and this is probably one of the most brilliant results of modern study in the last sixty or seventy years. From the very fact of their being products of our intellectual powers, they lead us back, by the elementary character of their organization, to an obscure distance, unreached by traditionary records. The comparative study of languages shows how races now separated by vast tracts of land are allied to each other, and have migrated from one common primitive abode; it indicates the course and direction of all migrations; and, in tracing the leading epoch of development, recognises, by means of the more or less changed structure of the language, in the permanence of certain forms, or in the more or less advanced destruction of the formative system, which portion of the race has retained most nearly the language common to all who had migrated from the general seat of their origin."

But comparative philology has not been content with furnishing the ethnographer with the most important data for the establishment of the great religious and moral

Comparative Philology.

Application of philology to the determination of the ante-historical condition and primitive belief of man.

truth, that all men spring from one blood, and are distinguished from all other living creatures not only by the common possession of reason, but by the common inheritance of a language impressed with the same laws, and bearing in the central and most civilized nations the most marked traces of its derivation from a common source. The comparative philologer not only undertakes to prove that mankind, now dispersed over the whole face of the earth, were at one time a united family; but he is enabled, by an examination of the common elements of language, to ascertain the nature of the civilization which men enjoyed, and of the religious belief and worship which represented their spiritual aspirations, at a period long anterior to their local separation. "Comparative philology," says Max Müller (*Oxford Essays* for 1856, p. 11), "has brought this whole period within the pale of documentary history. It has placed in our hands a telescope of such power that, where formerly we could see but nebulous clouds, we now discover distinct forms and outlines; nay, it has given us what we may call contemporary evidence, exhibiting to us the state of thought, language, religion, and civilization, at a period when Sanscrit was not yet Sanscrit, Greek not yet Greek, but when both, together with Latin, German, and other Arian dialects, existed as yet as *one* undivided language, in the same manner as French, Italian, and Spanish may be said to have at one time existed as *one* undivided language in the form of Latin."

Comparative mythology.

As these applications of comparative philology fall into two distinct classes, one referring to the primitive history, the other to the primitive belief of a race, it would be desirable to have them designated by two distinct names. To the latter application the name of "comparative mythology" has been given, and very high functions have been claimed for it by the eminent German writer to whom we owe the first English essay on the subject. "If," says Max Muller (*Oxford Essays*, 1856, p. 86), "Hegel calls the discovery of the common origin of Greek and Sanscrit the discovery of a new world, the same may be said with regard to the common origin of Greek and Sanscrit mythology. The discovery is made, and the science of comparative mythology will soon rise to the same importance as comparative philology." It appears to us that, in the delight which the comparative philologer feels in this application of his own grammatical principles to the examination of ancient beliefs, he is apt to be carried beyond the proper limits of the investigation, which he pursues with such justifiable enthusiasm, or, at all events, that he is liable to neglect the other considerations by which his theories should be guided and corrected. Mythology cannot always be treated strictly according to the laws of language. When we recognise a community of religious fable among a number of different nations, this may be the result of contacts subsequent even to a comparatively recent historical period, or it may arise from something common to the human mind, and suggested by circumstances which may occur in any country, and at any epoch. With regard to the former of these, it is clear that the dualism which prevailed among the Jews after their captivity, and which was not known to them before, was a direct result of their intercourse with the Medo-Persic race, which had for a long time cultivated this form of religion; and its adoption by the Teutonic nations, in connection with a corrupted Christianity, was only in part a result of their inheritance of a mythology ultimately traceable to their primitive home in Irân. On the other hand, the legend which we find in all countries of the interruption of some attempt to sacrifice a human victim, and the substitution of some lower animal as a sort of vicarious atonement, seems to be due in every case to an independent origin,—namely, to the feeling of revulsion with which a better instinct or a better culture must always, sooner or later, repudiate the practice of slaying human beings at the altar of a malignant deity. Not to speak of the interrupted sacrifice of Isaac, the legend of Iphigenia, the substitution of whipping the boys at the shrine of Artemis Orthosia instead of slaying them outright, and even the fight of gladiators at the grave of the deceased warrior instead of immolating the prisoners of war, as we see in the Homeric funeral of Patroclus, must be regarded as so many manifestations of the instinct of humanity, whether the original practice of homicidal adoration, and the cannibalism which was its still earlier prototype, was or was not connected with the Semitic worship of Moloch. The attempts made by some of the German scholars (who have taken up this application of comparative philology with the enthusiasm peculiar to their class) to support their inferences by etymological researches, have not often been very happy. Conceding, for example, that the elements of the Greek and Sanscrit Ἐτεοκλῆς and *Satyáçravas* may be referred to identical roots, and that the compounds convey in every way precisely the same complex notion, it seems to us little less than absurd to suppose, as Dr Kuhn has done (*Zeitschrift f. Vergl. Sprachf.*, iv., p. 100), that the son of Œdipus, who died in fratricidal strife at Thebes, is the same mythological personage as the *Satyáçravas* mentioned in the *Rig-Vêda*, who is designated as *Sahîyas*, "the strong" or "victorious," and who is called the offspring of *Vayya*, to be identified with Λάιος by a change of *v* into *l*.! Comparative mythology, as it appears to us, is only valuable, when viewed in connection with ethnography, and when a due regard is paid to the antiquity of the myths and to the circumstances under which they originated. Every nation is capable of working up the old materials into new forms and combinations; and even at a comparatively late period fresh additions to a pantheon are devised or borrowed. Only imperfect information would confuse between the Sarapis of the Ptolemies and the old deities of the Pharaohs; and no Indian scholar would suppose that the Siva worship, which was introduced during the historical ages, or that of Krishna, which exhibits some traces of the influences of Christianity, and perhaps echoes even the name of the Author of our faith, were connected by direct descent with the Vaidic ages, when the Arian forefathers of the Hindus were offering the *Soma-drink* (*i.e.*, the juice of the *Asclepias acida*) to their primæval and elementary divinities. If, therefore, worship could change, and mythology could be created in the comparatively later ages of Egyptian and Indian history, we ought surely to allow an equal elasticity to the plastic imagination of the ancient Greeks, and abstain from impugning by precarious comparisons their well-established claims to poetical originality.

Linguistic records of civilization.

To the other of these new applications of comparative philology,—namely, the attempt to make language tell the history of ancient times long anterior to the commencement of written annals,—we would propose to give the name of "linguistic records of civilization;" and we recognise in this a means of making discoveries at once certain and important. By examining words of constant occurrence which are common to all the branches of the Indo-Germanic family, we are carried back to a time anterior to the separations of the different branches, and we find in the interpretation of the terms themselves distinct glimpses of the mode of life which could alone have given rise to such designations. In the same way, we argue that the words which are common to only a limited number among the different languages must either show that these branches remained in contact, after the others had left the common home, or, perhaps, in some new home, or must be received as a proof that the separation from the primitive stock was in these cases a very early one. We may take as an example the word designating "son" in the chief Arian languages. The common Sanscrit term is *putra*, and in Celtic we have a form virtually identical—*paotr*. But this exact resemblance is not recognisable in the synonyms found in other branches of the family. As we

Comparative Philology.

know that the Celts were not in contact with the Indians at a late period, this phenomenon alone is a strong confirmation of the theory, resting mainly on other considerations, that the Celtic tribes were those which first left Irân, and that they did so when *putra* or *paotr* was the one term for "son" used by the Iranians; that is, before other terms were introduced or generally adopted. Conversely, there is no term in Sanscrit, or in the Teutonic and Sclavonic branches of the family, corresponding immediately to the Greek φυιός or υἱός, and its Latin congener *filius*, both of which are derived, the latter with a patronymic affix peculiar to the Italian races, from the common root φυίω or *fio*, "to be born." From this we infer with certainty a contact or union between the forefathers of the Greeks and Italians long after their separation from the one Arian race, and before they branched off into the two peninsulas which they have rendered illustrious. The Sanscrit *sûnû*, Gothic *sunus*, and Lithuanian *sûnus*, as well as the received derivation of the Saxons as *Saca-sunus*, "sons of the Sacæ," point to a very ancient time when this was the common expression for sonship. The word is derived from *su* or *swi*, "to beget," which is as much older than φυι or *fi* as *svehrs* is than *fera*. So that the more recent contact of the Greeks and Italians is proved by the contrasts of the two sets of affinities. When, however, all the terms of a class are the same in the different languages, we are entitled to infer that the objects designated had a distinctive value in the earliest days of the Arian race; and if we can discover their etymology and primitive meaning, we are sometimes led to very interesting conclusions, which place the every-day life of our common ancestors before our eyes in the most vivid pictures. Thus every one of the Indo-Germanic languages, except the Latin, has the same word for "daughter,"—namely, some variety of our English term: Sanscrit, *duhitar;* Zend, *dughdar;* Sclavonic, *dukte;* Irish, *dear;* Greek, θυγάτηρ; Gothic, *dauhtar*. And the etymology of the Sanscrit word from *duh*, "to milk," paints the simplicity of a pastoral age when the daughter of the house was most naturally utilized as the milk-maid of the kine. Similarly, the "brother" bears our English name in every language of the family,—namely, Sanscrit, *bhrâtar;* Zend, *brâta;* Sclavonic, *brat;* Irish, *brathair;* Greek, φρατήρ; Latin, *frater;* Gothic, *brôthar*. And though the common Greek word to express this relationship is ἀδελφός "from the same womb," the use of φρατήρ to denote one of a more general fraternity, for the purpose of mutual assistance, is in more strict accordance with the original signification of the Sanscrit word, *i.e.*, "the bearer" or "helper" (root *bhri, fero*), which points to the mutual relations of the brothers in a primitive community. Although it is clear, from their linguistic records, that these primitive Arians recognised the sanctity of domestic relations; although they honoured the marriage tie in its only true form, that of monogamy, and had names for all the affinities which spring from that contract; and though there is every reason to believe that they were acquainted not only with domestic life and the domestication of animals, but even with navigation and the use of the oar (for we have the Sanscrit *naus* and *aritram*, corresponding to the Greek and Latin ναῦς, *navis*, ἐρετμός, *remus*), the fact that they have only one common name for grain (*java*, which means "spelt" and "barley" in Sanscrit; *jawai*, the Lithuanian name for "corn" in general; and ζεFά, which means "spelt" in particular), and the absence of any designation for agricultural implements, have been considered sufficient to justify the inference, that the Indo-Germanic tribes had not, at the time when they were still aggregated in Irân, passed from the pastoral to the agricultural mode of life. On the other hand, we see that the European branches of the family, before they separated into the Sclavonic, Teutonic, and Græco-Latin tribes, had made this further advance in civilization; and Mommsen has justly inferred from a number of specific facts that "the transition from a pastoral to an agricultural life, or, to speak more accurately, the combination of an agricultural with the more ancient pastoral economy, must have taken place after the Indians had separated themselves from the maternal bosom of the nations, but before the Hellenes and the Italians had become distinct peoples. Moreover, when these latter first began to practise tillage, they seem to have been united with other members of the great family; at least, it is a fact that the most important of those agricultural terms, though strange to the Asiatic members of the Indo-Germanic family, are common to the Roman and Greek, with the Teutonic, Sclavonic, Lithuanic, and even Celtic tribes." (*History of Rome*, Introduction, pp. 16, 17, Robertson's translation.)

With this brief notice of its latest and most important application, we must leave the subject of comparative philology. Before, however, we bring this paper to a close, it will be desirable that we should look back on the whole field which we have rapidly surveyed, and endeavour to indicate the place which philology, as a distinct science, is entitled to occupy in the encyclopædia of human knowledge.

Functions of philology in general.

Considered in its full compass, and in all the developments which belong to its definition as the methodical study of language with reference, in the first instance, to some fixed and ancient literature, philology may justly claim the following important functions:—

(1.) It forms the necessary basis of a liberal education in all countries which have been brought to regard their present position from the standing-point of universal history.

(2.) It is an important branch of inductive science.

(3.) It links together the present and the past, and enables those who would otherwise be bound down by the conditions and exigencies of every-day life, to cultivate their spiritual nature by more genial aspirations and a more comprehensive view of their own duties and destiny.

(4.) It rectifies ancient traditions, when, being erroneous or wrongly interpreted, they exercise a mischievous influence on the belief and practice of a generation.

(5.) It forms the key-stone of theology, wherever the knowledge of divine truth professes to rest on a rational interpretation of the documents of religious history.

We will make a few remarks on each of these subjects.

(1.) It is the necessary basis of a liberal education.

(1.) The proper idea of education, as distinguished from the mere acquisition of information or the amassing of stores of knowledge, includes the complete and progressive training of the individual, both mentally and morally. With the latter the science of language is indirectly concerned, because it is through the reason that the teacher acts on the will of his pupils, and because the first lessons of duty are always presented in a form which requires more or less of progressive interpretation. With respect, however, to mental or intellectual culture, philology in its elementary applications becomes of paramount importance. On this subject we have only to repeat the language which we have used on former occasions, and to maintain that the discipline of the mind depends entirely on that system of logical training, which gradually imparts the habit of methodically arranging our thoughts, and exercises the reasoning faculties in the practical processes of deduction. Intellectual education cannot advance beyond this; and educational training will undertake what does not belong to its own province if it does not confine itself to the cultivation and improvement of deductive habits. As far as the world has hitherto advanced, only two forms, under which this instruction is possible, have been excogitated or practised by man,—namely, *grammar*, which deals with the expression of our thoughts in language; and *geometry*, which applies the rules of language to a methodical discussion of quantities, magnitudes, and proportions, or, in Kant's phraseology, to a development of the intuitions of space and time. Practically, the higher education of Europe, since the days when Plato

first discovered and stated the leading principles of Greek syntax, has rested upon this basis and no other. That great philosopher, in whose view dialectics, or the method of language, was the primary science, is reported to have warned those who were unskilled in the geometry, lately brought to perfection by his friends Theodorus and Theætetus, not to enter the sacred precincts of his Academy. And, however, disguised in technical terminology, this has been the maxim of university training both in the middle ages and in modern times. We have already said that the *Trivium* and *Quadrivium* of the mediæval school of arts constituted the original department in the university of Paris and the similar institutions which followed in its wake; and these seven liberal arts,—namely, grammar, logic, and rhetoric, for the *Trivium;* and music, arithmetic, geometry, and astronomy, for the *Quadrivium,*—are represented respectively by the classics and mathematics of modern schools and colleges. It is true that, while the intimate connection of the latter with many branches of practical and professional life have shielded the study of mathematics from any formal attack on the part of those who take a utilitarian view of education, there has been a great outcry in some quarters against the importance assigned to philology, or rather to classical philology, in the higher education of Great Britain; and there are many persons who think that such studies are an anachronism, and that the time bestowed upon them would be better employed in learning modern and living languages, and in becoming well acquainted with the noble literature of our own country. It is not our business on the present occasion to enter into an argument on this subject, which we have sufficiently discussed elsewhere (*Classical Scholarship and Classical Learning*, Cambridge, 1856). But we must remark here, that no modern language, when acquired in the only way in which it can be learned completely,—namely, by a prolonged and generally an early residence in the country where it is spoken,—can furnish the means of that true grammatical training which is the first step in the formation of deductive habits; and that the literature of England and other modern countries rests so entirely on the wisdom of the ancients that it cannot be fully appreciated, and its most illustrious specimens can scarcely be understood, except by those who have made some acquaintance with the dead languages but immortal writings of Greece and Rome. And therefore philology, which, according to its definition, recognises its primary object in some language and literature in a fixed, if not unalterable form, and which, by the conditions of modern civilization, finds its scope and materials in idioms and in books which have become either classical or sacred, cannot really be divorced from the intellectual education of modern times without serious detriment to one great branch of deductive training,—namely, the study of language, on its own account, and for the sake of the mental discipline which it involves.

(2.) It is an important branch of inductive science

(2.) As a branch of inductive science, philology, in that final development which we call comparative philology, stands on precisely the same footing as geology and those other sciences which are "connected by this bond, that they endeavour to ascend to a past state of things by the aid of the evidence of the present" (Whewell, *History of the Inductive Sciences*, vol. iii., p. 481); for, as it has been well observed, "language is one of the most clear and imperishable records of the early events in the career of the human race" (Whewell, *Philosophy of the Inductive Sciences*, vol. i., p. 650). We have already seen how comparative philology enables us to classify the races and languages of man, and how it sets before us, with unmistakeable veracity, the primæval history of Indo-Germanic civilization. Its claim, however, to rank as a branch of inductive science, does not rest merely on its services in classifying the phenomena and interpreting the facts of language. It has also proved itself able to discover, like other inductive sciences, the general laws which prevail among the phenomena. One of the most important of these general laws is that of the "transposition of sounds" (*Lautverschiebung*), or, as it is sometimes called, "the law of the interchange of the mutes," which had been imperfectly indicated by Rask, and which Grimm demonstrated completely in its application to the Greek (Latin, Sanscrit), the Gothic, and the Old High German (*Deutsche Grammatik*, vol. i., pp. 584, sqq.), and which Bopp has extended to the Zend and Lithuanian (*Vergleichende Grammatik*, pp. 78, foll.) The general law is thus stated:—

Labials.

In Greek (Latin, Sanscrit),

P answers to the Gothic	F,	and the Old High German	B or V.
B „ „	P,	„ „	F.
F „ „	B,	„ „	P.

Dentals.

In Greek (Latin, Sanscrit),

T answers to the Gothic	TH,	and the Old High German	D.
D „ „	T,	„ „	Z.
TH „ „	D,	„ „	T.

Gutturals.

In Greek (Latin, Sanscrit),

K answers to the Gothic	{ H (init.) G (med.) }	and Old High Germ.	G.
G „ „	K	„ „	CH.
CH (H) „ „	G	„ „	K.

Or thus:—

Greek (Latin, Sanscrit).	Gothic.	Old High German.
Tenuis,	Aspirate,	Medial.
Medial,	Tenuis,	Aspirate.
Aspirate,	Medial,	Tenuis.

One example of each interchange will explain the application of this law.

	Greek (Latin, Sanscrit).	Gothic (Old Norse).	Old High German.
P, F, V (B),	Πούς=πόδ-ς, Pes=*ped-s*, *Pâdas*,	*Fôtus*,	*Vuoz.*
B, P, F,	*θόρυΒος*, *turBa*,	*thaúrP*,	*doroF.*
F, PH } B, P,	Φηγός, *Fagus*,	*Beyki*,	*Puocha.*
T, TH, D,	{ ὀδούς=ὀδόνΤ-ς, *dens*=*denT-s*, *danTas*, }	*tunTHus*,	*zanD.*
D, T, Z,	ὀΔούς, *Dens*, *Dantâs*,	*Tunthus*,	*Zand.*
TH, D, T,	Θυγατηρ,	*Dauhtar*,	*Tohtar.*
K, { H G } G,	ἑΚυρός, *soCer*,	*svaíHra*,	*schwaGer.*
G, K, CH,	Γένος, *Genus*,	*Kuni*,	*CHunni.*
CH, H, } G, K,	Χόρτος, *Hortus*,	*Gards*,	*Karto.*

Mr Winning has pointed out a curious interchange between the Greek and the Gothic, with regard to the relations established by this law (*Manual of Comparative Philology*, p. 111). Other modifications require to be introduced. And Dr Guest attaches so much weight to the exceptions which he has noticed, that he has arrived at a conviction of "the general unsoundness of these celebrated canons" ("On the Elements of Language, their Arrangements and their Accidents," *Proceedings of the Philological Society*, vol. iii., p. 180). The great majority of philologers, however, acquiesce in the general validity of this theorem of interchange: Bunsen calls it "one of the most fertile and triumphant discoveries of philological ethnology" (*Report of the British Association* for 1847, p. 262); and Max Müller accepts it as a proof of "the systematic regularity—the almost absolute certainty—to which the phonetic laws of different languages can be brought" (*Edinburgh Review*, October 1851, p. 319). The present writer ventures to attach a somewhat similar importance to his own discovery of another principle, which he proposes to call "the law of divergent articulations." Grimm's law of transposition applies only to the interchange of mutes of the same

Comparative Philology.

order, as far as the mode of their articulation is concerned, but distinguished as tenues, aspirates, and medials. For the interchanges of mutes with others belonging to different organs, he had no explanation to offer, and regards them merely as exceptions to the general rule (*Deutsche Grammatik*, i., p. 589). The older grammarians had only one name, *metalepsis*, for all interchanges, whether regular and easily explicable, as from P to B, or irregular, and at first sight inexplicable, as from P to K. The present writer was led to an explanation of these divergent interchanges by an inquiry into the nature of the Greek letter called the digamma, which he proved to be a complex sound, consisting of a guttural combined with a labial (*New Cratylus*, § 110), and he extended the same principle to all cases in which two words, undoubtedly of the same origin, exhibit articulations which could not have been interchanged. In all such cases, he concluded that the original form exhibited a combination of the two sounds. The brief but decisive induction by which this law was established in 1839 (*New Cratylus*, 1st edit., p. 136) was greatly extended by Mr Garrett in his valuable paper "On Certain Initial Letter-Changes in the Indo-European Languages" (*Proceedings of the Philological Society* for 1846, vol. ii., p. 233, sqq.). A simple example or two will show the application of this law. The Sanscrit *paktas* corresponds exactly in meaning to the Latin *coctus* and the Greek πεπτός. But as *p* cannot pass into *k*, the Latin differs from the Sanscrit in the initial, and from the Greek in the included sound, or, in Grimm's useful terminology, they differ reciprocally in *Anlaut* and *Inlaut*. Now the Latin *coquo* shows us that the guttural in this case was not pure, but that it was followed by a vocalized labial; and it is known that even in Cicero's time *coquus* was pronounced *quoquus*. (Quintil. *Inst. Or.* vi. 3, § 47.) The divergent articulations P and K converge, therefore, in the compound sound QV=KP, and the three words are accordingly reducible to an identity of origin as well as of meaning. Again, we have in Greek κελαινός as a synonym of μέλας, μέλαινα, μέλαν; and with the exception of the initial or *Anlaut*, the words are identical in root or crude form. But we cannot derive κ from μ, or *vice versa*; and, according to the law, we must assume the complex sound κμ as the origin of these divergent articulations. Fortunately we are not left to an inference in this case, for Pamphilus, of the school of Aristarchus, recorded the fact, that μέλαθρα, meaning "the rafters blackened by the smoke," were anciently called κμέλεθρα. (*Etymol. Magn.*, p. 521, 33.) Lastly, to take an instance in which we have all forms of the process, the Latin *vivus* exhibits no traces of a guttural in combination with the labial. But the perfect *vixi*, from the corresponding verb *vivo*, shows that the *Inlaut* at least involved a *k*-sound; whereas a comparison with the Gothic *quivs*=*vivus*, indicates that *qv* was also the original type of the *Anlaut*, or initial articulation; and thus we arrive with perfect confidence at the conclusion, that *vivus*=*qviqvus* was ultimately identical in meaning, as it is in signification, with the Old Norse *quikr*, Old Saxon *quic*, and modern English *quick*.

(3.) It releases the mind from the thraldom of the present.

(3.) If the science of philology had not existed, or had been irrecoverably lost at some early period, there must have been a total disruption of those nobler associations which connect the present with the past, and prevent civilized men from becoming the bond-slaves of their everyday requirements and exigencies. It may seem, to those who have not reflected on the subject, something like a paradox to assert that those who have forgotten the past very rarely bestow much thought upon the future. But this is really the condition of human nature. All belief in the future destiny of man necessarily connects itself with a belief in the facts of his past history. Without the latter the former is impossible; for the future is in our minds only the anticipated copy of our recorded experiences. Without this we have no future beyond the idea of proximate coming time; and he who has no past but "yesterday," has no future but "to-morrow":—

> To-morrow, and to-morrow, and to-morrow,
> Creeps in this petty pace from day to day,
> To the last syllable of recorded time;
> And all our yesterdays have lighted fools
> To dusty death.

The very structure of inflected language shows us that we cannot measure futurity beyond the vague statement that it is near and coming; whereas the past, so far as it is registered, stretches back in a lengthening vista, and is, by the mere expression of tense in the oldest languages of our family, declared to be distant. From a contemplation of this remote period, as it is unfolded in ancient history, not only does the present sink to its proper littleness as a mere fleeting unit in the onward progress of the seasons, but the future assumes new and larger proportions in the analogy of the past, till at last it expands in the eyes of faith, or it may be of imagination, into the grand conception of eternity. Dr Johnson, then, has said with great truth (*Journey to the Western Isles*, Works, x., p. 501),—"Whatever withdraws us from the power of the senses,—whatever makes the past, the distant, or the future predominate over the present,—advances us in the dignity of thinking beings." Now it cannot be doubted that the schools of philology, of which we have briefly traced the history in this paper, have alone preserved the records of the past life of man, and enabled the present and future ages to read and understand them. To the critical editorship, which commenced at Athens under the Pisistratidæ, and culminated at Alexandria under the Ptolemies, we owe all that we have of ancient Greek literature, the greatest inheritance of genius and wisdom, and the most influential instrument of liberal culture, that the world has ever possessed. The Jews, stimulated perhaps in part, and certainly guided in no small degree by the school of Alexandria, have preserved and transmitted to us a collection of sacred writings which still preaches to the civilized world the highest lessons of religious faith and divine morality, and breathes forth a spirit of prayer that ascends to heaven like the incense of the sacrifice. The Indians, by a very similar but independent effort, made, perhaps, under the intrusive pressure of Buddhism, have rescued from oblivion and placed on record the relics of their own primitive language and writings, which have enabled us to penetrate to the untold beginnings of Arian civilization, and to discover what the Indo-Germanic race did and believed before it was broken up into distinct nationalities, and scattered over the face of Asia and Europe. The labours of philologers, during the three centuries which have elapsed since the revival of literature and learning, have rendered all these early efforts to preserve the documents of ancient culture available for the purposes of modern speculation. The hieroglyphic annals of Egypt, and the arrow-headed inscriptions of Persia and Assyria, have been, in part at least, deciphered and interpreted. The languages called classical, and those of the Jews and Indians, have been analysed so thoroughly that little, if anything, remains to be done for their elucidation. Historical criticism and comparative grammar have corrected the mistakes of a credulous age, and have raised etymology from guess-work to science; and ethnography, which treats of the origin and growth of man, has been placed, by the aid of the philologer, on a basis as strong as that of physical science. With all these fields of research open to his view,—with these means of connecting himself with the past history of his species, and of basing his future hopes on manifold revelations,—educated men must blame themselves if they yield to the degrading thraldom of their present needs and enjoyments, and make themselves tools for the execution of some daily work.

Comparative Philology.

(4.) It rectifies mistaken traditions.

(4.) Valuable as the records of the past necessarily are, when read with that discriminating judgment which it is the business of philology to cultivate, their possession and use may, without this organon, lead to the most superstitious belief and the most criminal practices. This is especially the case in regard to branches of literature which have become sacred rather than classical. In the interpretation of these records of authoritative tradition it is often found that, so long as they remain in the sole custody of a sacerdotal caste, they are liable to be distorted and misread until they are made to say something quite inconsistent with their true meaning. And it is only when the scholar steps in with his matured and independent knowledge that the mistaken tradition is rectified, and the genuine statement re-invested with an articulate utterance. Thus, to take two most important instances from the sacred writings of the Hindus:—The Brahmins profess to derive the multitudinous practices which they enjoin from the infallible revelations of their Vêdas. The great majority of these ordinances, although childish and absurd in our eyes, have been wisely tolerated by the British government since it became paramount in India. But there was one practice so offensive, not only to morality, but even to humanity, that steps were necessarily taken to do away with it. This was the *suttee*, or compulsory immolation of the widow on her deceased husband's funeral pile. At the time when Christian feeling broke out into open revolt against this monstrous usage, it was supposed that the Brahmins had at least the excuse of believing that the practice of widow-burning was expressly enjoined in the oldest books of their religion; and even the great Sanscrit scholar Colebrooke had translated a passage from the *Rig-Vêda* in accordance with their interpretation of it (*Asiatic Researches*, vol. iv., pp. 209–219, Calcutta, 1795). But when the *Vêdas* were at length studied according to the principles of philological criticism as established in Europe, it was found that the sacred book, instead of countenancing the murderous custom, in the passage immediately before that which the Brahmins quoted as sanctioning it, said,—"Rise up, woman; come to the world of life; thou sleepest nigh unto him whose life is gone. Come to us." And that in the text cited by the Vêdolaters they had changed "*Â rohantu janayo yonim agre*" ("The mothers may go first to the altar"), into "*Â rohantu janayo yonim agneh*" ("Let the mothers pass into the womb of fire"). (See Max Muller, in the *Zeitschrift d. Deutsch. Morgenl. Gesells.*, vol. ix., part 4, p. xxv.; and in the *Oxford Essays* for 1856, pp. 22, 25.) If this discovery had been made only fifty years earlier, many innocent women would have been saved from a cruel death, and we should have escaped the risk of a religious outbreak, which we incurred when we put a stop to this mock martyrdom. Again, the dreadful mutinies which have raged in so large a part of our Indian dominions are attributed immediately to the apprehensions on the part of the Brahminical sepoys that the government intended to interfere with their sacred distinction of caste. In this case, also, philology has proved that the supposed religious sanction is not to be found in the sacred books. "If," says a learned and able writer, who is easily identified as perhaps the best authority on the subject (*Times*, 10th April 1858), "with all the documents before us, we ask the question, Does caste, as we find it in Manu, and at the present day, form part of the religious teaching of the Vêdas? We can answer with a decided *No.* There is no authority whatever in the Vêda for the complicated system of castes; no authority for the offensive privileges claimed by the *Brahmins;* no authority for the degraded position of the *Sûdras.* There is no authority to prevent the different classes of the people from living together, from eating and drinking together; no law to prohibit the marriage of people belonging to different castes; no law to brand the offspring of such marriages with an indelible stigma." And he justly adds that, "As the case now stands, the government would be perfectly justified in declaring that it will no longer consider caste as part of the religious system of the Hindus. Caste, in the modern sense of the term, is no religious institution; it has no authority in the sacred writings of the Brahmins; and, by whatever promise the government may have bound itself to respect the religion of the natives, that promise will not be violated even though penalties were inflicted for the observation of the rules of caste." The evils which have resulted from this misapprehension on the part of the Hindu priests, or rather from the traditions with which they have overlaid and nullified the sacred books, and so substituted a new authority for that which should alone be paramount, have been remedied by a vigorous exertion of our military power; but it is clear that an ultimate pacification on this and other kindred subjects will be greatly facilitated when the spirit of modern philology, applied to the Vêdas and Puranas, shall have finally superseded the half-knowledge of the native pundits.

(5.) It is the key-stone of genuine theology.

(5.) In much the same manner as the sacerdotal caste in India have substituted a traditionary system of their own for that of the sacred writings on which they profess to rely, the priests of the Latin Church in the middle ages had superseded the Scriptures by an elaborate system of theology, and by the recognition of a visible head, whose decisions on questions of doctrine and practice were held to be infallible. The rectification of this erroneous tradition was called Protestantism; and it was due in a great measure to the revival of philological learning, which preceded it, and which has been briefly described in these pages. Indeed, it may be asserted with perfect truth, that the whole fabric of papal pretensions rested on precarious deductions from a philological blunder or oversight,—namely, the supposition or statement that πέτρος, *a stone*, was exactly synonymous with πέτρα, *a rock*,—that is, a mass or collection of similar stones. But although freedom of opinion achieved this partial victory in the sixteenth century, the necessity for an energetic exertion of Protestant principles has never ceased; and it is as urgent now as it was in the days of Luther and Melanchthon. Roman pretensions are not extinct; and the traditions of the Italian church are not the only adscititious envelopments which mar the beauty of the Christian revelation. Among Protestants themselves there are still traditions of infallibility, as degrading to the intellect of man, as prejudicial to true religion, and as untenable in themselves, as those which were put forth to support the dogma of transubstantiation or the practice of indulgences. For every individual Protestant now, as for Protestants in general at the time of the great Reformation, the significant saying of Zschokke (*Autobiography*, p. 29) contains at once a caution and a rule of action:—"He who does not like living in the furnished lodgings of tradition must build his own house, his own system of thought and faith, for himself." And it would be the greatest mistake to suppose that the duty of study and examination in a Protestant community devolves exclusively on the clergy or ministry. The laity cannot thus shift their responsibility in a matter which concerns themselves individually, and in which the general diffusion of education has made them quite as competent judges, while they are also more unprejudiced arbiters, and more free to express their convictions, than most of their authorized teachers. On this subject we need only refer to a temperate and well-considered argument which has just appeared from the pen, as we are informed, of a person who has won a distinguished place in Indian philology (*Free Theological Inquiry the Duty of the Laity*, by a Lay Member of the Church of England, London and Edinburgh, 1858; see p. 13). But for all Protestants, whether ministers or members of congregations, it is certain

that a critical period has arrived, fraught with momentous consequences to the religious and moral training of the age, and that the problems which await solution cannot be successfully encountered except in that spirit of historical and linguistic criticism, the origin, growth, maturity, and various applications of which we have endeavoured to exhibit.

On all these accounts, we claim for philology, or the methodical study of the fixed forms of language and literature, a place of honour in the first class of those branches of knowledge which find their appropriate place in the volumes of an Encyclopædia; and we are prepared to echo the words which Bunsen addressed to the British Association at Oxford (*Report* for 1847, p. 257):—"If man is the apex of the creation, it seems right, on the one side, that a historical inquiry into his origin and development should never be allowed to sever itself from the general body of natural science, and in particular from physiology. But, on the other hand, if man is the apex of the creation; if he is the end to which all organic formations tend from the very beginning; if man is at once the mystery and the key of natural science; if that is the only view of natural science worthy of our age; then ethnologic philology, once established on principles as clear as the physiological are, is the highest branch of that science for the advancement of which this association is instituted. It is not an appendix to physiology or to anything else; but its object is, on the contrary, capable of becoming the end and goal of the labours and transactions of a scientific association."

In the survey which we have now brought to a close we have contented ourselves with describing the first beginnings, successive developments, present condition, and manifold usefulness of linguistic science. It has not been our business to write a treatise on any branch of philology. Special views on certain departments of the subject have been set forth by competent writers in the articles on GRAMMAR and LANGUAGE. Those who wish to prosecute the study of philology in its details are recommended to the following books, which have been mentioned above, and some of which, we believe, are the generally-received representatives of the existing knowledge in the higher branches of comparative grammar and the philosophy of language:—

1. GRIMM (Jacob), *Deutsche Grammatik*, vols i.–iv. Göttingen, 1822–1837. A third edition of part of the first volume appeared in 1840.
2. POTT (August Friedrich), *Etymologische Forschungen auf dem Gebiete der Indo-Germanischen Sprachen*. Lemgo, 1833–6.
3. BOPP (Franz), *Vergleichende Grammatik des Sanskrit, Zend, Griechischen, Lateinischen, Litthauischen, Gothischen, und Deutschen*. Berlin, 1833–1852. This work, which is now in course of republication, has been translated into English by Mr Eastwick, with the co-operation of the late Earl of Ellesmere.
4. HUMBOLDT (Wilhelm von), *Ueber die Verschiedenheit des Menschlichen Sprachbaues und ihren Einfluss auf die geistige Entwickelung des Menschengeschlechts*. Berlin, 1836. Reprinted in the author's collected works, vol. vi. Humboldt's principles have found a special exponent in Dr H. Steinthal, *Sprachwissenschaft W. v. Humboldt's und die Hegel'sche Philosophie*. Berlin, 1848.
5. WINNING (W. B.), *A Manual of Comparative Philology*. London, 1838.
6. *The New Cratylus, or Contributions towards a more Accurate Knowledge of the Greek Language*. First edition, Cambridge, 1839; second edition, considerably enlarged, Cambridge, 1850; third edition, in the press.
7. *Varronianus A Critical and Historical Introduction to the Ethnography of Ancient Italy, and the Philological Study of the Latin Language*. First edition, London, 1844; second edition, considerably enlarged; London, 1852.
8. LATHAM (R. G.), *The English Language*. First edition, London, 1842; second edition, considerably enlarged, 1848; third edition, 1850.
9. GRIMM (Jacob), *Geschichte der Deutschen Sprache*. Leipsic, 1848.
10. SCHWARTZE (M. G.), *Aufstellung und Auseinandersetzung des Koptischen Sprachgebaudes mit Rucksicht auf die vergleichende Sprachforschung*, in his great work *Das Alte Ægypten*. Leipsic, 1843 (pp. 466–932).
11. ZEUSS (J. C.), *Grammatica Celtica*. Lipsiæ, 1853.
12. DIEZ (Friedrich), *Etymologisches Wörterbuch der Romanischen Sprache*. Bonn, 1853.
13. BUNSEN (C. C. J.), *Outlines of the Philosophy of Universal History*. London, 1854.
14. GARNETT (Richard), *Philological Essays*, edited by his son (in the press).

There are several periodicals devoted to the discussion of philology: of these the most important are the *Transactions of the Philological Society*, published in London; and the *Zeitschrift für vergleichende Sprachforschung*, published at Berlin. (J. W. D.)

PHILOMELA, a daughter of Pandion, King of Athens, changed into a nightingale.

PHILOPŒMEN, a celebrated general of the Achæan League, was born about 252 B.C., in Megalopolis, a city of Arcadia, in Peloponnesus, and from his very infancy discovered a strong inclination to the profession of arms. Having been nobly educated by Cassander of Mantinea, he was no sooner able to bear arms than he entered amongst the troops which the city of Megalopolis sent to make incursions into Laconia, and in these inroads never failed to give some remarkable instance of his prudence and valour. After signalizing himself in various services, he was appointed general of the Achæan forces, and applied himself to re-establish military discipline amongst the troops of the republic, strove to rouse the courage of his countrymen, and laboured to put them into a condition to defend themselves without the assistance of foreign allies. With this view, he made great improvements in the Achæan discipline, changing the manner of their exercise, as well as their arms, which were both very defective. After eight months of hard discipline, news reached him that Machanidas was advancing, at the head of a numerous army, to invade Achaia. He met the enemy in the territories of Mantinea, where a decisive battle was fought, about 204 B.C., in which the Achæans were completely victorious. But what most contributed to raise the fame and the reputation of Philopœmen was his uniting the powerful city of Lacedæmon to the Achæan commonwealth, by which means the Achæans were enabled to eclipse all the other states of Greece. (See ACHÆANS.) Philopœmen attacked the Messenians, but was wounded, taken prisoner, and poisoned by the magistrates; and thus died one of the greatest heroes whom Greece or any other country had ever produced. Philopœmen was called the last of the Greeks, as Brutus was afterwards styled the last of the Romans. (See ARMY.)

PHILOSOPHER'S STONE. See ALCHEMY.

PHILOSOPHY (φιλοσοφία, *love of wisdom*) is a term which is said to owe its origin to Pythagoras, who, disclaiming the presumptive title of σοφός, or *sage*, assumed by his predecessors, chose rather to designate himself as a φιλόσοφος, *a lover of the* σοφία,—as one who, though ardent in the pursuit of wisdom, yet could never properly arrogate to himself the possession of it. Cicero tells this story (*Tusc. Quæst.* lib. iv., cap. 3) on the authority of Heraclides Ponticus, who is, however, confessed to have been a fabulous writer. There was, however, a verb φιλοσοφεῖν, *to philosophize*, in the time of Herodotus; and the term, as a distinctive epithet, was brought into general use by Socrates, to denote the science that is conversant about the causes and existence of things. Philosophical knowledge, in the widest acceptation of the term, is the knowledge of effects as dependent on their causes. And as every cause to which we can ascend is also an effect, it follows that it belongs to philosophy to trace up the series of effects till we arrive at causes which are not themselves effects, and have reduced them to the fewest possible number. It follows, therefore,

that philosophy may be defined as *the science of first principles;* and the term is now limited almost exclusively to the mental sciences.

PHILOSTRATUS, the famous author of the *Life of Apollonius of Tyana*, was born most probably about A.D. 172. Eusebius calls him an Athenian, because he taught at Athens; but Eunapius and Suidas always speak of him as a Lemnian. He frequented the schools of the Sophists, and he mentions his having heard Damianus of Ephesus, Proclus Naucratitas, and Hippodromus of Larissa. He afterwards became known to Julia Augusta, the wife of Severus, and was one of those learned men whom this philosophical empress had continually about her. It was by her command that he wrote his celebrated *Life of Apollonius of Tyana.* His *Lives of the Sophists* contain many things which are to be met with nowhere else. The *Heroics* of Philostratus are only a dialogue between a vintner of the Thracian Chersonesus and a Phœnician; while his *Images* are elegant descriptions and illustrations of some ancient paintings, and other particulars relating to the fine arts. The last piece is a collection of Philostratus' *Letters.*

Of the collected works of Philostratus there is the edition of F. Morellius, Paris, 1608; that of Olearius, 2 vols. folio, Leipsic, 1709; and lastly, and by far the best, there is the edition of C. L. Kayser, 4to, Zurich, 1844. The first two books of the *Life of Apollonius of Tyana* were translated into English by the unfortunate Charles Blount, London, 1680; and shortly after prohibited.

PHILOXENUS, a celebrated dithyrambic poet, a native of the island of Cythera, flourished B.C. 398, being contemporary with Timotheus and Telestes, and died at the age of sixty, B.C. 380. He was a son of Euletidas, and, when Cythera was taken by the Lacedæmonians, he was carried off as a slave. He was sold to Agesylas; and on his death was bought by the poet Melanippides, by whose instruction he seems to have profited. He was devoted to the pleasures of the table, and became a great favourite of the elder Dionysius. It is said the luxury of the court of Syracuse furnished the theme of his poem Δεῖπνον (*Dinner*). His poem *Cyclops* or *Galateia* is said to have been one of the finest of his productions. Alexander the Great was a great admirer of the dithyrambs of Philoxenus and Telestes. The fragments of Philoxenus are almost all in Athenæus. Most of them have been recently edited by Meinekè, by Bergk, and by Schmidt.

PHILTER (φίλτρον, *a love charm*, from φιλέω, *I love*), was a potion given by the Greeks and Romans to excite love. Its composition is not known.

PHLEGON, a Greek historian, was a native of Tralles, in Lydia, and the freedman of the Emperor Hadrian (A.D. 117–138). He was the author of a History or Chronicle, in sixteen books, which ended A.D. 141, and which is now lost. Besides a fragment, *De Olympiis*, we have also two other works, *De Longævis libellus* and *De Rebus Mirabilibus liber.* The edition of Bast (Halle, 1822, 8vo) includes all the valuable annotations of his predecessors; but that of Westermann, in his *Scriptores Rerum Mirabilium Græci*, 1839, is unquestionably the best.

PHLIUS, an independent city in the north-eastern part of Peloponnesus, stood on a hill called Arantinus, on the left bank of the Asopus (*Asopo*). Its territory, bounded on the S. by Argolis, on the W. by Arcadia, on the N. by Sicyonia, and on the E. by Cleonæ, was an upland valley, well watered by mountain streams, and fruitful in vines. Its inhabitants are celebrated for their alliance with Sparta. The ruins of Phlius are still visible.

PHOCÆA (the modern *Phokia*), the most northern of the cities of Ionia, was situated on the coast, about 200 stadia from Smyrna. It was founded by a colony of Phocians, led by two Athenians, Philogenes and Damon. Its citizens are said to have been the first amongst the Greeks who extended their commercial voyages to great distances; and its inhabitants abandoned their city rather than submit to the Persians, B.C. 544. They settled in Italy, and founded Velia. Massilia in France, and Alalia in Corsica, were colonies of the Phocæans.

PHOCION, a very celebrated Athenian general, was descended from a family which at no time had been particularly distinguished in the political transactions of their country. He was born B.C. 402, and was condemned to death B.C. 317, at the age of eighty-five. His early years were spent under the direction of Plato and Xenocrates, and his subsequent career showed that he had profited by their instruction. His aspect was forbidding, though his disposition was mild and gentle. It was remarked that he was never seen to laugh or to weep. He commenced his military career under Chabrias, and gained so much influence with that general that he directed many of his proceedings. The victory at Naxos, B.C. 376, was in a great measure due to his prudence and military talents. Nor was he less distinguished as a statesman and orator. He was quick in perception, and ready in debate; so that Demosthenes feared him more than any other orator, and is said to have called him the *Hatchet.* (See DEMOSTHENES, and MACEDONIA.)

PHOCIS, a country of ancient Greece, was bounded on the W. by the Locri Ozolæ and Doris, on the N. by the Locri Epicnemidii and the Locri Opuntii, on the E. by Bœotia, and on the S. by the Corinthian Gulf. Its surface was occupied by a succession of lofty mountains and spacious plains. The Locrian chain of heights formed the northern frontier, hemming in the country. Extending along the inner side of these lay the fertile valley through which the Cephissus flowed. On the southern bank of the river the ground rose suddenly and abruptly into the lofty and rugged range of Parnassus. Then it sank gradually down, leaving many mountain offshoots and recesses, until it found a level in the spacious sea-shore plain of Crissa. Phocis held a prominent place in Grecian history from the very first. At an early date it received its name from a certain King Phocus. In course of time, two of its cities, Delphi and Elatea, became notable,—the former as being the site of the celebrated oracle of Apollo, and the latter as standing on the highway from Northern to Central Greece. Nor was its prowess in arms less remarkable. For many years its inhabitants drove back the repeated incursions of the Thessalians; and during the invasion of Xerxes, they stood at bay among the fastnesses of their native mountains. The chief event, however, in the annals of Phocis is the Phocian or Sacred War. (See MACEDONIA.) Besides Delphi and Elatea, the other important towns of Phocis were Lilæa, on the plain of the Cephissus: Daulis, on the Bœotian frontier; Crissa, on Mount Parnassus; and Cirrha and Anticyra, on the shore of the Corinthian Gulf.

PHŒBUS. See APOLLO.

PHŒNICIA. See SYRIA.

PHOOLGHUR, a small raj of British India, on the S.W. frontier of Bengal. Its centre lies in N. Lat. 21. 15., E. Long. 83.; area, 890 square miles. The surface is undulating; and buffaloes are allowed to run wild over the country. The people are idle and lawless. The revenue is calculated to amount to L.600. Pop. estimated at 40,000.

PHOSPHORUS. See CHEMISTRY.

PHOTIUS, a Patriarch of Constantinople, one of the most remarkable men of his time, was born in the early part of the ninth century, and raised himself by his merit to the patriarchate. When Bardas had driven Ignatius from the see, Photius was consecrated by Asbestus in 859 A.D. He condemned Ignatius in a synod, upon which the Pope excommunicated him, and, to balance the account, Photius anathematized the Pope. Basilius of Macedonia, whom

Photo-galvanography || Photography.

Photius had reproved for the murder of the Emperor Michael, expelled him, and restored Ignatius; but afterwards, upon the death of Ignatius, Photius was re-established, in the year 878 A.D. At last, being wrongfully accused of a conspiracy against the person of Leo the Philosopher, son and successor of Basilius, he was expelled in 886, and is supposed to have died soon afterwards. He wrote a Bibliotheca, an extraordinary monument of literary energy and immense erudition, which contains an examination of 280 authors; and we have also 253 Epistles of his, the *Nomocanon* under 14 *Tituli*, an abridgment of the acts of several councils; besides several other works, many of which are still in manuscript. There was no branch of literature, whether sacred or profane, and scarcely any art or science, in which he was not deeply versed. His rise to the patriarchate was very rapid; for when he was chosen to that office he was only a layman; but he was made monk the first day, reader the next, and the following days sub-deacon, deacon, and priest; so that in the space of six days he attained to the highest offices in the church. On the whole, however, his ardent love of glory and unbounded ambition led him to commit excesses which rendered him a scourge to those around him. It was brought to light by Andreas Scottus, and communicated by him to David Hœschelius, who caused it to be printed in 1601. The Greek text, together with Scottus's Latin translation, was afterwards printed at Geneva in 1611. A revised edition of this work was published by Bekker, in 2 vols., Berlin, 1824–25; but there has been hitherto no collected edition of this great scholar's writings.

PHOTO-GALVANOGRAPHY is a new art, invented by Mr Paul Pretsch of Vienna, and introduced by him into England. After securing his right by patent, he has published, in a series of folio plates, magnificent specimens of the art.

Solutions of glue and solutions of nitrate of silver, iodide of potassium, and bichromate of potash, are mixed according to a rule, and spread, as is done in the albumen process,[1] over the glass plate. A photograph or engraving is placed on the prepared surface, and a negative taken in sunlight or daylight. The glass plate is then placed in water with a little alcohol, and the darkened parts are rendered soluble, while the other parts are insoluble; so that in a few minutes we have a picture represented by the unequal thickness of the gelatine upon the glass. When the plate is dry, soft gutta percha is pressed upon the picture till it hardens. The gutta percha has consequently an image the reverse of the first. After metallizing it,—that is, rubbing it over with bronze powder or black lead,—it is placed in a solution of sulphate of copper, and an electrotype plate taken from it in the usual way with the voltaic battery. From this plate others can be readily taken, and, as in ordinary copperplate printing, thousands of copies exactly similar to the photograph can be thrown off. "By this process," says Mr Hunt, "pictures, in which the most delicate details are very faithfully preserved, and the nice gradations in light and shadow maintained in all their beauty, are now printed from the electrotype plate obtained from the photograph. The process of photo-galvanography is evidently destined to take a very high position as a means of preserving the beauties of nature and art."[2] (D. B.)

Photoglyphic Engraving || Photography.

PHOTOGLYPHIC ENGRAVING, the name given to a new art of engraving by the action of light, which was patented by Mr Fox Talbot on the 21st April 1858. A plate of steel, copper, or zinc is covered with a thin film of the following solution:—

Gelatine .... ¼ oz.	Saturated solution of bichromate of potash in water, 1 oz.
Water ..... 8 or 10 oz.	

The photograph or object to be engraved is then laid upon this film, and screwed down in a copying-frame. After exposure to light, solar or diffused, the plate is taken out, and a little finely-powdered gum copal carefully and evenly spread over its surface. The copal is then melted by holding the plate horizontally over a spirit lamp. Muriatic acid saturated with peroxide of iron, forming perchloride of iron, is the etching liquid employed, and is put up in three bottles:—

No. 1 is a saturated solution of the perchloride in water.
No. 2 consists of 5 or 6 parts of No. 1 in water.
No. 3 consists of equal parts of water and No. 1.

A little of No. 2 is first poured on the plate, and spread with a brush. The liquid will penetrate the gelatine wherever the light has not acted upon it, but cannot penetrate the parts upon which the light has acted, and "it is upon this remarkable fact that the art of photoglyphic engraving is mainly founded." Mr Talbot's specification, containing minute details of the process, has been printed in all the photographic journals.[3]

Mr C. J. Burnett proposed, in March 1858, another method of engraving on metals, which he calls *photo-metallography*, and in which galvanism regulates the etching, and prevents the gelatinous coating from being injured by removing the gas bubbles.[4] (D. B.)

PHOTOGRAPHY.

PHOTOGRAPHY, from φῶς, *light*, and γράφω, *I delineate* or *paint*, is the name given to the art of delineating or painting by light, whether solar, sidereal, or artificial, or by invisible rays which accompany those different varieties of light.

This art is one of modern invention, which, though some steps to it were taken by preceding writers, we owe to M. Nicephorus Niepce, Mr Fox Talbot, and M. Daguerre. So early as June 1802, Mr Thomas Wedgwood published in the *Journal* of the Royal Institution *An Account of a Method of Copying Paintings upon Glass, and of making Profiles by the agency of Light upon Nitrate of Silver*, with observations by Sir Humphry Davy.[5] "When white paper or white leather," says Mr Wedgwood, "covered with a solution of nitrate of silver (*one* part of nitrate to *ten* of water) is placed behind a painting on glass exposed to the solar light, the rays transmitted through the differently-painted surface produce distinct tints of brown and black, sensibly differing in intensity according to the shades of the picture, and where the light is unaltered, the colour of the light becomes deepest." Mr Wedgwood applied this method to take profiles or shadows of figures, by throwing the shadows on the prepared paper, the part concealed by the shadow remaining white. He employed it also in delineating the woody fibres of leaves, the wings of insects, and also to the copying of prints; but though he obtained pretty accurate representations of all objects that were partly opaque and partly transparent, yet he failed in the copying of prints. To copy the images of the camera obscura was the first object of Mr Wedgwood, but "the images were found to be too faint to produce in any moderate time an effect upon the nitrate of silver. He succeeded, however, in copying, without difficulty, the images of small objects produced by the solar microscope. Mr Wedgwood found that the muriate of silver was more sensible to light than the nitrate, and that both were more readily acted upon when moist than when dry.

Mr Wedgwood tried in vain to fix the copies which he obtained; that is, to prevent the uncoloured portion of the picture from being darkened by light. He was therefore obliged to keep his photographs "in an obscure place," and to examine them only in the shade for a few minutes, or by the candle or lamp light. The process of Mr Wedgwood seems to have excited very little notice. So long ago as 1803 Sir David Brewster called the attention of the public

to it in a Scotch journal, but no person seems to have improved or even repeated the process during the next thirty years. Some time previous to 1834, Mr Henry Fox Talbot, without any knowledge of what had been done by Mr Wedgwood, had been led to the same process; and in the spring of that year he had actually taken pictures in the camera by the agency of light upon paper washed with nitrate of silver, and had succeeded in fixing them. To this new art he gave the name of *Calotype*, from καλός, *beautiful*, and τύπος, *an impression*.

At an earlier period another branch of photography had taken its rise in France. So early as 1814, M. Nicephorus Niepce had attempted to fix the pictures produced in the camera obscura, and to copy engravings by means of light transmitted through them upon substances made sensible to its action. The substance used by M. Niepce was a tablet of copper coated with highly-polished plate silver; and he gave to his process the name of *heliography*, from ἥλιος, *the sun*, and γράφω, *I delineate*. In the year 1824, M. Daguerre had made experiments with the view of fixing the pictures in the camera, but he seems at that time to have obtained no definite results. M. Niepce, however, foreseeing the value of his art, went to London in December 1827, and submitted to the Royal Society an account of his heliographic experiments, and several plates, which proved that he possessed a method of taking pictures on metal (covered with a film of asphaltum or Jew's pitch) by the solar rays, and preventing them from being subsequently obliterated by the action of light. The society seems to have taken no notice of this interesting communication; and, thus discouraged, M. Niepce seems to have abandoned his researches, and to have given his heliographs to some of the members of the society who had seen their value.

Having heard of each other's labours, MM. Niepce and Daguerre entered into a copartnery in December 1829, in order to pursue for their mutual benefit the study of heliography. The processes of the two artists were essentially different. M. Niepce used as the groundwork of his picture a thin film of a solution of asphaltum, dissolved in essential oil of lavender, and spread over the clean surface of a plate of silvered copper. After the plate was exposed in the camera for about five hours, the picture was developed by covering it with a mixture of *one* part of essential oil of lavender with *ten* parts of oil of white petroleum. The parts of the picture upon which the light fell being more soluble in proportion to its intensity, a positive heliograph was obtained. In order to produce a better effect, M. Niepce darkened the silver surface with a film of iodine, which no doubt suggested to Daguerre the use of that material.

Into this process M. Daguerre introduced considerable improvements; and in the course of his investigations he discovered an entirely new photographic process, in the success of which M. Niepce did not live to share. He died in July 1833; and soon afterwards a copartnery was formed between his son, M. Isidore Niepce, and M. Daguerre, in which it was admitted that the process discovered by the latter was essentially a new one, and should be called the *daguerreotype*, after its inventor.

In order to reward the eminent inventors of heliography, M. Arago, who had been previously entrusted with the secret of the daguerreotype process, induced the French government to give Daguerre an annual pension of 6000 francs (L.250), and to Niepce a pension of 4000 francs (L.166); and a bill for this purpose was unanimously passed by both chambers, and signed by the king on the 15th June 1839. In proposing this measure to the Chamber of Deputies, M. Arago stated that "*France had adopted the discovery, and that from the first moment she had cherished a pride in liberally bestowing it* A GIFT TO THE WHOLE WORLD." Notwithstanding this declaration, M. Daguerre risked his public character in selling his invention to Mr Miles Berry, to whom the officers of the crown in England granted a patent in the face of a remonstrance by a few individuals who had the manliness to oppose it. England was thus restrained for eight years from the use of this important process; but the specification was afterwards found defective, and the patent invalidated. It is a curious fact, that Mr Talbot's patent for the sister art of the talbotype was also invalidated by an English jury; and it will never be forgotten in the history of art, that the rights of property over the two noblest inventions of the age, which the patent laws were enacted to secure, were wrested from their owners by the unjust decisions of an English jury, prompted by the selfish interests of individuals who had been fattening on the genius of the inventors.[1]

While these two ingenious Frenchmen were occupied with heliography, Mr Henry Fox Talbot was, as we have already stated, occupied with the same subject. On the 30th January 1839, six months before M. Daguerre gave his process to the world, Mr Talbot communicated his discovery to the Royal Society; and in the following February he published his process of *photogenic drawing*, to which he afterwards gave the name of *calotype*, which his friends changed to *talbotype*, in imitation of the example set by those of Daguerre. In this process he made paper sensible to light by nitrate of silver, and fixed the image by common salt.

About the same time (in April 1839) the Rev. J. B. Reade was led by Mr Talbot's paper to delineate objects of natural history by the agency of light, from their images taken by the solar microscope. He washed writing-paper with a strong solution of nitrate of silver, and immediately before using it he washed it with an *infusion of nut-galls, and while it was wet* he received upon it the microscopic images. These pictures were fixed by *hyposulphite of soda*.

On the 29th May 1839, our countryman Mr Mungo Ponton announced to the Royal Scottish Society of Arts, that paper soaked in a saturated solution of bichromate of potash became of a deep orange tint when exposed to the sun; so that in copying upon it dried plants or engravings a negative picture of them was produced. These negatives are dark orange on a yellow ground, and may be fixed by immersion in water, which readily dissolves the portion of the salt not acted upon by the light. This important discovery led M. E. Becquerel to his photographic paper with iodide of starch, Mr Hunt to his chromatype, Mr Sella of Piedmont and Mr Pouncey to their processes, and Mr Macraw of Edinburgh to one of great value. The photographic property of this salt is also the foundation of Mr Paul Pretsch's photo-galvanography, of Mr Talbot's photoglyptic process, and of some attempts at photo-lithography.

Notwithstanding the beauty of some of the pictures obtained by Mr Talbot with the process which he had published, the art was but in its infancy. The discovery of a more sensitive process was necessary; and after much experimental research, he was led to the valuable photographic method which he secured by a patent, sealed on the 8th February 1841. Mr Talbot subsequently took out a patent for an instantaneous process, a patent for photographic engraving, and, more recently, another for what he calls the *polygliptic* process, which promises to be of great value.

The talbotype process, after it became accessible to the public, underwent numerous improvements by Herschel,

[1] We of course suppose that Daguerre's invention had been justly secured by patent in England before he had been rewarded by the French government.

Photography.

Cundell, Bingham, Channing, Le Gray, Martin, Muller, Stewart. Hunt, Fyfe, Furlong, Blanquart, Everard, Collen, Ryan, Woods, Horne, Sagnez, Flacheron, and others; but the most important improvements were made by M. Victor Niepce and Mr Scott Archer, who introduced into photography, the one the use of albumen, and the other that of collodion, as substitutes for paper. A brief account of the most important of the photographic processes will exhaust the space allotted to us for this article.

Art. I.—*Account of the Daguerreotype Process.*

A plate of copper is coated with silver, and polished in the highest degree by means of animal charcoal and spirits of wine, or tripoli and essential oil of lavender. It is then rendered sensitive to light by the vapours of iodine or bromine, either separately or combined in various proportions, after it has been coated with the vapour of iodine. This is done in a box, the bottom of which is strewed with iodine, covered with a little sand or a card; and the plate is held above it till it has a fine *straw-yellow* colour. In order to accelerate the action of light upon this film, the plate is exposed to the vapour of bromine water till it attains a rose colour.

When the plate, thus prepared, has been placed in the camera, and received an impression from the figure or landscape to be photographed, it is put into a dark box, containing mercury, having in it a little pane of yellow glass, through which the surface of the plate can be seen. By the application of heat, the mercury rises in vapour, adhering to the lights of the picture in proportion to their intensity, so that the shadows are represented by the polished surface of the silver. When the picture, as seen through the yellow pane, is completely developed, it is fixed by immersing it in a solution of hyposulphite of soda; and when this salt has been completely removed by water, a solution of a salt of gold (the double hyposulphite of soda and gold introduced by Fizeau) is poured upon the picture, so as to cover it, and the gold is then burnt in by the heat of a strong spirit lamp. The picture is thus brought out with singular brilliancy. The plate is then washed and dried, and is ready to be put into its case or frame. When the surface of the silvered plate reflects white light, the shadows become white, and the lights dark, thus forming a *negative* picture; so that, in order to see a daguerreotype picture in perfection, the polished surface should reflect to the eye of the observer the darkest objects.

Great improvements in the practice of the daguerreotype have been made by Daguerre himself,[1] Mr Claudet, Mr Hunt,[2] Fizeau, Goddard, Bingham, Guerin, Seguier, and others.

The theory of the daguerreotype is still in its infancy. Much light has been thrown upon it by Mr Claudet,[3] Edmund Becquerel, Hunt, and Shaw.[4]

Art. II.—*Account of the Talbotype Process.*

In Mr Talbot's first process of 1839, a sheet of smooth and good writing-paper was dipped in a weak solution of common salt, and after being wiped dry, one of its surfaces was brushed over with a solution of nitrate of silver; namely, a saturated solution diluted with six or eight times its volume of water. When the leaves of flowers or engravings are laid upon the nitrated surface of this paper after it is dried, covered with a glass plate, and exposed to the sun, very perfect images of these objects will be obtained in a short time. As the light blackens the parts of the paper exposed to it, the pictures are delineated in *white* in place of *black* lines, or are *negative* pictures. For the same reason, the images of persons or of landscapes formed by the camera obscura upon nitrated paper will be negatively delineated. In order to *fix* these pictures, Mr Talbot at first washed them in a highly-diluted aqueous solution of iodide of potassium; but he afterwards used in preference a strong solution of common salt. When the negatives thus obtained were placed upon another sheet of paper prepared as before, a positive copy was produced, in which "the lights and shadows were brought back to their original disposition."

Mr Talbot's second and more perfect process, to which we have already referred as the one patented in 1841, is as follows:—Wash one side of the paper with a solution composed of 100 gr. of *nitrate of silver* in 6 oz. of distilled water, by means of a soft camel-hair brush. When dry, immerse it in a solution of *iodide of potassium*, consisting of 50 gr. in a pint of distilled water. The paper is then to be dipped in water, and dried, either by heat, blotting-paper, or spontaneously.

When a sheet of this paper is to be made sensitive for use, wash it with the following solution, which may be called No. 1:—Dissolve 100 gr. of nitrate of silver in 2 oz. of distilled water, and add one-third of its volume of strong *acetic acid*. Make another solution (No. 2), by dissolving crystallized *gallic acid* in cold distilled water, and mix the two solutions together in equal proportions when they are required for use. This mixture—*gallo-nitrate of silver*—is then spread by a brush on the nitrated side of the iodized paper, which, when it has absorbed the solution, should be dipped in distilled water and then dried, first with blotting-paper, and afterwards by heat. In this state it is ready for use, and should be used within a few hours.

After the paper has received the impression of a figure or landscape in the camera, it is taken to a dark room, and may appear either with or without the trace of a picture. In either case the picture, which is a *negative*, is developed by brushing it over with the *gallo-nitrate of silver*. When it is sufficiently distinct, it must be dipped in water, then partly dried by blotting-paper and afterwards fixed by washing it with a solution of *bromide of potassium* (or a strong solution of *common salt*), consisting of 100 gr. of the salt dissolved in 8 or 10 oz. of water.

From this *negative*, positive pictures are obtained by the processes described in art. xvi.

Art. III.—*Account of the Albumen Process.*

The great defect of the talbotype was in the use of paper as the material. M. Niepce de St Victor, in 1848, substituted for it a film of *albumen* spread upon glass. The following is the process by which Messrs Ross and Thomson have produced their splendid photographs[5] (15½ inches by 15½), which have excited so much interest. The whites of several eggs, having 18 drops of a saturated solution of iodide of potassium added for each egg, are beaten up into a large mass of froth, and allowed to stand for ten or twelve hours till the whole falls into a liquid. It is then poured plentifully over a plate of glass (which, by means of a bent wire and a piece of worsted thread, is made to revolve at a moderate rate before a clear fire), till, by the influence of the centrifugal force, a very perfect film of albumen is spread over the glass. When the albumen begins to crack at the edges, the plate is withdrawn from the fire, and appears covered with minute cracks over the whole of its surface. It is now dipped in a solution of nitrate of silver (70 grains to an ounce of water), having in it a twentieth part in quantity of strong acetic acid. When taken out, it is washed once or twice with water, and before it is dry, the picture may be taken on it. If the object is a light one, four minutes will be sufficient to impress the image; but anything red or green will take longer time. The picture is developed by pouring on the albumen a saturated solution of gallic acid, and spreading it with a piece of cotton wool. The negative will then appear slowly and gradually of a reddish colour, and when brought out as far as it will come, a little of the nitrate of silver solution, mixed with gallic acid, is spread over it with a piece of clean cotton wool. It now becomes darker and more distinct, and when fixed with hyposulphite of soda, and washed with clean water, positive pictures may be taken from it in the usual manner.

The albumen process is not suited for portraits, on account of the time required to take the picture, but its sensibility may be increased by the addition of grape-sugar or honey. M. Niepce, in place of albumen, has proposed to employ 70 grains of starch rubbed down in 70 grains of water, and then mixed with 3 or 4 oz. more of water. After adding 5½ grains of iodide of potassium, the whole is boiled till the starch is dissolved. When laid upon glass, it is said to give films of great sensibility.

For architectural subjects, and for still life, the albumen process comes nearest to the daguerreotype in delicacy.

Albumen positives upon glass.

We are not aware that this art has been to any extent practised either in this country or abroad. The following new process has been just published by R. M. Grier:—"A plate coated with asphalt varnish, known in Prussia by the name of *eisenlack*, diluted with rectified benzole or benzine (first product obtained by distillation of coal tar at a low heat), and when barely dry, and still slightly sticky, was placed in contact in the pressure-frame with a negative on albumen, and exposed to the direct rays of the sun for half an hour. On removal from the pressure-frame, the plate was breathed on over its whole surface, until the image became distinctly visible, the parts changed by the action of light absorbing moisture, and those covered by the blacks of the negative remaining unchanged, and repelling it. In this state, the image being distinctly visible

Photography.

it was quickly covered by the bronze powder known as *aurum musivum*, which at once changed the almost invisible image to a direct positive on black and gold, the gold adhering to the parts that had been protected from the light, and not adhering to those where the actinic rays had effected such a change in the molecular structure of the film as rendered them capable of absorbing moisture, thus producing a complete picture detailed in all its parts," which the editor of the *Photographic Journal* pronounces to be "a great novelty, and well worthy of attentive inspection."

The *eisenlack* used by Mr Grier is made as follows:—"To 176 lb. of asphalt, melted over a charcoal fire in a pear-shaped iron vessel, is added 279 lb. of oil of turpentine, and 16 lb. of well-boiled linseed oil well heated, the asphalt having been allowed to cool down as far as possible without becoming solid. The whole is then incorporated and heated until perfectly liquid." It resembles treacle when cold, and when diluted with benzine, and made to flow over the plate, it gives a film of a dark amber colour as really transmitted.[1]

ART. IV.—*Account of the Wet Collodion Process.*

The use of collodion, first suggested by M. Le Grey, was introduced by Mr Archer in 1850. It is the most valuable, the easiest, and the most sensitive of all the photographic processes, the daguerreotype and the albumen process being the most difficult. The number of first-class daguerreotypists has been very small, and we believe the albumen process has been practised professionally by no British photographers but Messrs Ross and Thomson; while the collodion process is universally employed.

Collodion process for negatives.

Collodion is a fluid like sherry, and is made by dissolving 15 grs. of gun-cotton in a mixture of *nine* fluid ounces of rectified sulphuric ether, and *one* ounce of alcohol, 60° overproof. The gun-cotton is made by mixing 70 gr. of fine selected cotton with water, nitre, and sulphuric acid, in the proportions of 3, 4, and 5 oz. When the cotton has been stirred and washed in this bath with two glass rods, it is taken out, and when freed from every trace of acid by copious washing in boiling water, it is hung up to dry. After the cotton, thus prepared, is put into the mixture of ether and alcohol above mentioned, it will be almost wholly dissolved, with the exception of some fibres which fall to the bottom. To the collodion thus made add 5 gr. of iodide of potassium, or iodide of ammonia, dissolved in the smallest quantity of alcohol, and also about 3 oz. of sulphuric ether, to make it run freely over the plate of glass. The sensibility of the collodion may be increased by dissolving a few grains of iodide of silver in the iodide of potassium, the superfluous iodide being allowed to settle before using it.

Six operations are necessary for obtaining a negative picture:—

1. The plate of glass (patent plate is the best) must be freed from stains, grease, &c., by a mixture of 2 dr. of cyanide of potassium, 2 dr. of tripoli, and 2 oz. of water, the tripoli being added to the solution of the other two. Cloths free from soap or grease must be used with the mixture, and when the plate is perfectly clean, particles of dust must be removed by a piece of chamois leather.

2. In order to coat the plate, it is held horizontally in the left hand by a corner, while the right hand pours upon its centre a pool of collodion sufficient to cover the whole surface. The plate is then inclined, to make the fluid run to one of the nearest corners, and then to the other two, the superfluous collodion being drained off into a bottle by the last corner which it reached. When a solid film has been left on the plate by the evaporation of the ether, it is ready to be excited, or made sensitive.

3. The exciting fluid recommended by Mr Thornthwaite is composed of

Nitrate of silver, fused..... 6 dr.	Alcohol.........................12 oz.
Iodide of potassium .... 3 gr.	Distilled water .... 2 dr.

Dissolve the *six* drams of the nitrate in $1\frac{1}{2}$ oz. of the distilled water, and the 3 grains of the iodide in 1 dram of distilled water; mix the two solutions, and shake them well together until the precipitate which is first thrown down is re-dissolved. When this takes place, add the remaining $10\frac{1}{2}$ ounces of the distilled water, and the 2 drams of alcohol." This solution is poured into a *dipping-bath*, and the coated plate is immersed "steadily and unhesitatingly" into the fluid, and kept there from *two* to *four* minutes,—for two minutes when the temperature is 60°, and longer at lower temperatures, but always rather longer than shorter. After it has been immersed half a minute, the plate should be lifted out of the liquid two or three times, and as often replaced, to get rid of the ether on its surface. These operations are performed in a room lighted only through an orange or red pane of glass.

4. When the plate has been lifted out of the solution, and the liquid drained off into the bath, it must be placed wet in the camera, and kept there for a sufficient number of seconds, which experience only can determine, depending on the intensity and character of the light, and on the sensitiveness of the film, which is so great that in fine weather, and in a well-lighted studio, the picture can be taken *instantaneously*.

5. The best developing solution, according to Mr Thornthwaite, is obtained by mixing and filtering the following materials:—

Pyrogallic acid. ... . 5 gr.	Glacial acetic acid .... 1 dr.
Distilled water .... 5 oz.	Alcohol .... $\frac{1}{2}$ dr.

Having added to a sufficient portion of the above mixture ($\frac{1}{2}$ oz for a plate 5 inches by 4) 12 drops of a solution of nitrate of silver, consisting of 50 gr. in an oz of water, pour it quickly over the surface of the plate till the picture is completely developed. When this is done the solution must be poured off, and the surface, when held horizontally, washed by pouring water over it.

6. In order to fix the image, which is done by removing the yellow iodide of silver, pour over the surface a solution of *hyposulphite of soda* of the strength of 4 oz. in a pint of water. Every trace of the hyposulphite must then be washed away by pouring water copiously over the picture. The plate must now be varnished, either by spirit varnish or by Dr Dymond's varnish, consisting of amber dissolved in chloroform.

With the negative picture thus prepared positives may be obtained, as shown in art XVI.

This process is, we think, the most important in photography. When collodion was first introduced, it was shown by Mr Horne that the *negative* pictures could be converted into *positive* ones by mixing a small quantity of nitric acid with the pyrogallic, and Mr Fry subsequently proved that a better effect would be obtained with the protosulphite or protonitrate of iron When

Collodion process for positives on glass.

Protosulphate of iron . ...10 gr.	Distilled water . ... 1 oz.
Nitric acid ... . 2 dr.	

are mixed, pour it over the plate to develop the picture. When one part of the protonitrate, with three of water, is used instead of the protosulphate, a fine clear picture is produced.

When the negative picture has been developed by either of the above solutions, a mixture of pyrogallic acid and hyposulphite of soda is immediately poured over, and when it has been slightly warmed, the darkened parts will become of a bright white by the formation of metallic silver. The picture must then be placed upon black velvet.

Mr Hennah, in producing positives, uses a thinner collodion than usual, excites with the ordinary bath, and exposes the plate not more than half the time necessary for a negative. The picture is brought out by immersing it in a bath containing

Protosulphate of iron ...40 gr.	Acetic acid............ ....30 gr.
Nitric acid .... 2 drops	Alcohol .. .. 1 oz.
Distilled water .... 1 oz.	

The pictures are then fixed, as is usual, with hyposulphite of soda.

Mr Archer has obtained delicate white pictures by treating the negative picture, when fixed and thoroughly washed, in the following manner;—Take a saturated solution of the bichloride of mercury, and after diluting one part of it with six of water, pour a small quantity over the picture at one corner, so as to make it flow uniformly over the surface. The tone of the picture will be immediately deepened, and though the positive image has nearly disappeared, yet a peculiar whiteness will immediately supervene, and a fine, delicate, white, positive picture will emerge, its negative character being wholly destroyed. It is singular, however, that this picture can be changed to a deep-toned black negative, very much darker than the original one, "by immersing it after a thorough washing in a weak solution of hyposulphite of soda, or of ammonia." "It is very singular," as Mr Hunt remarks, "that the picture can be alternately changed from a *white positive* to a *black negative* many times in succession, and very often with improvement."

A new method of taking collodion pictures on glass, by Mr William Ackland, is well worthy of the attention of photographers.[2] He iodizes his collodion with the following mixture:—

Iodide of potassium	12 gr.
Solution of iodine, (4 gr. in 1 oz. of alcohol)	4 drops.
Alcohol	1 oz.

and it must be mixed with the collodion at least 12 hours before it is used, in order to allow any sediment to subside. He develops the latent picture with

Protosulphate of iron ... .2 dr.	Glacial acetic acid .... 2 dr.
Nitrate of barytes...........$1\frac{1}{2}$ dr.	Alcohol .... 3 dr.
Rain or distilled water ....10 oz.	

[1] See *Journal of the Photographic Society*, Nov. 22, 1858, p. 87.

[2] This method is elaborately explained, and occupies *thirteen* closely-printed pages in Mr Thornthwaite's *Guide to Photography*, 14th edit., 1857.

Photography.

And he fixes with one scruple of cyanide of potassium (a poison), dissolved in 8 oz. of rain or filtered water.[1]

When the picture has been fixed and dried it is varnished on the collodion side, and when this is dried it may be placed in a frame with a black velvet or cloth ground to form the positive shades. In place of using the black velvet back of the frame or case, it is usual to cover the *glass* side, not the *collodion* side, of the picture with a black varnish. In this case the sides of the portrait are reversed, anything on the right side appearing as it were on the left; so that the picture is not an accurate representation of the sitter. A soldier, for example, without his right arm, would appear to have lost his left arm; and a sitter blind on the left eye would appear blind on the right one. To avoid this, the black varnish may be applied on the collodion side after the application of the transparent varnish.

Transference of collodion positives to paper, &c.

The art of transferring collodion positives from the glass plate to glazed cloth or leather has been practised in Paris for a long time, and is now becoming more common in this country. As the pictures thus produced may be sent by post, and resist various kinds of injury, the art has become a very important one.

Sir W. Newton was the first who transferred collodion positives to paper. He passed over the collodion picture a varnish composed of 1 oz. of pure gum mastic dissolved in 8 fluid oz. of alcohol, and 2 drams of oil of poppies. A piece of thin paper, a little smaller than the glass, and saturated by a camel-hair pencil in the same varnish, is then placed in contact with the collodion film, so as to exclude air, and the whole is allowed to become dry by evaporation.

The following is the simplest method of transferring the picture to leather or cloth. Dry the glass plate, and having poured spirits of wine upon it, allow it to drop; then take the black leather or cloth (which may be glazed or not), and damp it uniformly with spirit of wine. Lay this on the picture, and pass the hand over it so as to expel air-bubbles, if there are any. Then turn over the plate, and observe if there are any air-bubbles beneath the collodion. Lay the plate on a flat surface with the glass side uppermost, and apply pressure with suitable weights for half an hour. After this operation the collodion picture will be easily detached from the glass plate. Mr Ostell of Carlisle adds 4 or 5 drops of nitric acid to half an ounce of spirit of wine, and he pours this over the positive collodion picture after it has been dried at the fire or otherwise. It is then laid on the leather or cloth, the air-bubbles expelled, and pressure applied for about half an hour, by placing the combined plate and leather in the printing-frame. By holding the glass side to the fire it will be seen when the glass is leaving the collodion film. Mr Ostell recommends a stronger film of collodion, having either more gun-cotton in it, or made stronger with a few drops of the nitrate bath. The picture may be transferred to paper by means of a varnish.

Mr Ross of New York pours upon the collodion, when it is still wet from the fixing, a solution of sulphuric acid diluted to three degrees, and leaves it for one or two minutes. The cloth is then heated till it is soft and pliable, and while there is still a thin stratum of humidity upon the collodion, the film is applied to the cloth, and any bubbles of air driven off by passing the finger lightly over it. It is useful to wet the cloth with a little alcohol before it is applied. One of the corners of the film is then raised to see if it adheres, and if it does not, a stream of water is passed between the glass and the film thus raised to produce their separation.

Mr Howell of Ashtabula, Ohio, prepares the glass plate by coating it with a thin film of wax. The picture is then taken in the ordinary way, and after it is fixed, washed, and dried, it is "covered by flowing" with a black varnish, made more adhesive by a little Canada balsam. When the varnish is nearly dry, the paper (previously cut to shape, and soaked in water) is laid on and pressed into close contact with the varnish by means of a small roller covered with a cushion of cloth.

Art. V.—*An Account of the Dry Collodion Process.*

Although the wet collodion process possesses a high degree of sensibility, yet it loses it upon the drying or consolidating of the film. This is a great disadvantage to the travelling photographer, or to any person who takes a picture at a distance from his studio; and in order to remedy the evil, he must either take a portable tent with him, admitting only yellow light, or employ one of those ingenious cameras which will enable him to excite the plate, and develop the picture in the interior of the instrument.

One of the earliest methods of preserving sensitive collodion plates was employed by Messrs Spiller and Crooks, who used nitrate of magnesia and nitrate of zinc, which, by their deliquescent properties, keep the plate of collodion slightly moist. When the plate of collodion has been excited in the nitrate bath for five minutes, it is then drained, and immersed in a bath consisting of—

Nitrate of magnesia......... 4 oz	Glacial acetic acid .... 1 dr.
Nitrate of silver...............12 gr.	Water ....12 oz.

where it is left five minutes, and then drained for about half an hour, by placing it upright upon blotting-paper. Plates thus prepared have been kept three weeks without deterioration. The picture is developed as in the wet process.[2]

Mr Shadbolt employs a syrup of 3 volumes of pure honey and 5 volumes of distilled water, stirred with a glass rod till the honey is dissolved. One volume of alcohol is added to it when it has been filtered (a work of some hours) through blotting-paper. A portion of this syrup is poured two or three times over the collodion when it has been excited in the usual way. Glycerine has been used in place of honey by Mr Llewellyn, Mr Pollock, and other photographers. Mr N. Maskelyne seems to have first discovered it.[3]

Barnes' *dry collodion* is thus composed:—

Plain collodion .... 4 oz.	Camphor.... .... 4 gr.
Solution of iodide of potassium...... .... 5 dr.	Etherial tincture of chloride of gold ....10 drops.
Pyro-acetic spirit, purified, 4 dr.	Tincture of iodine......... 2 dr.

To this mixture 1 oz. of old collodion and 4 oz. of new should be added, to give it firmness. Plates thus prepared have acted well at the end of six weeks.

The following process for dry collodion has been successfully used by M. Dupuis, officer of health to the French army of occupation at Rome:—The collodion is formed of

Ether, sp. gr. 60,...80 cubic centilitres.	Gun-cotton ......1 gramme.
Alcohol, do. 36,...40 do. do.	Iodide of zinc ...1 gramme.

The exciting bath consists of

Fused nitrate of silver. .10 gram.	Distilled water ....150 gram.

Acetic acid of commerce......15 gram.

The developing solution consists of

Pyrogallic acid........... 1 gram.	Distilled water ....300 gram.

Citric acid, crystallized.........1 gram.

Plates thus prepared by M. Dupuis at Rome on the 6th of May 1857 were brought to London by Sir David Brewster, and developed there on the 27th of June. Some had received the picture at Rome, and others were only prepared. After being kept fifty-one days, the plates gave very fine pictures.

The following dry collodion process, given by the Rev. J. Lawson Sisson, has been regarded by competent judges as both simple and certain:—Having placed four dishes in a row, pour distilled water into Nos. 1, 2, 3, sufficient to cover a plate. Into No. 4 pour a mixture of half an oz. of raspberry syrup and 3 oz. of distilled water. A plate of collodion, made sensitive in the ordinary way, is put, with the collodion side upwards, into No. 1. A second sensitive plate is prepared, and when ready, the plate is removed from No. 1 and placed in No. 2, and the second plate is placed in No. 1. A third sensitive plate being ready, plates 1 and 2 are moved on to the next dishes, and plate 3 placed in dish No. 1. In like manner, when a fourth plate is prepared, plate 1 is placed in the syrup dish No. 4; the others are moved onward, and plate 4 placed in dish No. 1. After preparing a fifth plate, plate 1 is lifted from the syrup dish, and is then placed upright upon blotting-paper to drain and dry. In this order the process is continued, the time required for coating and making sensitive a plate being exactly the time during which any plate should continue in one of the four dishes. Plates thus prepared are as sensitive and will keep as long as any of those prepared by the existing keeping processes.

One of the best dry processes is that of Dr Hill Norris, who roughens the edges of the glass to the extent of 1-12th of an inch and pours upon it collodion rather old, made with

Rectified ether .... 5 dr.	Soluble cotton .... 5 gr.
Absolute alcohol .... 5 dr.	Iodide of potassium .... 5 gr.

the iodide being dissolved in 5 drops of water, and added to the collodion. Immerse the plate in a 36-grain solution of nitrate of silver, perfectly saturated with nitrate of silver; and, when well washed and dried vertically, cover its surface with a solution of 9 grains of pure gelatine (Nelson's patent) in 1 oz. of water and ¼th oz. absolute alcohol. When dried quickly, the plate will keep sensitive for six weeks. Before developing, cover the plate for a minute or two with distilled water, and then develop it well with a saturated solution of gallic acid in water, to every ounce of which 10 minims of a 40-grain neutral solution of nitrate of silver has been added. The development usually occupies from two to four hours.[4]

[1] See *Phot. Jour.*, vol. v., p. 10, Aug. 21, 1858.

[2] See *Phil. Mag.*, May 1857; and *Phot. Jour.*, i., p. 223, and ii., p. 6.

[3] *Phot. Jour.*, vol. ii., p. 273. Mr Pollock adds 6 drops of glycerine to 1 oz. of collodion (ibid., p. 309).

[4] See *Phot. Jour.*, ii. 151, and iii. 84, 179.

M. Müller of Bolbec has given a dry collodion process in which he forms *two* solutions,—the *first* of albumen in distilled water, with 10 to 12 drops of *creosote:* the *second*, of honey, 250 grammes, animal charcoal, 5, and water, 100. These two solutions are mixed, every 20 of the first with ten of the second, and applied to the collodion film when excited. Plates thus prepared retain their sensibility more than a month.[1]

Art. VI.—*Account of the Oxymel Process.*

The oxymel process, as first proposed by Mr Llewellyn, has been published in many of our treatises on photography, and has undergone various modifications by himself and others[2] After much experience of the process, Mr Llewellyn has, so recently as August 1858, published the following as his process:—An excited collodion plate, washed in two or three waters, is plunged for a few seconds into a bath containing

Bromide of potassium ...... 5 gr.	Alcohol .... $\frac{1}{4}$ dr.
Water .... 1 oz.	

When all traces of the free bromide have been washed away for about five minutes in several waters, the plate is excited, and the film preserved by the following solution:—

Ordinary oxymel[3]. .... $\frac{1}{2}$ dr.	Citric acid .. .. $\frac{1}{2}$ gr.
Water .... 1 oz.	Nitrate of silver .... $\frac{3}{4}$ gr.

which is poured on and off the film two or three times, after which the plate is placed vertically to drain and dry. One ounce will be sufficient for many plates, 10 × 12. It must be kept from white light. It will keep for a day or more. Before developing, the film should be moistened with water, and the ordinary pyrogallic solution, with a few drops of an 8-grain solution of nitrate of silver, used to develop the picture.

Art. VII.—*Account of the Collodio-Albumen Process.*

This process, invented by M. Taupenot, consists in first collodionizing the plate, dipping it in the silver bath, washing it with distilled water, and pouring over it albumen iodized in the proportion of $1\frac{1}{2}$ per cent. The plate is then placed upright to drain and dry. The plate is excited during ten or twenty seconds in the aceto-nitrate bath, containing 10 parts of nitrate of silver, 10 of acetic acid, and 100 of distilled water. The albumen used by Taupenot consists of

Honey .... 10 parts.	Iodide of potassium...... $1\frac{1}{2}$ part.
Albumen............ ....100 parts	Yeast . .. . a little.

After fermentation, the liquid is filtered, and stored in bottles containing only from three to six fluid ounces.

The defect of this process is the production of blisters in the film at the time of exciting. M. Julien Blot prevents the blistering by the use of dextrine, which "permits the baking of the albumen without altering at all its iconographic properties, and gives the possibility of restoring the albumen film, if cracked by the heat, to its normal condition, by cooling, or by breathing over it." The plate will remain sensitive for eight days in winter.

For an elaborate account of Taupenot's process, we must refer the reader to the *Photographic Journal*, vol. iii., p. 102, which contains an able article by a French photographer. This article is followed by a long and valuable paper on the same process by Mr William Ackland.[4] A variation of this process by Mr Fothergill, in which no honey is used, will be found in the *Photographic Journal* for September 1858.[5]

Art. VIII.—*Account of the Wax-Paper Process.*

This process, which has been used with great success by M. Le Gray and Mr Roger Fenton, is one of considerable interest. The best paper is that made by M. Lacroix of Angouleme, or the Messrs Canson Brothers of Annonay. It is laid on a metallic plate, which is rubbed over while hot with a cake of pure white wax, and when it has absorbed the wax uniformly, it is placed between some sheets of smooth bibulous paper, and smoothed with a moderately hot iron till it becomes equally transparent throughout. It is then iodized by immersing it for ten minutes in a bath thus composed:—

Iodide of potassium .... 4 dr.	Honey .... 1 oz.
Bromide of potassium ...... $\frac{1}{2}$ dr.	Distilled water .... 1 pint.
Iodine..................... ...... 4 gr.	

After being drained and dried, it is excited by the following aceto-nitrate:—

Nitrate of silver.. .. .. 3 dr.	Animal charcoal . ... . 2 scr.
Glacial acetic acid.. ... ... 3 dr.	Distilled water . . . 8 oz.

After exposure in the camera for eight minutes, when the lens is 14 inches in focal length, and the stop half an inch, the picture is developed by immersion in a saturated solution of gallic acid in 20 oz. of distilled water, and when well washed, it is fixed by the usual hyposulphite. The transparency, if diminished, may be restored by holding it before a moderate fire.[6]

Mr Hunt[7] gives the following formula from Le Grey for iodizing the paper:—Into $5\frac{1}{4}$ pints of distilled water put 4000 grains of rice; steep them till the grains are slightly broken, so that the water may contain only the glutinous portion. In a little less than a quart of the rice solution dissolve

Sugar of milk . ...620 gr.	Cyanide of potassium.... . 12 gr.
Iodide of potassium... .... 225 gr.	Fluoride of potassium...... 7 gr.

The wax paper is dipped in this solution, and drained and dried. It is excited by $77\frac{1}{2}$ (and for portraits by 150) grains of nitrate of silver dissolved in 2325 grains of distilled water, to which is added 186 grains of acetic acid. The picture is developed in a bath of 60 grains of gallic and 40 fluid oz. of distilled water, to which 15 or 20 drops of aceto-nitrate of silver is added. It may remain in it from ten minutes to two hours.

Dr Keith of Edinburgh iodizes with the following solution:—

Pure water .... 4 oz.	Sugar of milk . ...3 oz.
Iodide of potassium.........750 gr.	Common salt .... 30 gr.
Bromide of ditto ....250 gr.	Iodine .... 8 gr.

in which the thin paper (Canson Brothers' or Turner's for negatives) must be soaked for ten hours, and then hung up to dry. The paper is rendered sensitive by immersion for ten or twelve minutes in a bath containing the following solution—

Nitrate of silver ....360 gr.	Glacial acetic acid ...... 13 dr.
Water .... 12 oz	or citric acid . . 20 to 30 gr.

The strength of this bath must be kept up by adding two or three grains of the nitrate for every sheet rendered sensitive. When the sheet is well washed in a large basin of water, and the superfluous moisture blotted off, it is ready for use when required.

To develop the picture, place the sheet in a saturated solution of gallic acid, having one grain of pyrogallic acid added to 4 oz. of the solution. After it has remained four or five minutes, add 12 drops of the aceto-nitrate, agitating the bath to mix it. The development will require from twenty minutes to several hours. When well washed in several waters, the picture is then fixed by the hyposulphite of soda.

Art. IX.—*Account of the Metagelatine Process*[8]

M. Le Gray and other French photographers employed gelatine or isinglass in the calotype process on paper; but it is to Mr Maxwell Lyte that we are indebted for its application to collodion for a preservative process. It is a well-known property of gelatine that, after it has been dissolved in hot water, allowed to gelatinize, melted and again cooled, and this process repeated many times in succession, the jelly gradually loses its tenacity and continues liquid even while cool. In this altered condition Mr Maxwell Lyte gives it the name of *Metagelatine*, and has found it superior to all other substances as a varnish for preserving the collodion film in a dry state. In order to prepare it, "take $1\frac{1}{2}$ oz. of fine white gelatine, and dissolve it in 10 fluid oz. of boiling distilled water; then add 2 fluid drs. of strong sulphuric acid which has been previously diluted with $2\frac{1}{2}$ fluid oz. of distilled water, and boil these together gently for a quarter of an hour Take the vessel off the fire, and let it stand for twenty-four hours; then boil gently again for another fifteen minutes, and again remove it from the fire, and let it cool for an hour or two. Heat up the liquid once more to a boiling heat, and saturate the acid by adding powdered whiting till effervescence ceases. Separate the sulphate of lime which is thus formed by pressure in a linen cloth, and then stir into the liquid about a tea-spoonful of animal black, and filter once more through paper till perfectly clear. Add water to bring up the liquid to the bulk of 18 fluid oz., and then add two drops of creosote to prevent the liquid from becoming mouldy."

In order to prepare the preservative syrup, Mr Lyte takes

Solution of gelatine.. ....5 oz.	Fine honey .... $\frac{1}{2}$ oz.
Distilled water..................5 oz.	

When the collodion plate is withdrawn from the nitrate bath, it must be held for an instant with its corner resting on blotting-paper. The syrup is then to be poured upon it like the collodion,

[8] See *Phot. Jour.*, vol. iii., pp. 223, 253, 287.

and run off at a corner. Fresh portions of syrup must then be poured on and off several times, till it takes evenly over the whole surface. When it is to be used in the camera it should be dipped in cold distilled water, and then excited, developed, and fixed in the usual manner.

ART. X.—*Account of the Bichromate Process—Chromatype, &c.*

We have already referred to the valuable photographic properties of bichromate of potash, discovered by Mr Mungo Ponton, and to the experiments of Becquerel and Mr Hunt to which it led.

The chromatype of Mr Hunt is founded on Mr Ponton's process, which we have already described. A solution of 1 dr. of sulphate of copper in 1 oz of distilled water, with ½ oz. of a saturated solution of bichromate of potash, is applied to the surface of good paper, which, when dried, is fit for use. It is changed to a dull brown by the action of light, and gives a negative picture if checked at this stage; but if the action of light is prolonged, the dull brown disappears, and we have a positive yellow picture on a white ground. "In either case," says Mr Hunt, "if the paper is removed from the sunshine, and washed over with a solution of nitrate of silver, *a very beautiful positive picture* results." In order to fix these pictures, the nitrate of silver must be removed by washing in *pure* water.

According to Mr Bingham, the paper is more sensitive by using sulphate of nickel in place of sulphate of copper. Another bichromate process, and a very valuable one, has been proposed by M. Joseph Sella of Biella in Piedmont, "following," as he himself observes, "the suggestions of Mr Ponton."

1. The paper, when immersed in a saturated aqueous solution of bichromate of potash, is dried in the dark between sheets of bibulous paper.

2. It is exposed in the camera about two-thirds of the usual time, and then immersed for half an hour in water, which must be changed three or four times.

3. It is then immersed for three or four minutes in a filtered solution of proto-sulphate of iron containing 5 gr. of the salt to 100 gr. of water. It is then washed in several waters, and soaked for half an hour.

4. The picture is then immersed in a solution of gallic or pyrogallic acid more or less concentrated, and in a few minutes the image will be developed, having a beautiful black tint bordering on violet, and one highly appreciated by artists.

If, instead of pyrogallic acid, we use the yellow prussiate of potash, the picture will be in Prussian *blue*; with acids, it will become *green*; and with alkaline solution it will become deeper, and border on violet. The process may be applied to albumen, gelatine, &c. Its advantages are, "economy of time and silver, ease of execution, certainty of result, and permanence of the picture."[1]

The following bichromatic process, by Mr William Macraw of Edinburgh, being an improvement on that of Sella, was communicated by Sir David Brewster to the British Association at Leeds in September 1858, and promises to be of great value, both from the extraordinary cheapness of the materials, and the permanence of the pictures which it gives. In proof of its excellence, we have now before us two beautiful photographs, one of a female figure, and the other of Sir Walter Scott's monument, which were shown to the meeting.

First, To 25 per cent. of a saturated solution of common salt add the white of eggs, to be well beaten up and allowed to subside; float the paper on the albumen for thirty seconds, and hang up to dry. *Secondly,* Make a saturated solution of bichromate of potash, to which add 25 per cent. of Beaufoy's acetic acid. Float the ordinary albumenized paper on this solution for an instant, and when dry it is fit for use. This must be done in the dark room. *Thirdly,* Expose under a negative, in a pressure-frame, in the ordinary manner, until the picture is sufficiently printed in all its details,—but not over-printed, as is usual with the old process. This requires not more than *half* the ordinary time. *Fourthly,* Immerse the pictures in a vessel of water in the darkened room; the undecomposed bichromate and albumen then readily leaves the lights and half-tints of the picture. Change the water frequently, until it comes from the prints pure and clear. *Fifthly,* Immerse the picture now in a saturated solution of protosulphate of iron in cold water for five minutes, and again rinse well in water. *Sixthly,* Immerse the pictures again in a saturated solution of gallic acid in cold water, and the colour will immediately begin to change to a fine purple black. Allow the pictures to remain in this until the deep shadows show no appearance of the yellow bichromate; repeat the rinsing. *Seventhly,* Immerse, finally, in the following mixture:—Pyrogallic acid, 2 gr.; water, 1 oz.; Beaufoy's acetic acid, 1 oz.; saturated solution of acetate of lead, 2 dr. This mixture brightens up the pictures marvellously, restoring the lights that may have been partially lost in the previous parts of the process, deepening the shadows, and bringing out the detail; rinse finally in water, and the pictures are complete when dried and mounted.

The advantages of this process may be briefly stated as follows:—*First,* As to its economy: bichromate of potash, at 2d. per oz., is substituted for nitrate of silver at 5s. per oz. *Secondly,* Photographs in this way can be produced with greater rapidity than by the old mode. *Thirdly,* The pictures being composed of the same materials which form the constituent parts of writing-ink, it may be fairly inferred that they will last as long as the paper upon which they are printed

The bichromate of potash is an essential element in the process of printing on carbon, invented by Mr Pouncey. Pictures thus printed have been submitted to the Paris committee, appointed by the Duke de Luynes to adjudge the prize which he has offered for the best process of producing permanent photographs;[2] and M. Gerard has found that the black material in them is truly carbon, and that they resist the prolonged action of concentrated nitrate and hydrochloric acids, aqua regia, cyanide of potassium, cyanide of potassium with iodine, and alkaline sulphides, none of which, though energetic agents, affected it in the least.

The following is Mr Pouncey's process, in so far as he has published it in his provisional specification of the 10th April 1858. He prepares the paper or other material which is to receive the picture by applying over its whole surface a composition of vegetable carbon, gum-arabic, and bichromate of potash. Upon this surface the negative is placed, and exposed to the light in the usual way. The positive thus produced is washed with water, which dissolves the composition at the parts on which the light has not acted, but does not affect the part on which the light has acted. Mr Pouncey sometimes substitutes for the vegetable carbon, bitumen or other colouring matter.

ART. XI.—*Account of Fothergill's Dry Collodion Process.*

This process has been much praised by practical photographers as simple in its application and perfect in its results. The object of the process is to protect the sensitive film from the action of the atmosphere by a varnish of albumen, which is done thus:—

Having coated the plate with collodion, place it in a bath of 35 gr. of nitrate of silver in an oz. of water, "saturated with iodide in the usual way;" and after it has been in half a minute, move it up and down, and when taken out pour lightly on it at one corner, *four drams only* for a stereoscopic size plate, of filtered water (a proportional quantity being used for larger plates), causing the water to flow freely all over the plate from 15 to 20 seconds, till all appearance of greasiness is removed. Having made a solution of albumen, consisting of 10 oz. of white of eggs, distilled water 6 oz, and strong liquor of ammonia 80 minims, agitated into a froth and strained for use, coat the collodion surface with this, letting it run several times from corner to corner, and having poured it off, place the plate in a dish of water, so as to cover it to the depth of 3-8ths of an inch. Wash it well with two waters, moving the dish backward and forward, so that the water may flow over the plate. When taken out, place it on end upon several thicknesses of blotting-paper, and put it in a dark place to dry. After exposure in the camera, moisten the picture with distilled water, and develop with

Pyrogallic acid	1 gr.	Alcohol	10 min.
Glacial acetic acid	20 min.	Distilled water	1 oz.

adding to each dram one or two drops of the silver bath.[3]

ART. XII.—*Account of the Salts of Iron Process—the Ferrotype and the Catalysotype.*

Under the name of the *energiatype,* Mr Hunt published an account of a process in which the salts of iron were used; but he afterwards adopted the more appropriate name of *ferrotype,* as applicable to all processes in which these salts were employed. Good paper is washed over with the following solution:—

Succinic acid, pure	5 gr.	Common salt	5 gr.
Water	1 fluid oz.	Mucilage of gum-arabic	½ dr.

The paper when dry is drawn over the surface of a solution of 60 gr. of nitrate of silver in one oz. of water. When dried in the dark the paper is of a pure white, and may be kept for a consider-

[1] *La Lumière,* June 7, 1857.

[2] MM. Garnier and Salmon have sent in competition for this prize positive photographs both in carbon and sulphide of mercury.

[3] This process, by Mr A. Keene, differs slightly from that of Mr Fothergill. (See *Liverpool and Manchester Phot. Jour.,* Aug. 1, 1858; and *Phot. Jour.,* Sept. 21, 1858.)

Photography.

able time in a portfolio, for use, carefully preserved from the least light. After exposure in the camera, the picture is developed by drawing the prepared side of the paper over a saturated solution of *protosulphate of iron* and 2 or 3 dr of *mucilage of gum-arabic*. The picture will appear almost immediately. The paper, when well washed, is fixed as usual.

Under the name of the *catalysotype*, Dr Woods of Parsonstown has given the following iron process :—A sheet of wove post is steeped for a few minutes in a mixture of *two* drops of hydrochloric acid in *three* oz. of water. When well wet, it is washed over with a mixture of half a dr. of the syrup of *iodide of iron, water* $2\frac{1}{2}$ dr., and *tincture of iodine* 1 drop. When dried with bibulous paper, it is washed over evenly, in the dark, with a 10 gr. solution of nitrate of silver in an oz. of water. The paper is now ready for the camera, and the sooner it is used the better. The exposure should be from *two* to *thirty seconds*, and in clear weather without sunshine, *fifteen seconds* on an average. The picture, invisible at first, develops itself "gradually till it arrives at a state of perfection, which is not attained by photography produced by any other process." The picture is then fixed with a solution of bromide of potassium, 15 or 20 gr. to the oz, and iodide of potassium, 5 gr. to the oz.

Dr Woods has more recently recommended the following formula, which gives a darker negative, and in which soaking in the hydrochloric solution is not necessary.

Syrup of iodine............ 2 dr. | Tincture of iodine...10 to 12 drops.
Distilled water . .. . 2 dr.

With this solution brush over the paper, dry it after a few minutes, and after exposure in the camera, wash it with 1 dr. of nitrate of silver in 1 oz. of pure water. Fix it after washing in a solution of iodide of potassium, 5 gr. to the oz. of water, and then wash it again.

ART. XIII.—*On the Nitrate of Uranium Process for obtaining Positives on Paper.*

This valuable process consists in substituting *nitrate of uranium* in place of nitrate of silver. M. Niepce de St Victor has described three methods of obtaining positive pictures with this salt,—viz., with nitrate of silver, and with the chloride and bichloride of mercury.

1. Dissolve 20 parts of the nitrate of uranium in 100 of distilled water, and on the surface of this solution, kept from light, float the paper (thin paper is preferable) for five minutes, and suspend it in the air free from light. When exposed under a negative from one to ten minutes in the sun, and from fifteen to sixty in the shade, the picture will be slightly visible, and may be kept in the dark one or two days before it is developed. In a bath of 6 parts of nitrate of silver in 100 of distilled water, immerse the picture rapidly, and it will be developed in thirty or forty seconds, having a grey sepia tint, which becomes brown when kept ten minutes in the bath. The proof is now to be washed in two or three waters, and will be permanent, because unassailable by boiling cyanide of potassium.

2. In using chloride of gold, immerse the picture in a bath of 2 grammes of chloride of gold in 1000 grammes of water, adding some drops of hydrochloric acid. The picture will appear instantaneously, its blue tone deepening into a black when the exposure to the sun has been double that which is required with the nitrate of silver. When developed withdraw it rapidly, wash it well, and fix it.

3. The bichloride of mercury gives to the picture grey-black tones, and the black of engravings. The paper prepared by the nitrate of uranium must be exposed *three* times as long as in the two preceding processes. It is then immersed in a bath of 100 grammes of ordinary water and of bichloride of mercury to saturation, at a temperature of 50° Fahr. After two or three minutes the proof loses its colour, and when it becomes white it is carefully washed, put into the silver bath, where it develops itself slowly, and in from ten to fifteen minutes arrives at a black. It is then washed in several waters [1]

M. Crespon of Nismes, M. Brebisson, and other photographers, have obtained very fine positives by this process; but M. Humbert de Molard has questioned its excellence and the permanency of the pictures produced by it; while M. Bayard asserts that he has produced as good and permanent pictures with the *ammonio-citrate of iron* and the nitrate of silver, or the chloride of gold.[2]

In the year 1855, at the meeting of the British Association in Glasgow, Mr C. J. Burnett described a new process for obtaining positives on paper by means of the nitrate or other salts of uranium. He exhibited specimens developed in four different ways: 1. By salts of silver, fixed by the hyposulphite of soda, and toned by an acid, neutral or alkaline, gold chloride bath, or by platinum palladiates or aurates. Paper thus prepared will keep very long in hot climates, especially if the picture is developed with salts of iron. One of Mr Burnett's specimens showed a radiation of actinism absorbed by a newspaper;[3] 2. By chlorides of gold, acid, alkaline, and neutral; 3 By ferrid-cyanide of potassium, tonable by a very weak iron bath, and 4. By the ferro-cyanide of potassium.

A uranium printing process, based on the fact that all bodies absorb light more or less, has been recently patented by Mr Wm. Clark. It is called "Photography by Absorption of Light," and is thus performed :—A sheet of paper that has been a number of days in the dark is impregnated by immersion in a solution of salt of uranium, which the patentee says "has the property of absorbing a very large quantity of light." He prefers a solution of the nitrate of the oxide of uranium. When of a nice straw-yellow colour it is dried, and kept in the dark. After exposure to the sun, under a negative, it is exposed for a quarter of an hour. The negative is removed, and the picture is brought out with a solution of 6 parts of nitrate of silver, and 100 of water. It is then fixed with water only. The chemical picture thus produced may be made black by a solution of chloride of gold, and red or blue by combinations of the salts of gold and silver [4]

In using the uranium process, M. Hagen obtains great sensitiveness by removing the size from the paper with boiling water. When pressed between sheets of blotting-paper, and still damp, it is floated on the uranium solution. Pictures of greater intensity are obtained by adding a little alcohol or ether to the silver salt.[5]

ART. XIV.—*Photography on Porcelain, Parian, Alabaster, Enamelled Glass, Ivory, and Enamelled Metals.*

So early as 1851 Mr Fox Talbot and Mr Malone took out a patent for taking negative photographs on semi-transparent unglazed porcelain, the results of which we have not seen. On the 14th July 1857 Mr Tunny and Mr Macraw exhibited to the Photographic Society of Scotland the results of processes, to which the one gave the name of *vitro-heliography*, and the other that of *vitrotype*. On the 5th November Mr Tunny communicated to the Photographic Society in Edinburgh the process by which he obtained portraits upon porcelain, parian, enamelled glass, and enamelled metal. A plate of any of these substances is coated with collodion and albumen, separately or combined. When collodion is used, excite the film in the ordinary nitrate bath. Lay the porcelain plate on its back in a vessel, cover the film with water, and lay the negative upon the film. It is next exposed for a second to diffused light, or for 5 or 6 seconds to gas-light; and the picture is developed by first pouring over its surface a solution of nitrate of silver, 12 gr to the ounce of water, acidulated with a few drops of acetic acid; and, second, by a solution of protosulphate of iron, 25 gr. to an ounce of water, with 25 drops of acetic acid. The picture will develop itself rapidly, and when complete it is washed copiously in water, and fixed as usual.[6]

Previous to Mr Tunny's communication, Mr Macraw had, on the 2d July, specified a patent, which he did not complete, for taking positives direct in the camera, on porcelain, china, earthenware, opal glass, ivory, bone, prepared wood, or white or coloured enamels. An unglazed slab of porcelain, coated with collodion, is excited in the nitrate of silver bath, and exposed in the camera. When taken into a dark room, the film is saturated with weak protosulphate of iron or pyrogallic acid, which is immediately washed off It is then momentarily exposed to subdued daylight or artificial light, and immediately treated with a developing fluid, when the latent image will appear as a positive, with the lights and shadows correct. The picture is then developed as usual. The picture thus obtained is left-handed; and in order to remedy this, Mr Macraw places a negative photograph of the object to be depicted on the porcelain at such a distance in front of the camera, with a mirror placed behind the image at an angle of 45°, as that a well-defined image is obtained on the porcelain.[7]

We have now before us two very fine female portraits, of great softness and delicacy, executed on porcelain by Mr Macraw.

In July 1857 Mr C. J. Burnett pointed out the importance of burning in photographic portraits in porcelain, and he described processes for this purpose, and exhibited specimens which he had produced by them.[8]

Photographs under the name of *alabastrine* have been advertised as a new discovery by Messrs Squire & Co. They are, however, only glass positives with another name, and are produced by what is called the alabastrine solution, the composition of which is a secret.

ART. XV.—*On the Recent Discoveries in Photography of M. Niepce de St Victor.*

Having exposed to the sun for a quarter of an hour an engraving which had been kept several days in the dark, he applied it to a sheet of sensitive paper, and after four hours' contact in the dark, he obtained a negative picture of the engraving. If the distance between the engraving and the paper is one-eighth of an inch, or if a film of collodion or gelatine is interposed, the picture will still be obtained, but not if the film consists of mica, glass, or rock-crystal. If we take an opaque tube, closed at one end, and lined with white paper, and expose the open end to the sun for an hour, and if at the end of twenty-four hours we place a sensitive paper on the open end of the tube, we shall obtain a negative image of the opening. If we place a sheet of white paper that had been in the dark in the camera, to receive for three hours a picture brilliantly illuminated by the sun, and having taken it out, apply it to a piece of sensitive paper, it will in twenty-four hours reproduce in the dark a very visible copy of the picture in the camera

This "persistent activity," or "storing up of light," as M. Niepce calls it, he exhibits in the following experiment:—A glass or paper negative having been placed on a sheet of paper that has been several days in the dark, he exposes it for a sufficient time to the sun's rays, and after taking out the paper in the dark, he develops the picture with a solution of nitrate of silver, and fixes it by merely washing it in pure water.[1]

In another Memoir, just published, M. Niepce has described another action of light, which opens up a new and immense field to photography, in so far as it proves that almost all chemical actions are fit to give photographic pictures. Take a solution of any soluble substance whatever, and impregnate with it a sheet of paper. Allow the impregnated sheet to dry in the dark; expose it under a negative to the sun, and having taken it out in the dark, treat it with any re-agent capable of transforming the soluble substance, or entering into combination with it, and we shall have a visible image, the chemical becoming a photogenic action. The process may be reversed with the same result, by impregnating the paper with the re-agent and developing with the soluble substance. The principal re-agents to be employed are the salts of gold and silver, the dyes of turnesol and curcuma, and iodide of potassium for common paper sized with soap. If nitrate of uranium is the soluble substance, and red prussiate of potash the re-agent, the picture will be of a fine blood-red colour, and will be fixed by washing in pure water. If the picture is put into a solution of a salt of copper without washing, it will take different shades according as the heat is more or less intense. If the picture is treated with the prussiate of iron instead of the prussiate of potash, its colour will be a beautiful blue.[2]

ART. XVI.—*On the Processes for Printing Positives.*

When a good negative picture—that is, one in which the lights are black and the shades white—has been produced, positive pictures may be obtained by placing the negative above paper or any other substance sensitive to light; cover it with a thick plate of colourless glass, pressed against it in what is called a copying-frame, and exposing it to the sun, or to daylight, or to artificial light. The best copying-frames are those which have a jointed back to allow the artist to observe the progress of the picture without displacing the negative.

The best paper for positives are Turner's positive, and the new German positive, or *papier Saxe.* When the paper is cut of the proper size, it is soaked for five or ten minutes in a solution of 110 gr. of muriate of soda (common salt) in 24 oz. of water; or in a solution of 1 scr. of muriate of ammonia in 10 oz. of water. They are then hung up, or pinned up with "photographic pins" to dry. The sensitive solution (which was first suggested by Mr Alfred Smee) is obtained by dissolving 108 gr. of nitrate of silver in 3 oz. of water, and adding liquor ammonia, drop by drop, until the dark precipitate which is formed by the first drops is nearly dissolved, a slight turbidity remaining A sheet of the salted paper, when dry, is laid on a flat board in ordinary light, with its smooth side uppermost, and marked with a pencil. It is then brushed over with a camel-hair pencil or a pellet of cotton, and when dry may be placed in the copying-frame beneath the negative, and exposed to the sun. When it is printed it is soaked for an hour or two in water, and then fixed and toned in a bath thus composed:—To a solution of 4 oz. of hyposulphite of soda in 6 oz. of water add 2 dr of a solution of chloride of gold in 4 oz. of water; and afterwards add a solution of 30 gr. of nitrate of silver in 1 oz. of water. The picture is kept in this bath from 10 minutes to an hour, till it has acquired an agreeable tint, and is sufficiently fixed.

The sensitive solution most commonly used is a solution of 1 dr. of nitrate of silver in 1 oz. of distilled water. It is applied to the paper in the same manner as the ammonio-nitrate, and the picture is toned and fixed in the same manner.

The paper may be albumenized by the following process:—Take the white of an egg 1 oz., and water 1 oz., beat them into a froth, adding 10 gr. of muriate of ammonia or soda to each ounce of the mixture. Float the paper upon this solution for a few minutes, pressing out any air-bubbles, and then hang it up to dry. A hot iron is then passed over its surface to set the albumen, and render it insoluble. When wanted for use it is excited by a solution of 60 gr of nitrate of silver in 1 oz. of water; and it is toned and fixed by the process already described. All positives, however produced, must be long soaked in hot and cold water repeatedly changed.

ART. XVII.—*On Microscopic Photographs.*

In our article on the MICROSCOPE[3] we have devoted a separate chapter to the "Application of Photography to the Microscope," and we have briefly referred to microscopic photographs, or those which are so exceedingly minute that the objects are invisible to the unassisted eye. Mr Dancer of Manchester seems to have been the first photographer who executed these remarkable productions. It was obvious that no new principle was involved in the execution of these portraits; but one could not but admire the dexterity and delicacy of manipulation in taking photographs between the 30th and 40th of an inch square, in developing and fixing them, and in placing them between two plates of glass, with Canada balsam interposed

Mr Dancer did not describe the optical process which he employed; but Mr Shadbolt, who executed and exhibited photographs from the 20th to the 40th of an inch in diameter so early as March 1854,[4] has given a drawing and description of the method which he employed.[5] In this delicate art a *structureless collodion* is necessary, which is obtained by the formula—

Pure ether .... 5 dr.	Chloroform.................. 20 min.
Alcohol (60 overproof)..... 3 dr.	Iodide of potassium...... 5 gr.

Soluble cotton[6] till the solution is slimy.

After adding the chloroform to the ether and cotton, and *one* dram of alcohol, add the other 2 dr. of alcohol containing the iodide.

An achromatic object-glass, 1 or $1\frac{1}{2}$ inches in focal length, is made the lens of a small camera, and the negative picture to be reduced is placed in front of it at such a distance that the image in its focus is sufficiently minute; or it may be stuck into the sub-stage of the microscope, as done by Mr Shadbolt, and the focusing and union of the actinic and luminous rays effected by another object-glass in its place in the microscope. Mr Jackson[7] and Mr Hardwick[8] had small cameras, the one made by Ross, and the other by Horne and Thornthwaite. Either daylight or artificial light may be employed in illuminating the negatives, which may be taken directly from living figures.

ART. XVIII.—*On the Production of Photographs from Coloured Objects.*

Although M. Biot in 1840 regarded it as an illusion to attempt to obtain the colours of nature photographically, yet in the same year Sir John Herschel actually procured upon photographic paper a coloured image of the solar spectrum; and by subsequently using paper long kept, he obtained a better representation of it, *light upon a dark ground.* Mr Hunt frequently obtained coloured pictures of the spectrum, *dark upon a light ground;* but the most beautiful were upon "the daguerreotype iodidated tablets." By preparing metallic plates with chlorine, M. E. Becquerel obtained, and exhibited to the Academy of Sciences, "a photographic image of the solar spectrum, and coloured photographs from the camera obscura." These colours, though durable for a long time in the dark, resisted every attempt to fix them. M. Niepce de St Victor has been more successful, by using the purest silver; and he is said to have obtained "all the colours of a picture by preparing a bath composed of the deuto-chloride of copper." Some of these *heliochromes* in the possession of Mr Malone were, as seen by Mr Hunt, "perfectly coloured in correspondence with the drawings of which

[2] Ibid., tom. xlvii., p. 866, Nov. 29, 1858. [3] Vol. xiv., p. 801. [4] *Phot. Jour.,* i., p. 194. [5] Ibid., iv., p. 79.
[6] The linen of old cambric is recommended by Mr Hardwick (*Phot. Jour.,* iv. p. 82). [7] *Phot. Jour.,* iv. 81. [8] Ibid., iv. 93.

they were copies;" but no successful mode of fixing them has yet been discovered, though M. Niepce de St Victor has made a hundred attempts to do this.

The colours of nature have been produced accidentally by several photographers. In taking a stereoscopic picture on collodion of ruins covered with ivy, a gentleman in Durham, who signs himself "Magnet," was surprised to find the *ivy green*, the trunks of old trees *brown*, the stones *gray*, and "the whole with the colours varied in a high degree." The colours were not altered in fixing the picture, but in drying it they lost their lustre, with the exception of the green, which remained perfectly distinct. The same effect was produced in a second picture, taken in a bright sun in twenty seconds. The collodion employed was perfectly colourless, and was two months old. It gave a thin film. It was prepared with iodide of potassium and a little bromine.[1]

M. Raymond,[2] a French photographer, has observed similar colorific effects. When a picture upon collodion began to be developed under the combined action of the pyrogallic and acetic acids, he exposed it to light without previously washing it; and he observed it *transform itself quickly into a direct positive, and assume with more or less perfection the colours of the model.* The most perfect picture he obtained required a quarter of an hour for its development. It lost none of its brightness by an exposure of some months to the air, and even after two years it was not completely effaced.

Some of the colorific effects observed by photographers are *the colours of thin plates*, and have no connection whatever with the colours of nature. The action of light upon the collodion film changes either its thickness directly, or indirectly by changing its solubility; so that the light and dark parts of the picture exhibit different tints in Newton's scale of colours. We have observed this effect in very thin films of collodion on glass, and also in the same films after having been transferred to paper.

ART. XIX.—*On the Applications of Photography.*

Our limits will not permit us to dwell at any length on the numerous and important applications of this beautiful art. The employment of photography in the arts of painting and sculpture has been recommended by artists of the highest name. "Instead of superseding the arts of design, photography will supply them with new materials—with collections of costume, with studies of drapery and of form, and with scenes in life and facts in nature which, if they possess at all, they possess imperfectly, and without which Art must be stationary, if she does not languish and decline."[3] The instantaneous process, as it is called, of taking pictures on collodion in half a second has enabled the artist to delineate "a thoroughfare in London with its noonday crowd," to seize the momentary attitudes and expressions of passion, and to fix on his tablet the gestures of the orator and the furious movements of the lunatic. Such pictures have been erroneously represented as the results of *mere mechanical dexterity*, to which the mind of the artist had not imparted "the impress of thought;" but if the portrait is taken with *optical truth*, which has yet to be done, and if, in the twinkling of an eye—if in half a second, a portion of time less than the duration of the expression of thought or sentiment—a portrait is taken, that portrait must be perfect, and superior to anything that art can produce. It is absolute truth, to which art cannot arrive. It is as true as the portrait of the sitter seen by reflection in the most perfect mirror; and though the artist might improve the material picture by a deviation from truth, he cannot add a single iota to its expressions of thought or of feeling.

To the sculptor, photography, whether simple or binocular, is of inestimable value. He can fill his portfolio with copies of all the treasures of the Vatican, the British Museum, and the repositories of art in Berlin, Munich, and other European cities. "They all exhibit to him forms more than human, though human still, embodying all that is true and beautiful in what might be man;" and when taken binocularly, they may be raised by the stereoscope into true relief, and studied, as if the originals were placed before him. The living, the dying, and the dead may thus be modelled without the rude contact of a mask, and those noble forms perpetuated which affection or gratitude has endeared.

To the pursuits of the architect, the engineer, and the mechanist, photography is equally applicable; and in the diffusion of knowledge, and for the purposes of education, its power will be speedily recognised. Nor will it be less influential in humanizing the humbler classes of society. Portraits of their families in beautiful frames and morocco cases can be purchased for a shilling, and even for sixpence each. The emigrant may carry to his distant home the portraits of those from whom he has been obliged to part, and the humble peasant may adorn his cottage not only with likenesses of his family and friends, but with accurate photographs of various objects in art and in nature which he may desire to contemplate.[4]

The calico-printer may multiply his patterns photographically; and the carpet manufacturer and general decorator may fix in paper all the beautiful patterns which are given by the kaleidoscope.[5]

In the sciences of astronomy, zoology, geology, meteorology, ethnology, electricity, and magnetism, photography has been advantageously employed. The spots of the sun, the surface of the moon, the forms of the planets, and even groups of stars, have been delineated by their own light; and it has been stated "that the photographic moon indicates an atmospheric stratum of considerable density." Mr De la Rue has obtained pictures of this luminary analogous to binocular ones, which, when aided by the stereoscope, exhibit her as a solid globe. The meteorologist registers photographically in his absence the indications of the barometer, thermometer, and hygrometer; the variations of the earth's magnetism are recorded for every minute on chemically-prepared paper, and the electricity of the atmosphere, brought down into the observatory, is made to exhibit on paper the number of its variations and the intensity of its action. The ethnologist has begun to collect accurate pictures of the different races of man. The zoologist has obtained forms of animal life which the painter had attempted in vain to procure. The geologist has obtained delineations of phenomena which defied the highest efforts of his pencil; and the botanist has transferred to imperishable tablets those beautiful and complex forms of vegetable life which we seek in vain in the richest botanical collections.

The last, and certainly the least application of photography, is one which was introduced last year at Nice. The Duke of Parma had his portrait at full length placed upon his visiting-cards. Some English gentlemen imitated his example; and it has been partially followed in London and in Paris.[6] In order to diminish the expense, M. Besson of Paris takes 24 negatives at once on the same sheet of paper with a 24-lens camera; and he is thus able to print 24 cards at the same time, and greatly reduce the expense of their production.

ART. XX.—*On the method of taking correct Photographic Portraits.*

In our article OPTICS,[7] we have devoted a separate section to prove that all portraits taken by large lenses[8] are monstrous representations of the human form, and that all pictures of solid bodies so taken are incorrect. The defects of such lenses may be shortly enumerated.

1. They introduce into the picture parts of the solid figure which cannot be seen from any one point of sight

2. Every picture taken by a large lens is a combination of an infinite number of incoincident pictures, as seen from every point of the lens.

3. A large lens introduces into a picture objects eclipsed by or placed behind other objects.

4. In portrait lenses consisting of two separate lenses there are eight surfaces, each of which reflects back upon the sensitive surface a portion of light more or less intense.

5. In such lenses their combined thicknesses is such as to injure the distinctness of the picture, if there is any defect (as there must be, however small) in the homogeneity of the glass.

6. In the images formed by such lenses, lines which should be straight are curved, and curved lines have not their proper curvature.

7. With the most perfect lens, the parts of objects at different distances have different degrees of distinctness on the gray glass. The degree of indistinctness increases with the diameter of the lens, because it is measured by the section of a cone of rays whose base is the lens itself.

8. In passing through such a thickness of glass, many of the actinic rays are lost by absorption.

From all these objections small lenses are free; and as very sensitive photographic processes have been discovered, we would press

[1] *Phot. Jour.*, April 21, 1858, vol. iv., p. 204. The editor of *Cosmos* has published these observations in his No. for the 26th Nov. 1858, p. 651, as made by *M. Muguet* (a misprint for *Magnet*, not for *M. Magnet!*) and refers to the *Bulletin de la Société Française* as his authority!

[3] Brewster's *Treatise on the Stereoscope*, chap. x., p. 166.

[4] The application of simple and binocular photography to these various purposes has been treated at great length by Sir David Brewster in his *Treatise on the Stereoscope*, chaps. x., xi., xii., and xiii.

[5] Brewster's *Treatise on the Kaleidoscope*, 2d ed., ch. xxi., p. 148.

[6] The expense of these cards was L.1, 10s. per 100.

[7] Vol. xvi., pp. 569, 570.

[8] Lenses above half an inch in diameter (vol. xvi., p. 571).

upon the photographer the necessity of abandoning large lenses, and employing single plano-convex lenses of rock-crystal $\frac{1}{4}$ inch in diameter, such as we have described in the article OPTICS.[1]

In addition to the deformities produced by large lenses, photographic portraits are rendered hideous in consequence of every imperfection of the human face being *magnified*.

Those who already possess large lenses and large cameras, and are unwilling to abandon them, might obtain good portraits by taking them at considerable distances; and if the picture is deemed too small, it may be enlarged to any size in the copying camera. Very small portraits may be taken by the achromatic lenses of compound microscopes placed in cameras an inch or two long (art xvii.), and the picture subsequently enlarged.

Should it be wished to take a portrait as seen at a certain distance by two eyes, it should be taken by an achromatic lens 6 inches in focal length, and having all its surface covered, with the exception of two apertures, each a quarter of an inch in diameter, and placed at the distance of $2\frac{1}{2}$ inches.[2]

The defects of large lenses have an important bearing on stereoscopic photography, which is at present practised in open violation of scientific principles. (See article STEREOSCOPE.)

ART. XXI.—*On Photographic Apparatus.*

The most essential part of photographic apparatus is the camera, which has been described in its simplest form in our article OPTICS. Many ingenious forms of this instrument have been devised and constructed for sale; some portable, and some not; while others have been so constructed that the photographer may perform in their interior all the operations of developing and fixing his negative pictures.

A camera of the common form, as made by Mr Ottewill, is shown in the annexed figure 1, where A is the tube holding the lens or lenses, and BC the body of the camera, the back of part of which slides into the front part, in order that the person or landscape to be photographed may be distinctly represented on the ground glass at D. The adjustment is completed by a rack and pinion at S (figs. 4 and 5), which moves out and in the tube holding the lens or lenses. In order to ascertain when the part of the object which is wished to be most distinctly seen is most sharply depicted on the ground glass, or is in the true conjugate focus of the lens, Sir David Brewster first suggested the use of what is called a focusing glass, which is a tube with an eye-piece of one or more lenses, which has its or their focus at the end of the tube. When the end of the tube is placed on the ground glass, the observer will ascertain when the image is distinct. The roughness of the glass, however, makes such a method very imperfect; and therefore Sir

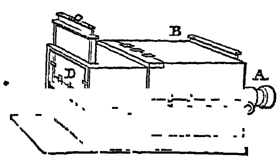

Fig 1.

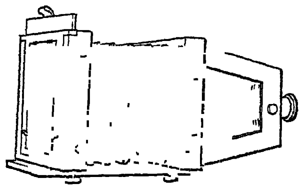

Fig 2.

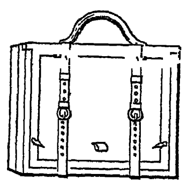

Fig 3

David Brewster long ago proposed either to cut a hole in the glass, or polish the central part of it, or fit up the camera precisely like a telescope, and thus obtain the most perfect adjustment of the luminous focus of the lens, the usual means being taken to obtain a coincidence of the luminous and actinic focus.

The portable form of the camera, as constructed by Captain Fowkes, is shown in the annexed figures—when it is open (fig. 2), and when it is shut (fig. 3).[3]

A section of the tube containing the achromatic lenses of almost every camera is shown in figs. 4 and 5, where AB, CD, are

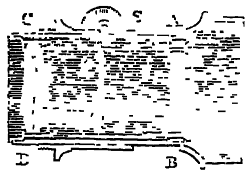

Fig. 4.

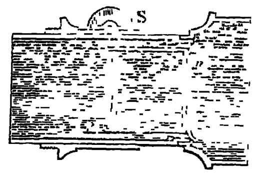

Fig. 5.

the two lenses used in taking portraits, with a suitable stop, *mn*, between them. In order to take landscapes, the lens CD is removed, and the lens AB placed as in fig. 5, with the stop *mn* in front of it. Mr Skaife uses what he calls a *pisto lcamera*, with a single lens three-fourths of an inch in diameter, to produce photographs on small concave lenses.[4]

In all these cameras the picture is inverted on the glass, so that the artist cannot possibly form a correct judgment of the *posé* of individual figures, or of the grouping of several figures whose portraits are required. We would recommend, therefore, the use of an erecting camera,[5] for the single purpose of enabling the artist to judge of the *posé* or grouping of the picture. When the artist is satisfied with this, the erecting camera should be replaced by the inverting one. (See arts. xvii. and xx.)

Among the various lenses used by photographers or proposed by optical writers, that of M. Petzval has been ascertained, not only by theory, but by direct experiment, to be the best. It has been the practice to test a lens by the pictures which it produces; but the picture thus used as a test is influenced by various causes, so that it is impossible to separate the effect produced by these causes from that which is due to the lens. The lens of every camera should be made the object-glass of a telescope, and tried with different eye-pieces and different apertures; and from the data thus procured a photographer of any optical knowledge will have no difficulty in ascertaining the value of his lens. With large apertures, it will doubtless be found, especially from the projected pictures of rectilineal objects, that straight lines are much bent into curves; and the photographer will learn, what so few of them know, that if he wants a *true picture* he must attend to the aperture of his lens. M. Petzval has proposed the excellent test of copying a map on the scale of a fifth part of the original, and observing the difference between the copy and the original.

In almost all the cameras used in taking portraits, the focal length of the lens exceeds, and is sometimes double, the focal length of the eye; so that all the irregularities in the human skin are magnified, thus adding imperfections not generally visible to those of large and imperfect lenses.

In an article of limited extent like the present, we cannot find room for drawings and descriptions of copying and enlarging cameras; of the ingenious pieces of apparatus invented by Mr Claudet, such as the photographometer, dynactinometer, and focimeter; and of the various pieces of apparatus which are used in photographic processes. For an account of these, we refer the reader to the Abbé Moigno's *Repertoire d'Optique Moderne*, parts ii., iii., iv.; Hunt's *Manual of Photography*, 5th edition, 1857; Hunt's *Practice of Photography*, 1857, Thornthwaite's *Guide to Photography*, 14th edition, 1857; and Ross and Thomson's *Plain Answers to Common Questions regarding Photography*, 1853. (D. B.)

PHOTO-LITHOGRAPHY, the name of a new art which we owe to Mr Macpherson of Rome. A photograph, impressed on the surface of a lithographic stone, is treated in the ordinary way, and copies afterwards taken of it. Two different processes have been patented in England, one by M. Poitevin, and the other by Mr Newton as the invention of Messrs Culling and Bradford of Boston.

In M. Poitevin's patent the stone is covered with one or more films of a mixture of albumen or gelatine, and a concentrated solution of bichromate of potash. This film is then dried if a negative picture is to be copied upon it; but it may be used in a moist state if it is to receive the picture in the camera. When the surface is dry it is moistened with a sponge, and while moist the lithographic ink is applied to the surface by a ball or dabber, or other means, when it will be found to adhere only to those parts which have been affected by light.

In Messrs Culling and Bradford's process, a film of prepared gum-arabic is used which has been deprived of its power of intimate union

[1] See the *Photographic Journal*, vol. iv., p. 83, where this subject is treated at considerable length.
[2] On the subject of photographic portraiture, we would refer the reader to a clever article in the *Art-Journal*, No. xlv., p. 273.
[3] An improved camera on this principle, by Mr Kinnear, is described in the *Phot. Jour.*, vol. iv., pp. 116, 165.
[4] *Phot. Jour.*, vol. v., p. 98, Dec. 11, 1858.
[5] This camera may be a very common one, with a small single lens, and may be constructed at a small expense.

with the stone, while at the same time it is rendered capable of becoming fixed or insoluble by the action of light. When this film is submitted to the action of a solution of soap, the parts acted upon by light are not injuriously affected by it, and an insoluble soap is formed on the stone to produce the printing surface. The exciting solution is

Water .... 1 qt.	Sugar or molasses .... 160 gr.
Gum-arabic .... 4 oz.	Bichromate of potash...... 160 gr.

The sugar retards the immediate fixing of the gum upon the stone, and the chromic salt causes it to be more firmly fixed, or to be less soluble when exposed to light. When the film is dried, it may be exposed in the camera, or placed under a negative.

In the first of these processes the blacks are produced by the parts on which the light has acted, and on the second by those upon which it has not acted. (D. B.)

PHOTOMETER (from φῶς, *light*, and μέτρον, *a measure*) is the name of an instrument for measuring the intensity of light, whether it proceeds from a luminous body, or is reflected or refracted at different angles from opaque or transparent bodies. In our article on OPTICS,[1] we have referred to the photometrical researches of Bouguer and Lambert, whose methods of comparing different degrees of illumination we shall now explain.

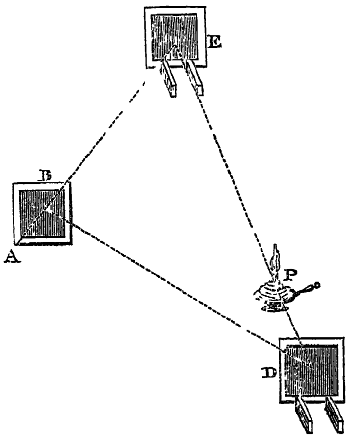

Fig 1.

In order to measure the light reflected from a mirror B, Bouguer placed the light P between two surfaces of paper D, E, equally white and parallel to each other. He then placed his eye at A, so that he could see at the same time the paper E directly, and the image of the paper D reflected from the mirror B. When the direct and reflected images were brought into contact, the light P was moved along the line ED, so as to throw more or less light upon E and D, till their degree of illumination appeared perfectly equal. The light of E seen directly from A is then to the light reflected from B as EP^2 is to DP^2.

The method used by Lambert is shown in the annexed figure. Upon a plane white surface ABCD draw a line ILK, uniformly black; place a plate of glass EFGH at right angles to the white surface, so that the angle HLK is a few degrees less than a right angle. When the white surface ABCD is equally illuminated, the observer at O views the part IL projected into LQ, and the anterior part KL, seen by reflection at PL; and when he finds the position of the eye at O when the lines LQ and LP are of equal paleness, he measures the angle of incidence In one experiment he found this angle $75\frac{1}{2}$ degrees; and supposing the glass to be perfectly pellucid, he concluded that at that angle the quantity of reflected light was exactly equal to the quantity of transmitted light.[2]

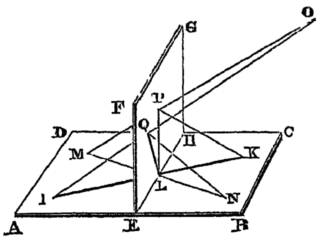

Fig 2.

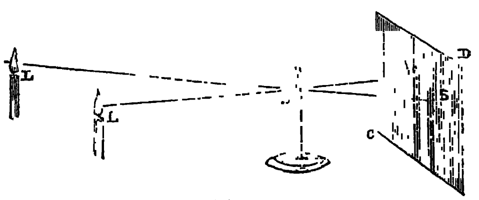

Fig 3.

The method of equal shadows given by Count Rumford is shown in fig. 3, where L, L are the two lights to be compared, S an opaque cylindrical rod, and CD a screen of white paper. The lights are then placed at such distances from S that the shadows A, B are equally dark. In this case the squares of the distances of the shadows from the lights, that is LB^2, LA^2, are a measure of the relative intensities of the light The rays LB, LA must be equally inclined to the surface of the screen.[3]

The ingenious photometer of the late Mr William Ritchie, founded upon Bouguer's method, is shown in fig 4, where ABCD is a section of a rectangular box, CF, DF the plane mirrors cut from the same plate, EG a rectangular opening covered with oiled or fine paper, and F a small division of blackened card to prevent the lights mingling with each other. The lights to be compared are then placed in the same straight line parallel to AB or CD, and equidistant from them, at the distance of 6 feet from each other, and the box is moved along this line till EF, GF are equally bright. The illuminating powers of the lights will be directly as the squares of their distance from the centre of the photometer[4]

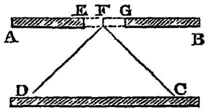

Fig 4.

The photometer of Sir John Leslie,[5] which was merely his differential thermometer with one of its balls blackened, exhibited the difference of temperature of the two balls, and was not a measurer of light. Mr Ritchie invented a photometer having some resemblance to it, but differing essentially in principle. It is shown in fig. 5, the lower part of which is a differential thermometer, surrounded by two air-tight cylinders of tin ABCD, EFGH, composed of two plates of fine and thick glass AB, FG, and two circular tin plates CD, EH, the dotted line representing circular pieces of black bibulous paper. The light of one flame enters the glass plate AB, and the other FG. The heat is assumed to be absorbed by the thick glass, and the light is absorbed by the bibulous paper and converted into heat, the amount of which is shown on the differential thermometer. When each branch of the thermometer is at zero, showing that the light converted into heat is equal on the two cylinders, then the intensities of the lights are directly as the squares of their distances from the instrument.[6]

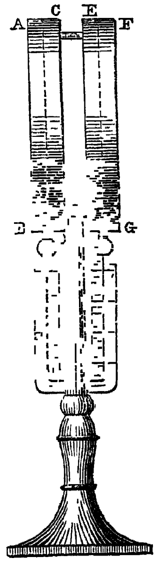

Fig. 5

The photometer used by Professor Potter for measuring the light reflected at different angles by plane metallic specula, will be found in Brewster's *Journal of Science*, October 1830, vol. iii., new series, p. 284.

A photometer, in which a variable light is produced by rotation, has been long ago proposed by Sir David Brewster. An opaque or a semi-transparent arm, ground glass for example, having its breadth decreasing to a point as it recedes from the centre of rotation, is made to revolve in front of a uniformly illuminated white surface, so as to produce every degree of illumination from absolute darkness to the light of the surface. Any law of variation may be obtained by the form of the sides of the revolving arm being either rectilineal, curvilineal, or in steps, and by the angular distance between their extreme points. All light less bright than the surface may thus be measured by comparison with the reduced light at a distance from the centre of rotation. The same principle may be applied by reducing to equality with the other the brightest of two unequal lights received on a white surface by looking through the slits of a revolving disc.

Photometers have been constructed by viewing through a binocular instrument differently illuminated surfaces, and reducing them to an equality by different circular apertures applied to each eye. A photometer of this kind has been described by M. Doppler,[7] and another has been recently proposed by Mr Mungo Ponton.[8] Many objections, both physiological and optical, may be urged against the accuracy of such instruments.

The transition of a polarized ray from evanescence to light of a given intensity, and the determination of the law of variation by Malus, must have suggested to every person familiar with that class of phenomena the construction of a photometer.[9] (D. B.)

PHRASE, in *Music*, signifies a passage of melody or of harmony which contains a musical idea more or less complete in respect of cadence. A melodic phrase may consist of two or three sounds only, rhythmically disposed, but generally consists of more. It may begin on an accented or an unaccented part of the measure, and end on either. A compound phrase consists of two or more simple phrases symmetrically disposed, so that the whole may present a regular ordonnance, and a satisfactory balancing of its component parts. Several of such phrases joined together form a period, and the most regular period consists of four symmetrical phrases or numbers. As there are various kinds of phrases, some vague and some symmetrical, so there are various kinds of periods. A melodic phrase may occupy one measure, or even less; or it may extend over two, three, or even more; and may either be confined to the key in which it began, or may modulate into another. The well-known air by Galuppi—adapted to the English words, "Taste life's glad moments"—offers, in its first eight measures, an example of four phrases, each of two measures, symmetrically arranged, and confined to one key. A harmonic phrase consists of a succession of chords forming a more or less determinate cadence; and may be prolonged by introducing dissonances, so as to avoid the perfect cadence. (See MUSIC, § *Melody*.) (G. F. G.)

PHRASING, in *Music*, applies to the executant of a piece of music, and signifies the presentment of each phrase or period with elegance and propriety, and the adorning of it with such accents and graces as are suitable to its character, and are calculated to give it the best effect. (G. F. G.)

PHRENOLOGY.

PHRENOLOGY, a term derived from Φρήν, mind, and λόγος, discourse, designates a science which professes to be a philosophy of the human mind founded on the physiology of the brain. It was first offered to public consideration on the continent of Europe in 1796 by Dr Gall, a German physician. (See GALL.) In Britain, it attracted little attention until 1815. It has met with strenuous support and determined opposition during the last half century, and its claims as an established science are still *sub judice*.

Phrenology claims preference over all other systems as a professedly practical science of mind. Starting from its fundamental principle, that the brain is the essential organ of the mental powers, it attempts to show in what respects, and by what methods, the mental nature of man can be developed, and his material and moral welfare advanced. In other words, it systematically applies our knowledge of the anatomy, physiology, and pathology of the brain to education, legislation, religion, morals, the fine arts, and the science and art of medicine.

The principles of phrenology are as follows:—1. Phrenology maintains that the mind and the body are inseparable in this world, and cannot be investigated apart from each other. It is man as a "concrete Ego," and not as an immaterial Ego, that it examines. This principle is controverted by the doctrine of "spirits," and the views of speculative theologians and metaphysicians, but it is evidently in concurrence with the daily practice and common sense of mankind. 2. The brain is the immediate organ of the mind; or, in other words, all the modifications of our consciousness, known as feeling, thought, and will, take place within that portion of the body contained within the skull, *i.e.*, the encephalon or cerebral organs. This is a doctrine founded also on the common sense of mankind, and admitted by a preponderating majority of philosophers and physiologists. 3. The brain is a double organ, one-half of which may act independently of the other. That is to say, just as we can see with one eye, hear with one ear, or see or hear differently with the two organs, so the one-half of the brain may act independently of, or differently from, the other half. This principle is now admitted by the best modern writers, as it was by the most distinguished of the ancients. Nevertheless, as in seeing and hearing, the two organs of the senses usually act consentaneously, so in thought and will the two mental organs, or cerebral hemispheres and their connections, commonly act consentaneously. 4. Phrenology affirms that there are separate and distinct mental faculties, and that each has its corresponding seat or organ in each of the cerebral hemispheres; in other words, although consciousness is one, its modes of manifestation are diverse, according to the development of certain corresponding portions of the cerebrum. There is an exception to this principle in the love of the sexes, which has only one organ, and that the cerebellum. This principle has been much controverted, on grounds which we will shortly examine. 5. It is further maintained that power of mind is, *cæteris paribus*, dependent upon size or development of the cerebral hemispheres; and since what is true of the whole must be true of the parts, it follows that the power of particular faculties is also, *cæteris paribus*, dependent on the size of special organs. This doctrine has also been much controverted.

Phrenologists have founded upon these principles:—1. A system of psychology, in which the nature, mode of action, sphere of operation, and relations of distinct mental faculties, are set forth. 2. A system of physiognomy, founded upon (*a*) the form of the skull, as determined by the size and form of the cerebral hemispheres, or of particular portions of them; (*b*) upon the natural language of the feelings and faculties, as displayed in the attitudes, &c. 3. A practical sociology, or the application of these systems of psychology and physiognomy, in connection with the fundamental principles of cerebral physiology, to the welfare of society and the ordinary business of life.

Organology of Phrenology.—We will notice some of the most important of the phrenological principles, still *sub judice*; and first as to the Organology of Phrenology. This doctrine is twofold in its nature, being psychological, as it respects the arrangement of the modes of consciousness into faculties; anatomical and physiological, as it respects the assignment of a portion of the brain to each faculty. The proofs adduced by the advocates of phrenology in support of these doctrines are as follows:—

(*a*.) As to the psychological division into faculties and the like. 1. It is an undisputed truth that varying mental states characterise the different stages of man's development. Reasoning powers appear later than emotional states; a child observes much sooner than he reflects; he fears and loves before he venerates. 2. But it is not only the individual man, at various stages of his life, that manifests various faculties. Man, when examined in the mass, as in families, races, or nations, presents great varieties of faculties, desires, sentiments, instincts. Metaphysicians do but re-echo popular opinion when they arrange these varying states of consciousness under such generic terms as the instinctive, emotional, and intellectual faculties. Every thoughtful father is anxious to discover whether his son has congenitally or "naturally" any predominant faculties, modes, or powers of action, so that his course of life may be so shaped as to give scope to the free exercise of the so-called "talents" he possesses. It is within the experience of every observing man that there are so-called "talented families," one member of which excels perhaps

Phrenology in mathematics, another in poetry, another in music, another in painting, and so on. It was, in fact, this diversity of character which first suggested to Gall to observe whether there was any connection between it and diversity of external form. Observing accordingly, he at last connected these diversities of character with diversities of physiognomy, and at last was led to the idea that the variety of faculties was connected with varieties in the form and size of the cranium, and therefore with the form and size of the brain. The observation of races of mankind led to similar results. Thus the psychological observation of the faculties preceded the physiognomical observation of the organs. It follows, therefore, that the psychology of phrenology is not dependent upon either the physiology or the physiognomy of the science; or, in other words, it may be considered and applied as a distinct system of mental philosophy, independently of the latter.

It being determined by observation and induction that there are distinct faculties, sentiments, propensities, and the like, and it being also determined that the brain is the organ of the mind in general, it remains to determine, further, whether special portions of it are the seat or mechanism of special faculties or propensities, the existence of which is as necessary to the manifestation of those special mental states as the existence of the organ, as a whole, is necessary to the manifestation of mind as a whole. The following are the arguments adduced in favour of a multiplicity of cerebral organs:—

1. It is noticeable, that in every organism there is a division of labour or function, with corresponding distinctness of organ. "In the economy of the human frame," Mr Combe remarks, "there is no ascertained example of one nerve performing two functions, such as feeling and communicating motion, or seeing and hearing, or tasting and smelling. The spinal marrow consists of three double columns; the anterior column of each lateral division is for motion; the posterior for sensation; the middle for respiration;" or at least their functions *are* different, however physiologists may vary in opinion as to the nature or character of those functions. In like manner as to the general functions of the organism. Each function has an organ for itself; the stomach, for instance, digests food, the liver secretes bile, the heart propels the blood, the eyes see, the ears hear, the tongue tastes, and the nose smells.[1] This is the argument founded on differentiation of structure and function, and is by no means so forcibly put by phrenological writers as it might be. 2. We have seen that the various mental powers of man are manifested in succession from childhood to adult life. And concurrently with this order of manifestation there is an order of development of the component parts of the brain. In childhood, for example, the middle part of the forehead generally predominates; in later life, the upper and lateral parts become more prominent,—changes in strict accordance with the consecutive order of evolution of the observing and reasoning faculties. 3. Genius is almost always partial; which it ought not to be if there were no partial development of the organ, and if the whole brain were the seat of all and every faculty; in that case every faculty would be equally manifested, and none would be above another in power. 4. The phenomena of dreaming, insanity, and idiotcy are equally at variance with the theory of singleness of the organ of mind, but quite consistent with the theory of its plurality. Were the organ single, it is clear that all the faculties should be asleep or awake at the same time, and to the same extent; or, in other words, there could be no such thing as dreaming. But that change of the functional activity of the brain which constitutes sleep being only partial in its intensity, or in the extent to which it involves the brain, those portions which are less affected are partially active, so that partial manifestations of the consciousness take place which in an infinite variety constitute dreaming. Again, in partial idiotcy, whilst some faculties are manifested to a singular extent, others are absolutely deficient. Concurrently with this partial development of the intellect there is a partial development of the cerebrum. But, independently of the observed phenomena, it is a just *à priori* inference, that if the brain were a single organ, there would not be this remarkable absence of some mental powers with the presence of others. Not dissimilar are the conclusions to be drawn from the phenomena of mental disease, occurring in persons with ordinary development of the body and mind. Just as in idiotcy and dreaming, so in monomania there is a morbid manifestation of special mental states. Now, the same argument, *à priori*, applies here as in the other instances; and it is inferred that there is a special disease of a portion of the brain upon which the special morbid manifestation depends. Partial injuries of the brain, and their accompanying phenomena, come under this category of disease, but are more demonstrative of the general principle.

All these phenomena are of daily occurrence, and the conclusions to which they point have been forced upon the attention of philosophers and physiologists from Aristotle and Galen downwards. The Aristotelian philosophy arranged the faculties under three heads, namely, the judgment, imagination, and memory. In the thirteenth century, Albertus Magnus divided the cranium phrenologically into three regions, so as to correspond to this arrangement: the anterior portion was allotted to the judgment or intellect, the middle to the imagination, the posterior to the memory. Petrus Montagnana published a similar chart in 1491.[2] Mr Combe figures in his "System"[3] a more elaborate craniological chart of this kind, published in 1562, at Venice, by Ludovico Dolce, in a work upon strengthening and refreshing the memory. In the second volume of the *Phrenological Journal*, drawings of human and comparative physiognomy are given from a work by John Baptista Porta (1596), entitled *De Humana Physiognomia.*

Modern anatomists and physiologists in general, from Willis downwards, have asserted the principle of multiplicity of cerebral structures as organs of mental powers, or seats of mental states. Willis made careful dissections of the brain, with a view to determine the seat of the various faculties, or, in his own words, the particular "canals" or "passages" through which the "animal spirits" pass when various mental states are induced or manifested. His dissections and engravings of the brain are interesting even now; for in some respects he taught doctrines similar to, and even in advance of, those of modern physiologists. He made the *corpora striata* the seat of consciousness, in connection with doctrines as to diversity of function of other portions of the encephalon. "As to the offices and uses of the *corpora striata*, though we can discern nothing with our eyes, or handle with our hands, of those things that are done within the secret conclave or closet of the brain, yet by the effects, and by *comparing* rationally the *faculties* and acts *with the workmanship of the machine*, we may at least conjecture what sort of works of the animal function are performed in these or those, or within some other parts of the head; especially because it plainly appears that the offices of the interior motions and senses, as well as of the exterior, are acted by the help of the animal spirits ordained within certain and distinct paths, or as it were small little

pipes."[1] Willis's researches were instituted in relation to the current theory of the animal spirits (subsequently replaced by the *vis nervosa* and "nervous fluid"), as the efficient agents of sensation, motion, and thought, and which were generated in the brain. This was the doctrine of Galen, and held its ground until the commencement of the eighteenth century. In accordance with this theory, the Arabian writers, following Galen, fixed upon the ventricles of the brain as the special seat of the mental faculties; one of the anterior ventricles they made the seat of common sensation; the other of the imaginative faculty; the third ventricle was the seat of understanding, and the fourth of memory. These doctrines were also maintained by Duns Scotus, Thomas Aquinas, and other philosophers as late as Descartes; Caspar Bauhin was the first to question them, and to maintain that the "animal spirits" were generated in the substance of the brain and distributed directly from thence through the nerves to the organs of sensation and motion. Plater, Varol, Spigel, Caspar Hoffmann, and others, also opposed the ventricular theory of localization, especially the last mentioned, and who in consequence drew down upon him the anathemas of those who supported the ancient theories. He was particularly charged by Riolan the younger with ignorance, and with unsettling, by his new dogma, both the entire pathology and therapeutics of the brain; for he actually had the temerity to fix the seat of epilepsy and apoplexy in the substance of the brain, and not in the ventricles, as Galen taught. "And this is the argument," Prochaska remarks (from whom we have taken the preceding facts), "with which physicians are accustomed to meet new dogmas when opposed to their own, even if true; lest they should be compelled by shame to unlearn, when old, those theories which they have learnt in youth. Harvey was met with almost a similar argument, and considered as an audacious man."[2]

It was after the "animal spirits" were ejected from the ventricles that Malpighi, Sylvius, and Willis attempted to show that they were secreted by the cortical substance, whence they were received by the medullary substance, to be transmitted by it to the nerves of the whole body. To these, therefore, is due, and of these more especially to Willis, the first indication of the established doctrine of modern physiology, and which Gall and Spurzheim more fully developed—namely, that the cortical part of the brain, or the cineritious neurine, is ganglionic, or the seat of *action* or energy; and that the medullary or fibrous is a conducting structure, analogous to the trunks of the nerves. Willis retained some of the other Galenical doctrines; but he peculiarly advocated that the cerebrum subserves to the animal functions and the voluntary motions, the cerebellum to the involuntary; that a perception of all the sensations takes place in the ascending fibres of the *corpora striata*, and that through the descending fibres voluntary movements are excited; that the understanding and imagination have their seat in the *corpus callosum*, and the memory in the convolutions, which are its "storehouses."

A host of physiologists supported or opposed the doctrines of Willis; but amidst the innumerable controversies which arose, the doctrine of mental organology, or of cerebral differentiation of structure, with specialization of function, continually advanced. In 1784 Prochaska summarized the views of previous inquirers generally, and indicated the advance which the doctrine had reached at this period, when Gall began his researches and teaching. The 3d section of the 5th chapter of Prochaska's *Dissertation* (1784) is headed, "Do each of the divisions of the intellect occupy a separate portion of the brain?" In answer to this proposed problem, Prochaska proceeds thus: "It is our consciousness, and a certain peculiar feeling, which convinces every one that he thinks with his brain. But since the brain as well as the cerebellum is composed of many parts variously figured, it is probable that nature, which never works in vain, has destined those parts to various uses, so that the various faculties of mind seem to require different portions of the cerebrum and cerebellum for their production. Since, however, the *sensorium commune* reflects the sensorial impressions into motor by definite laws peculiar to itself, and independently of consciousness, and since we have laid down that the *sensorium commune* comprises the *medulla oblongata*, *medulla spinalis*, and the origin of all the nerves, it follows that the cerebrum and cerebellum, together with their connections, the *sensorium commune* excepted, constitute the organs of the faculty of thought; and as in some animals these are entirely wanting, it is fair to conjecture that the faculty of thought is also wanting, and that they exist solely in virtue of the *vis nervosa* of the *sensorium commune*, and of the nerves with which they are endowed."[3] Prochaska thus eliminated the hemispheres with the *corpus callosum* and cerebellum from those portions of the encephalon which he allotted to the sensorium,—namely, the ganglionic origins of the cerebral nerves, the *crura*, the *medulla oblongata*, and *medulla spinalis*,—and constituted them the organs of mind.

This was the state of knowledge when Gall first attempted to allocate portions of the hemispheres to special faculties. But in doing this both Gall and Spurzheim limited the term *medulla oblongata* to that portion of the central axis which extends from the lower border of the *pons Varolii* to the occipital foramen, and thus deviated from the anatomical definitions of their predecessors,—for Prochaska was not alone in his doctrines. Long previously Willis had stated, "where the *corpus callosum* is thought to end, there the *medulla oblongata* begins," and he anatomically describes it accordingly. All the successors of Willis used the term *medulla oblongata* more or less in a similar sense. Hence the older writers marked three great divisions of the encephalon—the cerebrum, brain, or hemispheres, including their commissure, the *corpus callosum*; the cerebellum or little brain, with its crura, and the head of the spinal column; and the *medulla oblongata* or oblong medulla, including from the *corpora striata* downward. The *medulla spinalis* and *oblongata* were also termed the *cerebrum prolongatum*, the *prolonged* brain,—the theory being, that this portion of the central axis arose, or was prolonged from, the cerebrum. Now the *medulla oblongata*, thus defined, was considered to be the point of origin of the encephalic nerves, and (through its continuation into the spinal cord) of all the nerves of the body. In this way it came to be considered the seat of sensation (the *sensorium commune*, the common centre of consciousness), or point of union between the sensory nerves on the one side, and the hemispheres on the other. This doctrine disappeared almost wholly with the advance of Gall's views, and the ganglia constituting that portion of the *medulla oblongata* situated above the *pons Varolii* were considered to be part of the brain or cerebrum. It is only within the last few years that Dr Carpenter has revived it as a new theory, giving the name "sensory ganglia" to these structures, instead of *sensorium commune*.

With this explanation, we can better understand Prochaska's conclusions as to a plurality of organs of the mental faculties.[4] When he proceeds to discuss the question,—after

[4] Ibid. *loc. citato.*

alluding to the obscurity of the subject, and remarking that he is of opinion with Haller, that "careful dissections of the brains of fatuous persons, apoplectics, and such as have other disorders of the understanding," are the only means of throwing light upon it; and after advancing various arguments in support of the doctrine of organology, he adds, "It is therefore by no means improbable that each division of the intellect has its allotted organ in the brain [or hemispheres], so that there is one for the perceptions, another for the understanding, probably others also for the will, and imagination, and memory, which act wonderfully in concert, and materially excite each other to action. The organ of the imagination, however, amongst the rest, will be far apart, I should think, from the organ of perceptions, since the organ of perceptions being asleep and at rest, the organ of the imagination may be in action, a condition which produces dreams;" an argument identical, as we have seen, with that brought forward in support of the doctrine by modern phrenologists. It thus appears, therefore, that when Gall promulgated his views, the doctrine of plurality of mental organs was one which had been universally admitted since the time of Galen. The only questions that arose were as to the portions of the encephalon to be allotted to each: theologians, philosophers, schoolmen, physicians, anatomists, physiologists, all adopted without question the general principle. Mr Combe is completely justified, therefore, in his conclusion, "that the presumptions are all in favour of a plurality of mental faculties manifesting themselves by a plurality of organs."[1] Modern physiologists have, however, objected to these doctrines. Dr Carpenter, for example, says that it "seems to be a fundamental error to suppose that the entire intellect can be *split-up* into a certain number of faculties; for each faculty that is distinguished by the psychologist expresses nothing else than a *mode of activity*, in which the whole power of the mind may be engaged at once,—just as the whole power of the locomotive steam-engine may be employed in carrying it forwards or backwards, according to the direction given to its action. And if this be true, it must be equally erroneous to attempt to parcel out the cerebrum [meaning the hemispheres] into distinct 'organs' for these respective faculties; the whole of it (so far as we [Dr Carpenter] can form a judgment), being called into operation in every kind of intellectual process which occupies the attention at the time."[2] The analogy drawn between the human mind and a steam-engine is rather too wide to help in the elucidation of an argument, and need not be examined, the more especially because Dr Carpenter really elsewhere expresses other and sounder views on this point. After noting the correspondence between the development of the brain, and the manifestations of intelligence in lower animals, and specially the "very decided evidence furnished by the great enlargement of the cerebrum [the hemispheres], and the corresponding alteration in the *form* of the cranium, which present themselves in those races of dogs most distinguished for their educability," Dr Carpenter adds, "This general inference, drawn from comparative anatomy, is borne out by observation of the human species. When the cerebrum [cerebral hemispheres] is fully developed, it offers innumerable diversities of form and size among various individuals; and there are *as many diversities of character.* It may be doubted if two individuals were ever exactly alike in this respect."[3] We have placed within brackets an interpolation of the meaning of the word cerebrum in accordance with one of the senses in which it is used by the writer. Dr Carpenter evidently means to say (in common with the best of modern neurologists), that the hemispheres of the brain of man and the higher animals present as many diversities in form and size as there are diversities of individual character. Now, the phrenologists say no more, except that they have carefully observed, and to a certain extent determined by observation, the relations which these diversities in the form and size of the hemispheres bear to the diversities in the characters of individuals. We may add, that one of the most distinguished of living physiological psychologists fully admits the phrenological doctrine of plurality of faculties and organs, although he is by no means in favour of phrenology generally. "The phrenologists rightly regard it as probable," Sir H. Holland remarks, "or even as proved, that there is a certain plurality of parts in the total structure of the brain corresponding to, and having connection with, the different intellectual and moral faculties. The undoubted natural diversity of these faculties makes this probable, seeing that we must regard a certain organization as ministering in the present life even to the higher powers of our nature. The partial and varying effects of accident, disease, or other less obvious change in the brain, in producing derangement of the mental functions, furnish more direct evidence, and such as we cannot refuse to admit."[4]

On the side of modern psychology, we have equally strong testimony. Mr Herbert Spencer, one of the most profound thinkers of the day, remarks,—"No physiologist who calmly considers the question in connection with the general truths of this science can long resist the conviction that different parts of the cerebrum subserve different kinds of mental action.. Localization of function is the law of all organization whatever; separateness of duty is universally accompanied with separateness of structure; and it would be marvellous were an exception to exist in the cerebral hemispheres. Let it be granted that the cerebral hemispheres are the seat of the higher psychical activities; let it be granted that among those higher psychical activities there are distinctions of kind, which, though not definite, are yet practically recognisable; and it cannot be denied, without going in direct opposition to established physiological principles, that these more or less distinct kinds of psychical activity must be carried on in more or less distinct parts of the cerebral hemispheres. To question this, is not only to ignore the truths of physiology as a whole, but especially those of the physiology of the nervous system."[5] Mr Spencer further adds,—"either there is some arrangement, some organization in the cerebrum, or there is none. If there is no organization, the cerebrum is a chaotic mass of fibres incapable of performing any orderly action. If there is some organization, it must consist in that same physiological division of labour in which all organization consists; and there is no division of labour, physiological or other, of which we have any example, or can form any conception, but what involves the concentration of special kinds of activity in special places."

Now, although phrenology thus rightly connects those operations of the mind, or states of consciousness which are intellectual in their nature, with special centres of activity situate in the hemispheres, is it equally correct in placing the mere propensities or instincts, *i.e.*, when devoid of ideas, exclusively in the same category? We think not, for it has been clearly shown, from arguments founded on the comparative anatomy and pathology of the encephalic structures, that this portion of the phrenological organology is very doubtful, and more particularly as to the seat of the sexual instinct, although we are not at all clear that doctrines like those of Dr Carpenter (certainly not new) are more valid.[6] Just as Gall and Spurzheim used the term *medulla oblongata* in a more limited sense than preceding

anatomists, and thereby gave rise to discrepancies of opinion and to novelties of doctrine more apparent than real; so, it is to be feared, will be the case with Dr Carpenter's peculiar and varying use of the terms "cerebrum" and "brain," to which we have previously referred. If we must have a change in terms, the philosophical nomenclature of Professor Owen or Lamarck is the most in accordance with the laws of development of the encephalic structures. Lamarck termed the hemispheres the *hypocephalon*, and the ganglionic structures below them the *cephalon* or brain proper, inasmuch as these are to be found in all vertebrate animals, and are essential structures, while in man and others the hemispheres are only superadded or superimposed structures.[1] A classification of the convolutions, first begun by Gall, and carried out by his disciples, has been attempted by some of the most distinguished physiologists of the day,—viz., MM. Foville, Leuret, and Owen. It is very probable that a more philosophical application to phrenology of recent discoveries in comparative neurology will ultimately force on a modification of its organology as to the mere instincts. In especial, the doctrines of Willis on this point will perhaps have renewed attention and development given to them. When the phrenologist takes a larger grasp of this part of his system, and brings more comprehensive methods of psychological analysis and of physiological research to bear upon it, he will be better able to reconcile conflicting facts and conclusions. In particular, it will probably be found that the instincts and propensities have a two-fold relation to the organism, so that when manifested in connection with higher psychical states (as they almost always are in man), they are in relation with changes both in their own special or primary seats (the brain proper), and in the superadded structures (the hemispherical convolutions) the seat of the higher psychical faculties. Perhaps it will some day be proved that the several layers of gray and white matter which make up the hemispherical ganglia have themselves distinct functions, as ganglionic and conducting tissues. It is generally admitted that Baillarger's arrangement of six layers,—namely, three gray and three white—is well founded, while Baillarger himself is inclined to adopt the views of Foville and Gratiolet, who have shown that there is a seventh layer, one of white or conducting matter, accompanying the innermost layer of gray matter throughout its whole extent.[2] We might add more on this head, but it is obvious enough already that much has yet to be done before mental organology can be placed on a satisfactory foundation.

The Dynamics of Phrenology.—The neurological anatomy generally of phrenology does not differ in any essential respects from the doctrines of neurologists generally, or at least more than these differ from each other. Having indicated the special points of difference, we need only refer to Mr Solly's valuable work on *The Human Brain* as an admitted text-book of phrenologists in other respects. We now proceed to examine the dynamics or cerebral physiology of phrenology. It is a fundamental principle that *power* of mind is, *cæteris paribus*, dependent upon *size* or development of the cerebral hemispheres; and since what is true of the whole must be true of the parts, it follows that the power of special faculties is also, *cæteris paribus*, dependent on the size of special organs, *i.e.*, portions of the hemispheres. No principle of phrenology has been more controverted than this, yet it is one upon which there is a singular unanimity amongst all classes of observers, whether popular, psychological, or physiological. A talented modern metaphysician remarks, in summary of the teachings of all the most distinguished physiologists,—"There is an indisputable connection between size of brain and the mental energy displayed by the individual man or animal. It cannot be maintained that size is the only circumstance that determines the amount of mental force; *quality* is as important as quantity, whether in nerve, muscle, or any other portion of the animal structure. But just as largeness of muscle gives greater strength of body as a general rule, so largeness of brain gives greater vigour of mental impulse."[3] This, the doctrine, we repeat, of all the best physiologists, is none other than the doctrine of all the phrenologists. Yet, when enunciated by them, it has usually been treated with derision, or if seriously controverted, controverted most usually on false premises, or on a false statement of the doctrine,—as, for example, that phrenology teaches that size corresponds absolutely to manifestation. But those physiologists, strange to say, who controvert the doctrines when applied by phrenologists to the hemispheres, adopt it themselves when they wish to demonstrate the functions of other portions of the encephalon. It is particularly from the facts of comparative anatomy that evidence can be deduced as to the functions of the complicated encephalon of man; and it is upon these, with especial reference to *size* or extent of organic development in lower animals in relation with *manifestation*, that the latest views as to the functions of the cerebellum and of the cerebral ganglia are founded. Now, the method of research applicable to various portions of the encephalon generally is equally applicable to the various portions of the hemispheres. If size of portions of the encephalon, taken in correspondence with energy of psychical manifestation, indicates in lower animals the functions of those portions of the encephalon, surely the size of portions of the hemispheres, taken in correspondence with energy of mental manifestation, indicates the functions of those portions, and proves the law of *energy = size*. Hence it must be conceded to the phrenologists that the law, *within the limits* and *under the conditions laid down*, is founded on both facts and general principles.

Laws of Action of the Brain as the Organ of Mind.—The phrenologists do not differ from neurologists in general as to the laws and modes of action of the nervous system, except in so far as they differ on points of anatomy or organology. Gall and Spurzheim had the duty of combating errors as well as of developing truths. In this particular they were of great service to neurology, inasmuch as by uprooting errors they cleared the ground for the more accurate views of the functions of the nervous system recently promulgated. It is certain, however, that being so fully occupied with their new views as to the anatomy and organology of the encephalon, they neglected any deep inquiries into its laws of functional activity, and in particular omitted to apply the general laws of nervous action, first lucidly developed by Unzer, then summarized and extended by Prochaska, and in more recent times resuscitated, and very ably applied by Marshall Hall to the pathology of the *medulla spinalis* and encephalon, as far as the *tubercula quadrigemina*. The early cultivators of phrenology, however, taught the important general doctrine, that the modes of action of the organs are instinctive in their nature. In September 1844 Dr Laycock read a paper before the British Association for the Advancement of Science, in which he showed that the laws of reflex action were not limited to the *sensorium commune*, as held by Prochaska, nor to the spinal system as Dr Marshall Hall then taught, but were the laws of action of the instincts and of every por-

[1] *Philosophie Zoolog.*, tom. ii., p. 223. His words are, "Or, cet *hypocephale* est l'organe spécial dans lequel se forment les idées et tous les actes de l'intelligence; et le *cerveau* proprement dit, cette partie de la masse médullaire principale que contient le centre de rapport des nerfs, et à laquelle les nerfs des sens particulier viennent de réunir, ne sauroit lui seul donner lieu à de semblables phénomènes."

[3] *The Senses and the Intellect*, by Alexander Bain, A.M., 1855, p. 11.

tion of both the cerebro-spinal and sympathetic systems.[1] Dr Laycock subsequently developed his doctrines so as to demonstrate their application to the fundamental laws of consciousness and thought.[2] In 1845 Mr Combe applied Dr Laycock's discoveries to an elucidation of the modes of action of the cerebral hemispheres, according to the phrenological doctrines, but more especially showing their capability of explaining the production of the natural language of the faculties, and the nature of the various forms of impulsive insanity.[3] Some years subsequently (1853) Dr Carpenter also adopted Dr Laycock's views, and gave them a special application to those various states which agree in the common characteristic of mental activity without volitional control, and which he designated by the unfortunate phrenological[4] term of unconscious "cerebration."[5] Dr Carpenter has, however, added to the doctrines the theories of Willis and Lamarck as to the so-called "sensory ganglia" Later psychological writers of great eminence have referred to Dr Laycock's views, and noted their value in explaining the laws of cerebral action in mental operations. On the doctrines thus put forward by Dr Laycock, Mr Morell remarks:—"We certainly see in them the most complete co-ordination established between psychology and physiology in the widest extent."[6] Now, since the very foundation of phrenology is mental organology, this exhaustive co-ordination between physiology and psychology is of fundamental importance to its further development; and that, whether we consider phrenology as a new system of philosophy or of cerebral physiology. This new field of mental dynamics the scientific phrenologist should therefore cultivate.

Phrenological Psychology and Physiognomy.—The middle and close of the eighteenth century, until the outbreak of the French Revolution, was a period remarkable for the culture and development of neurology and physiological metaphysics. Stahl had given the latter a great impulse by his revival of the Aristotelian doctrine of the soul, and his application of it to the phenomena of healthy and morbid action, and the treatment of disease. After the promulgation of the Stahlian doctrines, neurological anatomy and physiology were widely cultivated, especially in Germany. During the period named, Pfeffinger, Haase, Lobstein, Metzger, Sömmering, Meckel, Hirsch, Wrisberg, Boehmer, Asch, Bang, Andersch, Murray, Bose, Platner, Brunn, Heineken, Behrends, Ludwig, Ebel, Isenflamm, Thaer, Ploucquet, Baur, Zinn, and others, investigated the anatomy, physiology, and pathology of the nervous system, some of whom have left their names connected with their discoveries.[7] Very distinguished systematic writers also flourished during this period, as Albinus, Winslow, Vieussens, Haller, Bonnet, Unzer, Prochaska, Vicq d'Azyr, and others. Gall pursued his medical studies in the midst of all this struggle after a knowledge of the anatomy and physiology of the nervous system, for, being born in 1757, he would probably be at the university of Vienna about 1777. His first attempts at observation were purely physiognomical. He found himself excelled in powers of memory of words by fellow-students and schoolmates who had prominent eyes. After much reflection, he conceived that if a memory for words was indicated by an external sign, the same might be the case with the other intellectual powers; and thereafter all persons distinguished by any remarkable faculty became the object of his attention. He thus became acquainted with individuals remarkable for the determination of their character, and he observed a particular part of their heads to be very largely developed. This fact first suggested to him the idea of looking to the head for signs of the dispositions or affections. Gall at first therefore endeavoured to establish a cranial physiognomy, and in this respect was a follower of Lavater, then popular: it was only after a more extended study that he was convinced of the need to investigate the anatomy and physiology of the brain. "In every instance," says Mr Combe, "where an individual whose head he had observed while alive happened to die, he requested permission to examine the brain, and frequently was allowed to do so; and he found, as a general fact, that on removal of the skull, the brain, covered by the *dura mater*, presented a form corresponding to that which the skull had exhibited in life." This general principle being established, it necessarily followed that, if the mental character corresponded to a particular form of skull, or a predominant faculty to a special development of a portion of it, the character or the faculty was manifested in connection with a particular development of the brain; and the solution of the problem put by philosophers and physiologists, from Aristotle downwards, became possible. Thus, by the method of observation and induction, Gall built up his physiognomical system, which professes to supply the elements for determining the mental character from the form of the head. His psychology was perhaps the weak point in his doctrines; for he had to shake off the trammels of the old philosophy in which he had been educated. This led in particular to a less definite application of the conclusions to be drawn from pathological phenomena, as local diseases or injuries of the brain, and morbid developments of it in idiots, imbeciles, the insane, and incorrigible criminals.

Psychological Arrangement of Phrenology.—Gall's psychology, as well as his first physiognomical conclusions, although founded upon researches continued through many years, were subsequently modified to a great extent; in the first instance by himself, on the acquisition of fresh data, afterwards by his disciples, more especially Spurzheim. Individual phrenologists differ to the present day as to the number of the faculties and the locality of the corresponding organs; and it is acknowledged by all that more remain to be discovered. There are certain general principles, however, which appear to be settled. The term *faculty* is used by them "to denote a particular power of feeling, thinking, or perceiving, connected with a particular part of the brain." (Combe.) "A faculty is admitted as primitive—1. Which exists in one kind of animal, and not in another; 2. Which varies in the two sexes of the same species: 3. Which is not proportionate to the other faculties of the same individual; 4. Which does not manifest itself simultaneously with the other faculties,—that is, which appears or disappears earlier or later in life than other faculties; 5. Which may act singly; 6. Which is propagated in a distinct manner from parents to children; 7. Which may singly preserve its proper state of health or disease."[8] Spurzheim largely modified Gall's arrangement of the primitive faculties (which was almost wholly empirical), and from time to time altered his own, until finally, in 1825, he fixed upon the psychological arrangement now generally adopted by phrenologists of the present day, although admittedly imperfect. He placed the faculties in two orders, corresponding to the feelings and the

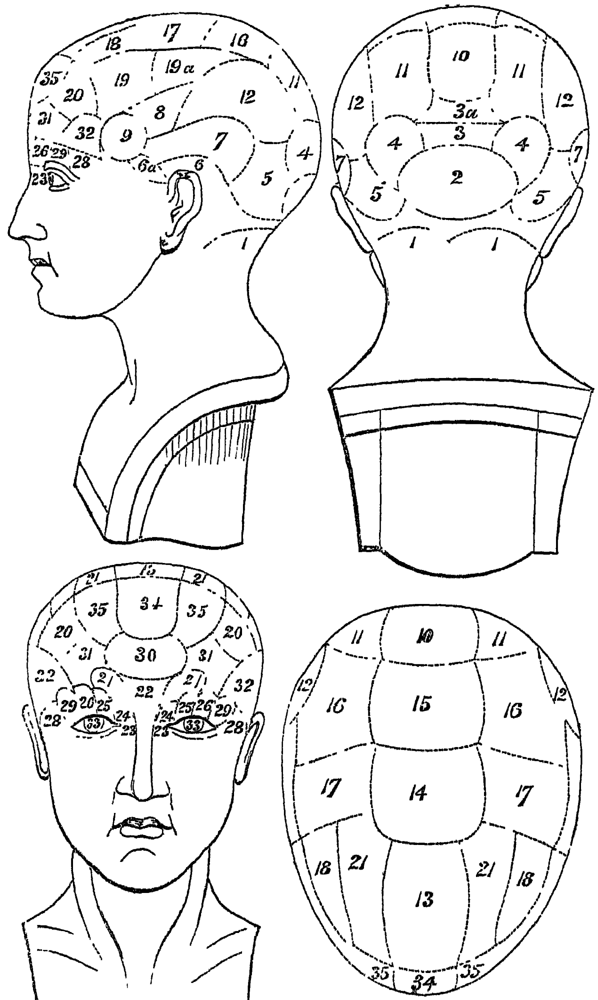
intellectual powers of metaphysicians in general, and termed them the *affective* and the *intellectual* faculties. The feelings were arranged in two genera,—those of the propensities and the sentiments. A propensity is an "internal impulse," which impels only to certain actions; in common language, is an instinct. A sentiment is an internal impulse or inclination to action, with an emotion superadded; in common language, an emotional instinct, emotion, or passion. Acquisitiveness, for example (a propensity), is the mere impulse to acquire. Veneration (a sentiment) gives a tendency to worship, accompanied by a particular emotion, which latter quality is the reason of its being denominated a sentiment.[1] The intellectual faculties make us acquainted with objects which exist, and their qualities and relations. Spurzheim divided them into four genera: "The first includes the external senses and voluntary motion; the second, those internal powers which perceive existence, or make man and animals acquainted with external objects and their physical qualities; and the third, the powers which perceive the relations of external objects. These three genera are named *perceptive faculties*. The fourth genus comprises the faculties which act on all the other powers—which compare, judge, and discriminate; these are named the *reflective faculties*.[2] Complex faculties, sentiments, and propensities arise out of combinations (in excess or defect) of the primitive. Veneration, Hope, and Wonder in normal combination constitute the sentiment of religion; if in excess, of superstition. Large Acquisitiveness and Secretiveness will constitute the propensity to steal, if Conscientiousness and the reflecting faculties be defective; if these be large, they will constitute good elements in a noble character. This psychological arrangement may be considered as the basis of a system which is wholly independent of organology, or even of cerebral physiology. Considered as simply a system of metaphysical nomenclature, many are disposed to agree in opinion with Archbishop Whately, who thinks that, as such, it is "far more logical, accurate, and convenient, than those of Locke, Stewart, and other writers of their school."[3]

Physiognomical Arrangement of the Organs of the Faculties.—Each faculty, or group of faculties, has a corresponding portion of cerebral matter allotted to it. With the exception of the sexual instinct, this consists in certain convolutions of the hemispheres. The skull being moulded upon the convolutions in youth and middle age (though not in old age or in cerebral atrophy, when the convolutions shrink, but the cranium remains unchanged), it is practicable at these ages to mark out on the surface of the head the size and extent of the organs of the faculties,—*i.e.*, to form a chart of the development of the various convolutions. We subjoin a phrenological chart of this kind,[4] as well as a psychological arrangement of the organs, the numbers of which correspond to the numbers of the chart:—

Order I.—Feelings.

Genus 1.—*Propensities common to Man with the Lower Animals.*

1. *Amativeness.* Sexual love, instinct, feeling.—2. *Philoprogenitiveness.* Parental affection for young, affection for young and tender beings. *Abuses*—Pampering and spoiling children, foolish affection for pet animals.—3. *Concentrativeness.* Gives the desire of permanence in place, renders permanent emotions and ideas in the mind. *Abuses*—Aversion to move abroad, morbid dwelling on internal emotions and ideas to the neglect of external impressions. —3 *a. Inhabitiveness* A modification of the preceding and following, but the organ doubtful.—4 *Adhesiveness.* Attachment to persons, friendship, love of society; generally strong in women. *Abuses*—Attachment to worthless individuals, union for worthless ends.—5. *Combativeness.* Courage to meet danger and to overcome difficulties; propensity to oppose and attack whatever excites opposition, and to resist injustice; enables man to meet difficulties and dangers. *Abuses*—Love of contention, and propensity to provoke and assault. —6. *Destructiveness.* Desire to destroy noxious objects, or for the well-being of the individual (as to food, clothing, &c) *Abuses*—Cruelty, murder, anger and severity in conduct and language.—



6 *a Alimentativeness*, or appetite for food. *Uses*—Nutrition. *Abuses*—Gluttony and drunkenness. This is also the supposed site of the organ of *Love of Life*.—7. *Secretiveness* Propensity to conceal the person, or the thoughts, words, and actions; an ingredient in prudence. *Abuses*—Lying, deceit, duplicity, cunning.—8. *Acquisitiveness* The desire to possess, and propensity to accumulate articles of utility, to provide against want *Abuses*—Selfishness, avarice, theft —9 *Constructiveness.* Desire to build and construct.

Genus 2 —*Sentiments.*

(*a*) *Sentiments common to man and the Lower Animals.*—10. *Self-Esteem.* Self-respect, self-interest, love of independence, personal dignity. *Abuses*—Pride, disdain, love of dominion, overweening conceit, great selfishness —11. *Love of Approbation.* Desire to obtain the esteem of others, to acquire fame, praise. *Abuses*—Ambition, vanity, thirst for unmerited praise.—12. *Cautiousness.* The desire to shun danger, circumspection, prudence. *Abuses*—Undue fear, excessive timidity, unfounded apprehensions, despondency.—13. *Benevolence.* Desire to give happiness to others, mildness of disposition, universal sympathy and charity. *Abuses*—Profusion, injurious indulgence of the appetites and fancies of others, facility of temper.

(*b*) *Sentiments proper to Man.*—14 *Veneration.* Tendency to respect whatever is great and good, gives origin to religious adoration. *Abuses*—Superstition, love of antiquated customs, abject

subserviency to authority.—15. *Firmness.* Determination, steadiness of purpose, perseverance. *Abuses*—Stubbornness, infatuation, tenacity in evil.—16. *Conscientiousness.* Sentiment of justice, respect for the rights of others, openness to conviction, the love of truth. *Abuses*—Ignorant adherence from conscientious motives to noxious principles, excessive refinement in views of duty and obligation, excessive remorse or self-condemnation —17. *Hope.* Tendency to expect future good, sentiment of faith. *Abuses*—Credulity as to attainment of things desired, absurd expectations.—18 *Wonder.* The desire of novelty, admiration of the new, the unexpected, the surprising *Abuses*—Love of the marvellous and occult, belief in false miracles and supernatural absurdities.—19. *Ideality.* Love of the beautiful and splendid, desire for excellence; the poetic feeling. *Abuses*—Absurd enthusiasm; preference of the fanciful, showy, and glaring, to the neglect of the duties of life.—19 *a.* The function of these convolutions is not yet determined.—20 *Wit.* The sentiment of the ludicrous, feeling of mirth —21. *Imitation.* Disposes to copy the manners, voice, actions of others, and the appearances in nature generally.

ORDER II.—INTELLECTUAL FACULTIES.

GENUS 1.—*The External Senses.*

GENUS 2.—*Knowing Faculties.*

(*a.*) *Knowing Faculties which perceive the Existence and Qualities of External Objects.*—22. *Individuality.* Takes cognisance of existence and simple facts —23. *Form.* Renders man observant of form of objects.—24 *Size* Gives the idea of space, and the power to appreciate dimension and distance.—25. *Weight.* Communicates the perception of momentum, weight, and resistance; aids equilibrium.—26 *Colouring.* Takes cognisance of colours and their harmonies.

(*b.*) *Knowing Faculties which perceive the Relations of External Objects.*—27. *Locality.* Gives the idea of direction in space.—28. *Number.* Gives the talent for calculation —29. *Order.* Communicates the love (or the power) of physical arrangement —30. *Eventuality.* Takes cognisance of occurrences or events —31. *Time.* Is the faculty of perceiving duration.—32. *Tune.* Is the source of melody and harmony.—33. *Language.* The faculty of acquiring a knowledge of arbitrary signs to express thoughts, of inventing and recollecting them, and of readily using them.

GENUS 3.—*Reflecting Faculties, which Compare, Judge, and Discriminate.*

34. *Comparison.* The faculty of discovering analogies, resemblances, and differences.—35. *Causality.* Traces the dependencies of phenomena, and the relation of cause and effect.

Phrenologists are not all agreed as to the details of this arrangement, and have proposed others. Dr Vimont criticises it on some points; Mr Robert Cox has published a very able and interesting essay on its defects;[1] Mr Sidney Smith, in his *Principles of Phrenology*, has some acute remarks; Mr Joshua Toulmin Smith gives an almost entirely new arrangement in his *Synopsis of Phrenology*, based on philosophical views more advanced than those of Spurzheim. It is improbable that, in the present state of knowledge, any arrangement can be made complete. The difficulties inherent in the subject itself are perhaps insurmountable. But imperfect though these conclusions may be, they are worthy of respect, as being well-tried deductions from observations made on many fields of research by numerous observers. The collections of crania, casts, drawings, and the like, in the possession of private persons or public societies, may be taken as some slight index of the extent and industry with which these observations have been made. Gall's own collection contained 354 skulls, casts of skulls, brains, &c., illustrating the phrenology of man; 120 heads of quadrupeds; and 138 heads of birds. A manuscript descriptive catalogue of this collection is amongst the MSS. in the museum of the Phrenological Society of Edinburgh. It is a copy of that drawn up by Dr Dauncey, the pupil and friend of Gall, and contains the record of the facts and correspondence of each subject, as observed by the latter.[2] The Edinburgh museum is remarkably rich in crania and casts of crania illustrative of characteristics of nations and races. Of these there are 313, besides 150 miscellaneous skulls, many of great interest. It contains also 280 busts and 100 masks of eminent or notorious individuals.

In 1817 a Mr Deville, a lamp-manufacturer of London, was a member of the institution of civil engineers. He had been originally a pot-boy, then a journeyman plasterer, and afterwards kept a shop for the sale of plaster figures, which he cast. He had risen to a respectable position simply by the force of his natural powers. Mr Bryan Donkin, a civil engineer, was an early auditor of Gall at Vienna, and subsequently a friend of Spurzheim. He was also, like Mr Deville, a member of the institution of civil engineers; and when, in 1817, he with others determined to make a collection of casts as records of phrenological facts, Mr. Deville was applied to for his assistance, which he rendered as a matter of business for three or four years. In 1821 he became interested in phrenology, and began to form a collection of casts on his own account. Already, in 1826, Spurzheim said it was finer than any he had seen elsewhere. At Mr Deville's death in 1846, this collection consisted of about 5450 pieces; of these 3000 were crania of animals, and the remainder (2450) illustrations of human phrenology. There were 200 human crania, and 300 casts of crania; amongst the latter, those which Baron Cuvier permitted Mr Deville to take from all the authenticated human skulls in the Museum of Comparative Anatomy of Paris. Mr Deville was a practical observer, and possessed the large number of 1500 casts of heads taken by himself from persons while living. Amongst these were 50 casts of persons remarkably devoted to religion; 40 of distinguished painters, sculptors, architects, &c.; 30 of eminent navigators and travellers; 80 of poets, authors, and writers; 70 of musicians, amateurs, and composers of music; 25 of pugilists; 150 of criminals; 120 pathological cases illustrative of insanity, &c. Perhaps the most interesting of all are 170 casts which illustrate the changes caused in the cranial conformation of from 60 to 70 individuals by age, special devotion to one pursuit, and the like. Mr Deville's account of some of these has been published.[3] Other instances of this kind may be mentioned. Dr Vimont, a disciple of Gall, and the author of an important work (*Traité de Phrenologie Humaine et Comparée*), saw that the illustrations which Gall drew from comparative anatomy and psychology were too few and too imperfect. He therefore resolved to develop this branch of phrenology; and in 1827, when competing for the prize for physiology of the French Institute, sent in a "few fragments" of his researches in this direction. His Memoir was accompanied by 2500 crania of animals; 1500 of these belonged to animals the manners and habits of which were well known to him. In addition, there were 400 wax models of cerebra, and an Atlas of more than 300 drawings. This Memoir was the basis of his great work; and the Atlas of 120 plates (folio) which accompanies it contains 600 separate drawings, all beautifully done. Again, Dr S. G. Morton of Philadelphia has a collection of skulls, human and comparative, made for the purpose of comparing the characters of the skulls of the different races of men, and these again with the skulls of lower animals, more especially with reference to the internal capacity of the cranium, as indicative of the size of the brain. This collection contained in 1841 above 1000 crania, of which more than five hundred were human skulls. One hundred of these belonged to ancient Egyptians, the same number to native-born Africans, and a still greater number to ancient Peruvians, Mexicans, and nomade Indians of the American continent. It was this collection which sup-

plied the materials for Dr Morton's magnificent work, *Crania Americana*.

Modes of Determining the Size and Activity of the Organs.—In practically determining whether the organs thus indicated externally are present in any person, the phrenologist depends primarily upon the size of the cranium, or extent of certain portions of it—considering that the bony covering corresponds (with certain recognised exceptions) to the contained viscus in its subdivisions, both in magnitude and form. Various instruments have been invented, and rules are laid down, both for measuring the size of organs and for avoiding the fallacies into which the observer may fall, in consequence of anatomical or pathological conditions interfering with the determination of size, or the universal application of the general law of size=power. Thus the development of the frontal sinuses, the differences coincident with age and size in the development of the skull and the thickness of the bony parietes, the influence of morbid states of the organ, as in hydrocephalus and the like, are examples of sources of fallacy against which the phrenological observer must guard.

Nor, when he has at last accurately determined the dominant size of an organ, does the practical phrenologist draw absolute conclusions therefrom. The organ is but living tissue, liable to be influenced in power and functional activity by various vital conditions, of which he takes a due estimate. The following are the points to be attended to phrenologically in estimating the value of size of a cerebral organ with reference to functional activity:—(*a.*) The temperament of the individual modifies the power or activity, so that in a person of lymphatic temperament there will be no more manifestation of a faculty with a large organ, than in a person of a neuro-bilious temperament (more active) with a moderate or even small organ. It is therefore necessary to mark well the difference between power and activity in reference to both size and temperament. (*b.*) Conditions of the organ as regards *health* have great influence. In mania, very forcible manifestations may proceed from a brain or an organ unusually small. In old age, atrophy or disease is not uncommon. (*c.*) Education or activity increases the size, and therewith the power of an organ; it may also increase the activity by improving or modifying the condition independently of size. (*d.*) The combination of two or more organs may increase the power or force of manifestation of a faculty. (*e.*) The combination of temperament or quality, of size, and of exercise, may have a greater effect than each singly, or any two in combination; and this effect is still further intensified if two or more organs so modified act together. "Thus, in playing on a musical instrument, the organ of Time co-operates with the organ of Tune; and the music will be good or bad in proportion to the perfection of *both* organs in point of *constitution, size,* and *exercise.*" (Mr Combe.) (*f.*) There are circumstances as yet unknown which modify the *condition* of the brain. "We are not at present acquainted with the external signs of the highest of all qualities of brain which, when combined with adequate size, constitutes genius; whether it consists in an extraordinary development of the gray matter, in a peculiar fineness of constitution, or in some other form of endowment of the brain, we are uncertain."[1] There are also other circumstances, as habits, age, sex, race, and the like, which must be taken into account in estimating the relations of organ to manifestation of faculty.

Every faculty of the mind, and every state of consciousness, is represented in the facial movements, or in the general movements of the head, trunk, limbs; *i.e.*, it is signified in expressions and attitudes. If, then, these be considered as a language, and duly read, or, in other words, if physiognomy proper be brought in as an aid, the observer may be directed in his observations by the predominant attitudes, &c. These are termed by phrenologists the natural language of the faculties. "The laugh of Destructiveness is bitter, and that of Self-Esteem is scornful; that of Benevolence is soft and pleasing, that of Love of Approbation is insinuating, that of Secretiveness is sly. . . . . The crying of a child animated by an injury which has roused its Destructiveness is quite different from that of one excited to cry by mortified Love of Approbation. . . . . When the organ of Self-Esteem predominates in size over all other organs, it gives a cold, selfish, imperious air to the individual. He carries his head high, his look is full of disdain, and his walk and speech are solemn and pretentious."[2] This natural language is also used for determining the locality of organs, because, according to Spurzheim and his disciples, "the motions are conformable to the seat of the organs. If, for instance, a faculty, the organ of which is situated in the posterior part of the brain, be active, the general motions are backward; and if its organ be in the forehead, then the motions are forward."[3] In the portraits of Sterne, this principle of the phrenologists is said to be illustrated by the attitude in which that humourist is painted; he sits leaning on his hand, with his fore-finger resting over the organ of Wit.

Combinations of the Faculties.—These occur in varying extent in all forms of mental action: two or several may be predominantly active or powerful; few, if any, act singly. The action of the faculties or organs in combination is a very important branch of phrenology. Gall divided men into six classes, with leading characteristics founded on the combinations of organs or faculties into groups. For example,—1. Individuals with the organs of the highest faculties and qualities completely developed, while those of the faculties man has in common with lower animals (the mere animal organs) are small, present a high type of moral character. Their conduct is in accordance with reason and justice. 2. Men with a converse development are more allied to the animal; they are the slaves of sensuality and error. 3. If the organs of both groups are large, the man often manifests the most opposite qualities; there is often a struggle between the higher and lower sentiments and motives of human nature: "the flesh lusteth against the spirit." 4. Certain organs are sometimes highly developed, while others are at par or a maximum. This class includes men of great but partial genius, or of great strength of character. 5. Or there may be men of general ability, but with some marked deficiency of mind or feeling. 6. And lastly, in the sixth class are the average of mankind, with a moderate and nearly equal development of all the organs. There are also combinations in *activity* as well as of size. It is evident that these combinations of organs may vary almost *ad infinitum.* The six classes above given Dr Gall allows "are subject to thousands of modifications."[4] Mr Combe tried to state in methodical order the effect of the combinations so far as observed, but found it to be so difficult that he contented himself with setting forth three rules to be followed, appending copious illustrations to each. "The reader," Mr Combe observes, "in whom the reflecting organs are amply developed will not only easily comprehend the rules here laid down, but be able greatly to enlarge the sphere of their application."

Regional Phrenology.—Now, this physiognomy of groups of allied or related organs is one of some special interest, not only because certain modifications of the doctrine of Gall have been founded on it, but also because of its important bearings upon ethnology. Observers finding that the discrimination of special organs is far more difficult,

[1] *Phrenology applied to Painting and Sculpture*, by George Combe, 8vo, 1855, p. 101.
[2] Mr Combe, *op. cit.*, pp. 75, 76.
[3] *Phrenological System*, p. 269.
[4] Mr Combe's *System*, &c., vol. ii., p. 297.

and the results much more unsatisfactory than that of groups of organs, have turned their attention to a few large regions of the head. Many who oppose phrenology as it is in its details, admit freely that the development of certain cranial regions is coincident with certain definite manifestations of character, both individual and ethnic. They admit the connection, *e.g.*, of intellectual power with well-developed anterior convolutions—of the higher sentiments and emotions with the middle convolutions—of the instincts and propensities with the posterior and basic; or, more definitely (with a distinguished anatomist and physiologist, Dr Carus of Dresden), they divide the head into distinct *regions* rather than *organs*, and assign faculties, feelings, instincts, to the corresponding regional portions of the encephalon. This may be termed *regional phrenology*. Dr Carus' views attracted a good deal of attention at the time he published his *New Cranioscopy*, in opposition to that of Gall and Spurzheim.[1] They are founded mainly upon the laws of development of the nervous system in vertebrates, or rather upon comparative psychology in relation to the comparative anatomy of the brain. He divides the head from before backwards into three regions, making the auditory foramen the starting-point of each line of demarcation. Mr Combe rejects Dr Carus' doctrine, but, like him, also divides the head into three regions. The first includes the organs of the intellectual faculties (*vide* chart); the second, the moral and religious sentiments peculiar to man; the third, the sentiments and propensities manifested by him in common with the lower (vertebrate) animals. Mr Combe has laid down rules for measuring these regions.[2] Mr Morton proposes, and has followed another method.

Ethnographical Phrenology.—Phrenology has investigated the coincidences between the natural talents and dispositions of nations and the development of the organ of mind. These ethnological researches are, indeed, amongst the most interesting of phrenology, and have an important bearing upon diplomacy, legislation, and the art of government. Regional physiognomy has been most used in this department. As we have no space for the examination of the questions mooted, we simply refer the reader to the works of Gall, Spurzheim, Combe, Vimont, &c.

Comparative Phrenology.—We have seen that the same method of research has often been applied to the higher vertebrate animals (mammals and birds) as to man. A comparative phrenology supplementary to, and corroborative of, human phrenology, has been the final result. Dr Spurzheim states that the heads and skulls of birds which sing and of those which do not sing, and the heads of the different individuals of the same kind which have a greater or less disposition to sing, present a conspicuous difference at the place of the organ. The heads of males, for instance, and those of females of the same kind of singing birds are easily distinguished by their different development.

Gall seems to have compared the skulls of animals of *different* species, with a view to determine the situation of an organ. His disciples have objected to this method as unphilosophical,—animals of the *same* species should alone be compared. Dr Vimont of Paris is the most recent and able investigator of the cranial physiognomy of animals, and is justly regarded by phrenologists as the highest authority. He has been led by direct observations to the opinion, that the cranial conformation is as indicative of the feelings, instincts, and faculties of mammals and birds, as it is of those of mankind. In the Atlas to his elaborate work already noticed, Dr Vimont gives cranioscopic charts of dogs and birds. Birds, of all vertebrates, he states, have the most regular cranioscopical development.

Applications of Phrenological Doctrines.

In his lucid and acute criticism of phrenology, Mr G. H. Lewes remarks that it has two distinct aspects. "It is a doctrine of psychology, and it is an art of reading character. The scientific doctrine is based on the physiology of the nervous system, to which is added psychological analysis and classification. The art is based on empirical observation of coincidences between certain configurations of the skull and certain mental phenomena."[3] These two aspects comprise two corresponding groups of applications of phrenology, which are really independent of each other. The scientific doctrines are capable of application deductively, although no special observations be made as to the configuration of the skull; they may be held to constitute the basis of a system of moral and mental philosophy, with its *à priori* truths, in which the physiognomical element is secondary. On the other hand, the art may be, and most usually is, practised without much, and sometimes with very little, knowledge of the scientific doctrines. Hence it is necessary to distinguish clearly between these two applications.

1. *Applications of Phrenology to Philosophy and Mental Science.*—To phrenology may be fairly conceded the grand merit of having forced the inductive method of inquiry into mental philosophy, and thus laid the permanent foundations of a true mental science. For two thousand years or more philosophy had ignored in all its various systems the great fact, that in the order of nature there is no consciousness manifested without a material organ. Two principles of inquiry arose out of this circumstance, and still continue their influence:—(*a.*) It is denied that the phenomena of consciousness are dependent at all upon organization. No physiology ever can explain, or help to explain (it is held), one purely mental phenomenon. Its analogies may sometimes suggest a mental law, but that at most is all it can do. Thought and the laws of thought can only be studied in self-knowledge. This is the actual teaching of an existing sect of philosophy; and all who attempt to investigate the necessary connection of mental and vital phenomena are stigmatised and repudiated by it as "materialists,"—a term implying, in their vocabulary, not only scepticism as to their philosophy, but heterodoxy as to the principles of sound morals. (*b.*) Another sect admits that mind is in some way or other connected with organization; but they hold, either that the nature of that connection is much too difficult and mysterious for investigation, or they admit the principle to be only partially true, and that the higher mental phenomena of man have no necessary connection with organization. Hence the practical result of both classes of doctrines has been to exclude the anatomy and physiology of the brain from the science of Thought. Now Gall and his disciples, in starting from their fundamental generalization that the phenomena of consciousness have all, necessarily and without any exception whatever, their corresponding phenomena in the living organism, established the other principle, that psychological and neurological researches, to be successful, must be inseparable. Deductions from the mere phenomena of consciousness, they affirm, can never establish singly a science of mind, because these phenomena are ever changing from moment to moment with the ever-varying conditions of the living organism, and especially of the encephalon. A knowledge, therefore, of the physiology of the encephalon is absolutely necessary to a knowledge of mind. This is the primary and fundamental application of phrenology to mental philosophy. "We may point to Gall," Mr Lewes therefore justly observes, "as having formed an epoch in the history of philosophy by inaugurating a new method."[4] This new method soon

1 *Grundzüge einer neuen und wissenschaftlich begründeten Cranioscopie*, von Dr Carl Gustav Carus, &c., Stuttgart, 1841.
2 In Morton's *Crania Americana*, p. 278. 3 *Biographical History of Philosophy*, p. 634. 4 *Op. cit.*, p. 645.

cleared away some of the useless questions of speculative philosophy. It established the principle, that there are connate tendencies or faculties, both affective and intellectual, which are inseparably connected with the structure that serves as the organ of mind. But it also established that other principle, that if the organ is not developed, or, if developed, not rendered functionally active by the appropriate stimuli, the faculty is not manifested. Hence, while phrenology taught the plurality of organs and of faculties, it also taught that the fundamental faculties cannot be created by education; they can only be evolved or developed by it.

Phrenology, as we have seen, founded upon these great principles a new theory and classification of the faculties. It attempted to discriminate between those which are simple and fundamental, and those which are complex or secondary—the result of two or more of the fundamental faculties acting in combination; and it pointed out what states of consciousness were attributes of all the faculties. Thus, pain or pleasure is an attribute of all the faculties; memory of all those that are intellectual, and dependent wholly upon the condition of the respective organs: judgment is the same. With this new classification a new but imperfect terminology was constructed, the terms of which have penetrated into the literature and language of the present day. As a system of practical philosophy, or of practical mental science, phrenology teaches those laws by which man exists and acts as a rational being, and maintains that he can only be governed and educated in accordance with those laws. It professes to discover the varying capabilities of races of men for civilization; or, in other words, their innate capacity for instruction and development, and thereby indicates the general principles of government as applicable to races. It maintains that men must be educated with reference to the connate predominance or defect of this or that organ or faculty; that is to say, that which is naturally defective must be developed, that which is in excess repressed; so that a harmonious balance of all the powers (the *summum bonum* of mental development) may be attained. External circumstances of parents or of offspring involving the health, or a long persistence in the exercise of some or one of the faculties,—such as minister to theft, licentiousness, gluttony, and the like,—will lead to the disturbance of this balance. These circumstances must be anticipated and obviated by society; and when individuals are plainly governed by an over-mastering faculty, and thus led into crime, they must be restrained by society, and put into circumstances such that they may be enabled to exercise a self-control. In other words, an enlightened prison discipline can only be based safely on phrenological doctrines. Healthy action of the organs is necessary to healthy manifestation of the faculties. Hence the laws of hygiene, deduced from an accurate physiology and the facts of experience, must be applied to man's corporeal wellbeing, if we would elevate him as a thinking and moral agent. For this reason, the phrenologists are amongst the most strenuous advocates for such an education of the people as shall put every man in the position to know and apply the laws of healthy existence to the wellbeing of himself and his offspring. Such culture, they also argue (and on the most irrefragable grounds), is as essential to the welfare of a nation as to the wellbeing of individuals. Without it, civilization can never advance beyond a limit which it is not impossible to trace out; with it, to fix a limit to man's progressive development would be difficult.

We will not here specify more particularly the applications of the doctrines of phrenology to theology, the arts, medicine, and domestic life. The whole subject is one beyond our plan, if it were not beyond our limits. We can only refer the reader to the systematic works of Gall, Spurzheim, Mackenzie, Andrew and George Combe, Vimont, Broussais, Caldwell, Friederich, Bray, Brigham, Sampson, and others, in which social questions are treated phrenologically. The general principles of the science thus applied are based upon an admitted science of human physiology, or on the common-sense of mankind; while the physiognomy that is used is of that regional character which few intelligent men question. It is mainly, therefore, in the conflicts of phrenology with dogmatic theology and speculative philosophy that doubts have been raised as to the soundness of its general principles and of its practical applications. With these at present we have no concern.

2. *Phrenology as an Art.*—Many animals are instinctive physiognomists. Every passion or emotion has its language, and this language can be read more or less accurately by the organism or being concerned in the reading. This, for obvious reasons, is markedly true of social animals, and most particularly of man. The history of a man's mental life is often written so ineffaceably on his features that no efforts of his can conceal from his fellow-men those lines which the workings of bad passions and of evil propensities have left. We have seen that phrenology, as a physiognomical science and art, originated in the strong desire which Gall had to read by external signs the characters of those about him. Many of his disciples—the large majority perhaps—have been attracted to his doctrines with the hope of gratifying a similar desire. It is not surprising, then, to find that what has been termed *practical phrenology*, or the art of reading character, has been the main object of culture and research since Gall, and has become, in the eyes of the public and of literary men, the principal department of phrenology,—nay, phrenology itself. Now it cannot be doubted that, amongst those persons thus attracted to phrenology, there is a large proportion who have a natural bias to physiognomical observation and research, and who therefore are endowed with those faculties which are necessary to constitute a successful physiognomist. Thus endowed, it is not surprising that they can practise the art of reading character with results for the most part so striking, as to impress both themselves and others with a strong conviction of the truth of the principles upon which the art is founded, and of the value of the methods by which it is practised. Their instinctive powers of perception, naturally great, are developed by exercise, and their conclusions corrected by the cranioscopical experience of those who have preceded them. Besides, they do not neglect, when practising their art, those other physiognomical characteristics by means of which persons, not phrenologists, can often discover with surprising accuracy the character and ruling motives of those about them. While examining the configuration of the skull, the phrenologist also observes the habit of body, gait, gestures, features, tones of voice, and facial expression of the subject of his inquiry; and it is from the results of all these observations that he determines the character. Thus the elements of a successful art of physiognomy—not necessarily phrenological—are numerous, and a higher value is placed upon phrenological physiognomy as an art, than can be fairly conceded to it if estimated independently of the skill of the artist and of the collateral aids he uses to help his conclusions.

The practice of phrenology having mainly fallen into the hands of a sort of professional body, the members of which claim for it and for themselves, without any special education, a larger share of public confidence than they are entitled to have conceded to them, its pretensions have undergone every form of criticism and attack. Now, it is not a difficult task to show that, apart from the follies and frauds of ignorant charlatans, the phrenological art of reading character, however useful, is, and always must be, a conjectural art. At every step of the process there are sources of uncertainty, some of which are wholly irremoveable. 1. It is a fact, that the determination of the fundamental faculties is as yet incomplete. 2. The organs of some of the faculties re-

cognised as fundamental have yet to be discovered. The discovery of the functions of certain convolutions is impeded by the circumstance that their relative size cannot be detected. This is confessedly applicable to those convolutions which correspond to the inner longitudinal surface of each hemisphere, to the superior surface of the cerebellum (upon which they rest), and to the wings of the sphenoid bone at the base of the skull. Now these surfaces may be roughly estimated to constitute from one-fifth to one-sixth of the entire surface of the convolutions. 3. Changes in the cranial bones give rise to varying thickness or thinness of the bony parietes, not easy, if not sometimes impossible, to detect during life. 4. This source of difficulty is increased when we remember that this condition of the bones is often the effect of obscure morbid states of the brain itself or of its membranes, or both; which states, although not easily recognised, profoundly modify the mental manifestations. We say nothing of minor sources of error provided against by phrenological rules, such as the varied size of the frontal sinuses,[1] the development of the hair and of the muscles attached to the cranium, and the condition of the other soft parts; nor of the difficulties afforded by atrophy of the convolutions, by age and sex, and by combinations of organs. But even were these difficulties overcome, greater remain behind, in the varying *vital conditions* which influence the manifestations of the organs independently of size. Some of these of the highest importance—*e.g.*, those connected with genius—are confessedly unknown; others require for their due estimate an amount of knowledge we are far from possessing. The connate powers of the blood and tissues generally known as *temperaments* vary greatly. Rules have been set forth for estimating their influence on the health and vigour of the body and mind far from satisfactory to those who have studied the physiology and pathology of "temperaments." In truth, there is no one branch of medicine which is more imperfectly developed; none in which there is a larger amount of floating, crude, indefinite knowledge. We feel we may be permitted to speak with some authority on this point, since we have made these innate conditions of the blood and tissues the subjects of special observation and inquiry for several years past, with a view to both the practice and teaching of medicine. But, besides the *temperaments*, there are *diatheses*, or constitutions predisponent to particular forms of diseased action which are often grafted on the former, often arise out of them, and always modify them greatly. Then these temperaments and diatheses are hardly ever met with in the typical form, but are commingled with each other in ever-varying proportions; so that the most practised observer may be at fault in his diagnosis.

But the condition of each organ, as regards health and disease, in the *same* individual, modifies its manifestation. Thus an active small organ may be in the same individual more powerful than an inactive large one. But this question of condition of special organs involves a knowledge of some of the most abstruse problems in the physiology and pathology of the nervous system. Certain faculties and organs, for example, are intimately associated, as to function, with the condition of certain viscera. A weak fatty heart or a diseased colon are not unfrequently in direct relation with various forms of melancholia. An aberration in the functions of the ovaria is sometimes the immediate cause of moral insanity in women; so that the very qualities for which the individual was remarkable are reversed,—*e.g.* truthfulness and candour are changed into habitual falsehood and dissimulation, affection for relatives into malice, and the like. The physiological influence of certain viscera upon the natural activity of organs, or groups of organs, is very remarkable. Thus, when the ovaria or testes are removed, various faculties are exalted or weakened; when they are developed or brought into unusual functional activity, various faculties are correspondingly weakened or exalted. This is particularly seen to be the case with animals in which the reproductive function is periodic. In birds, especially of the social or gregarious kinds, the development of the ovaria and testes is accompanied with a manifestation not of amativeness or philoprogenitiveness only, but of combativeness, cunning, constructiveness, time, tune, conscientiousness, &c. Further, changes in the composition of the blood have a direct influence upon special organs in the same individual. Thus, certain poisons introduced therein excite special faculties into action. We may mention alcohol, opium, haschich, henbane, and belladonna as striking examples. In some diseases, similar elective affinities are observed. In certain forms of pulmonary phthisis the patient is gay and hopeful to the last, even when the most extensive and most fearful disease is present—not in the lungs only, but in the liver, spleen, intestines. The *materies morbi* of gout seems to stimulate the organs of Combativeness and Destructiveness; for the gouty patient is so often irrepressibly irritable that a fit of the gout has been termed a fit of madness.

These are some of the many modes in which the condition of special organs may be influenced *dynamically*, and both power and activity be developed irrespectively of size. Of the whole of the latter class, it may be said that we have hardly attained to so much knowledge as even to discover the extent of our ignorance. It is not surprising, therefore, that with so many and such great sources of fallacy, cautious physiologists and pathologists, while granting its uses, hesitate to practise seriously the art of reading character, and feel indisposed to place more confidence in the professors of it than they feel in themselves.

But a weightier source of objection to the art, in the opinion of many, is to be found in the fact, that those least qualified by culture to practise it have most commonly exercised themselves therein. Persons without any education in physiology and pathology, or with little more than scraps of information gathered at random, do not hesitate to profess their capability to solve the most important practical questions in mental science. To the intelligent and instructed they are but mere charlatans, whose ignorance and pretensions would curse with fatal blight any science or art, however well established or noble. We are bound to add that Mr Combe (the great loss of whom by death while these pages were being written we have to lament), and others, frankly acknowledge that applied phrenology is an estimative art only—such, in fact, as is applied medicine itself.[2] But then every accomplished physician finds, as his knowledge and experience increase with his years, that his youthful confidence in the certainty of medicine was not well founded; he becomes more and more convinced of its conjectural character as a science, more cautious and prudent, therefore, in the application of its principles, and more reliant on a learned experience. If, then, doubts, or at least a hesitating caution, be a duty of the physician as to the art of medicine, based on the experience of ages, how much more are they justifiable as to an art confessedly imperfect in important details, and hardly half a century old? It is not difficult to understand from these considerations why the young and enthusiastic followers of Gall and Spurzheim cool in their estimate of phrenology as they get older, and even pass over to the ranks of its opponents. Thus, by not a few medical science and art are treated; and so, *à fortiori*, must phrenology be, since it is only a department of the great science of medicine, resting, as medicine itself rests, upon the great but imperfect science of life. (T. L.)

---

[1] Dr Vimont says he has examined the frontal sinuses in more than five hundred human crania, and has not found them alike in two. (*Traité de Phrenologie, &c.*, tom. i., p. 83.)

[2] Mr Combe, *On the Functions of the Cerebellum*, &c., p. 190.

PHRIXUS. See HELLE.

PHRYGIA, an important province of Asia Minor, of which the ancient boundaries are exceedingly various and indistinct. Phrygia proper was, according to Ptolemy, bounded on the N. by Pontus and Bithynia; W. by Mysia, Troas, the Ægean Sea, Lydia, Mæonia, and Caria; S. by Lycia; E. by Pamphylia and Galatia. The once extensive territory inhabited by the Phrygians was limited during the conquests of Cyrus to *Lesser Phrygia* on the Hellespont, and to *Greater Phrygia.* The former, as far as can be ascertained, included Troas, and bordered in the E. on Bithynia and the Greater Phrygia, and in the S. on Lydia. The Greater Phrygia, again, formed the central country of Asia Minor, bounded on the N. by Bithynia and Paphlagonia, E. by the river Halys, and S. by Mount Taurus.

The origin and nationality of the inhabitants of Phrygia is a subject wrapt in great obscurity. Some regard them as Thracians (*Bryges*), others as Armenians, and others again as of mixed origin. It seems most probable that at some very remote period they had descended from the Armenian highlands; for, as we may gather from numerous hints afforded by ancient writers, there must have been a time when the Phrygian race formed by far the most important part of the entire population of Asia Minor. The Pelasgian races seem to have belonged to the Great Phrygian stock; and the Trojans, Mysians, Mæonians, Mygdonians, and Dolionians are all traceable to the same origin. Moving westward, the Phrygians seem at an early period to have settled about the central parts of Emathia in Europe. These Phrygians (or *Brygians*) are met with in all directions; and indeed this important race seems at one time to have constituted the main element of the population of the greater part of Thrace, Macedonia, and Illyricum. Yielding gradually to the pressure of the northern peoples, the Phrygians seem to have migrated back to Asia—an event dated by Xanthus about ninety years before the Trojan war, and which may serve to account for the Thracian origin assigned to them by tradition. The Phrygians are repeatedly alluded to in the Homeric poems (*Iliad*, ii. 862; iii. 185; x. 431; xvi. 717; xxiv. 535); and are generally admitted to be one of the most ancient nations of Asia Minor (Herodotus, ii. 2).

The religious ideas of the Phrygians seem to have exercised a great influence over the mythological development of the Greeks. Phrygia was a country rich in all kinds of produce. Agriculture was their chief occupation; they bestowed much care on the cultivation of the vine; and the country was distinguished for the excellent breed of its sheep, and for the fineness of their wool. Phrygian marble was much prized, and gold seems to have been found in its streams. It possessed well-built towns in the time of Homer (*Iliad*, iii. 400), which were great commercial emporia. Such were Pesinus, Gordium, Celænæ, and Apamea, the last of which was long a chief centre of trade for the whole of Asia Minor.

After the overthrow of the Persian power in Asia Minor by Alexander the Great, Phrygia seems gradually to have lost its original boundaries in the distribution of territory which ensued, as well as by the frequent changes to which it was subjected by subsequent conquest.

PHRYNICHUS, a tragic poet of Athens, was the son of Polyphradmon or Phradmon, and the disciple of the celebrated Thespis, being a little earlier than Æschylus. He gained the tragic prize, B.C. 511, and is said to have introduced several improvements into the dramatic art, bringing on the stage female characters, and making the actors adopt the use of masks, instead of disfiguring their faces with the lees of wine. Suidas mentions the names of nine of his tragedies, and ascribes to another Phrynichus, son of Melanthus, a tragedy entitled *The Sack of Miletus*, which recalled so forcibly to the Athenians the melancholy fate of that Greek city, that they punished the poet by a fine of a thousand Attic drachmæ, or, according to Ælian, banished him from Athens. As the son of Phradmon is said to have died in Sicily, probably at the court of Hiero, where Æschylus also took refuge, it is not unlikely that this tragedy may have been his production.

PHRYNICHUS, one of the last and most noted writers of the old comedy at Athens, flourished B.C. 435, and was the contemporary of Eupolis, Euripides, and Aristophanes. He obtained the second prize, B.C. 405, the year before Athens was taken by the Spartans. Plutarch states that in one of his plays he defended Alcibiades when he was accused of having mutilated the statues of Hermes. Aristophanes ridicules Phrynichus for introducing too frequently on the stage characters in low life. The fragments of Phrynichus have been collected by Morel, *Ex Veterum Comicorum Fabulis quæ integra non extant*, Par. 1553; by Hertelius, *Vetustissimorum Comicorum Sententiæ*, Bâle, 1560; and by Grotius, *Excerpta ex Tragœdiis et Comœdiis, Gr. Lat.* Par. 1626. (See also Meineke, *Frag. Com. Græc.*; and Bergk. *Reliq. Com. Att. Ant.*)

PHRYNICHUS ARRHABIUS, a Greek grammarian, was a native of Bithynia, and flourished about the middle of the second century, in the reigns of Marcus Aurelius and of Commodus. He had devoted much time to the study of the Greek language, which he pretended to speak and write in the utmost purity. He made a collection of all the words used in the Attic dialect, of which an abridgment has been preserved under the title *A Selection of Attic Verbs and Nouns.* He rejected every word which could not be found in some work of Plato, Thucydides, or Demosthenes, and was particularly severe on the style of Menander. This little work, published first by Calliergi, Rome, 1517, was reprinted at Venice, 1524; but the best edition is that of C. A. Lobeck, with learned annotations, Leipsic, 1820, 8vo. Phrynichus had also collected examples of every different kind of style, in the form of a dictionary, divided into thirty-five books, which he dedicated to the Emperor Commodus. Some fragments of this work remain, which have been published by Montfaucon in the *Bibliotheca Coisliniana*, pp. 465–69.

PHUKOK, or KOTHROL, an island in the Gulf of Siam, off the coast of Cambodia, from which it is separated by a navigable strait. It is about 7 miles long, and 3 broad; and it has a harbour in N. Lat. 10. 17., E. Long. 104. 16. The surface is well wooded, and produces the eagle-wood (*Aquilaria Agallochum*), which yields a fragrant resin, used in India as a cure for gout. The natives are employed in spearing the *tripang*, or sea-cucumber (*Holothuria*), an animal which is used in China for the preparation of soups.

PHULOWDEE, a town of India, in the rajpoot state of Jodhpoor, 147 miles N.E. of Balmeer, and 1180 N.W. of Calcutta; N. Lat. 27. 8., E. Long. 72. 28. It stands on a hill, and seems to have been formerly surrounded with a wall, part of which still remains in a ruinous condition. Pop. estimated at nearly 15,000.

PHYLACTERY (φυλακτήριον, *a safeguard*) was a name applied in general to any amulet or preservative against any kind of evil. The term was employed, in particular, to denote those strips of parchment worn by the Jews, and inscribed with particular passages of Scripture. (Deut. vi. 4–9; xi. 13–21; Exod. xiii. 1–10, 11–16.) These phylacteries were folded up, and inclosed in a small leather box, and worn upon the forehead, nearly between the eyes, or upon the left arm near to the heart, being attached by straps of leather. They were considered as thus reminding the wearers to fulfil the law with the head and heart.

PHYSHARMONICA, a musical instrument, in which the immediate sonorous bodies are springs of steel or of brass, vibrated by a current of air.

PHYSICAL GEOGRAPHY.

(1.) Geography, or a description of the earth, may be considered under several distinct points of view, necessitated by the nature of so extensive a subject; three of which, however, are well distinguished from each other, and present it under aspects of primary importance, practical and scientific.

Political Geography considers the surface of our globe as parcelled out into states and empires, inhabited by communities and races of the great human family, variously affected by the different characters of soil and climate, by which their lands, manners, and occupations are modified; and continually encroaching on each other, and altering their mutual boundaries by conquest or colonization. This view of geography is therefore essentially arbitrary and conventional, as well as in a perpetual state of change from age to age. Commerce and statistics, aptitude for military occupation or defence, facilities for internal and external communication, and products available for human wants, form its chief subject-matter; and cities and towns, the centres of population, power, and enlightenment, its most important landmarks.

(2.) *Descriptive Geography*, while it neglects the boundaries of states, or uses them only for such convenience as they may afford for the subdivision of its subject, concerns itself principally with the exact delineation, in charts, of the coast-lines of continents and islands, internal seas or lakes—with the courses and embankments of rivers, the configuration of the surface of the land, as consisting of mountains, valleys, and plains, whether delineated in charts by conventional shading, or marked out by level lines, or described in words. Its scope embraces, moreover, a particular and detailed account of their external aspect, soil, scenery, and animal, vegetable, and mineral productions, which characterize and diversify each district; irrespective, or but little respective, of their uses to man, or of their connection *inter se*, or of the causes which have operated to produce them. Of all these, it would be the business of a perfect "Descriptive Geography" to exhibit a true and faithful picture, a sort of daguerreotype, without note or comment.

(3.) Such comment, or at least one of such comments, it is the object of Physical Geography to supply. Taking for granted such knowledge as we possess of the general laws of physics, and of the mode in which they are carried out into action, under given circumstances of time and place; and basing itself on the detail of particular features afforded by the last-mentioned department of the general science—it calls attention to those laws as displayed in operation whenever, so to speak, they project in relief, and stand forward as luminiferous examples (*instantiæ luciferæ*) of the application of theoretical views on the great scale. Its aim is to exhibit the heap of particulars gathered and stored up by descriptive geography, as constituting a harmonious whole, bound together by mutual relations and interagencies, and subordinate to a great scheme of providential arrangement. And this it does, not by going over the items *seriatim*, and following up the order of description with a running comment, but, by seizing on whatever is illustrative at one point, and comparing it with what is similarly illustrative at another; by bringing into notice the causes which either evidently are acting, or by reasonable implication must be presumed to have acted, to produce the more striking and characteristic phenomena of such regions as offer anything remarkable; and of such as do not, by shewing how this very monotony is itself the result of a prevalent uniformity of causation, of which a rational account can be rendered, and which it illustrates no less strikingly by the absence of salient features, than the complications observable elsewhere do by their number and variety.

(4.) With these general laws, with the principles which govern their application, and with the methods which science affords of deductively tracing out their application from the abstract enunciation of the laws themselves, under specified circumstances, to precise and intelligible results, the physical geographer must be conversant; so far at least, that he must possess a familiar acquaintance with physical principles, and such an insight into their application as shall enable him to take on well-grounded trust the conclusions of others more advanced in such knowledge. For all such knowledge in its detail, we must refer our readers to those articles of the present work which treat specifically of the several branches of physics, appeal to which is involved in any part of our treatment of the subject. But some of its leading points require to be briefly recapitulated, as embodying the first elements and material *out of* which, as well as exhibiting the ground-plan and general design *on* which, the whole superstructure has to be raised.

(5.) And first, then—from Astronomy we learn that the figure of this our earth is nearly that of an oblate ellipsoid of revolution, having an equatorial diameter of 7925·65 British statute miles, and a polar one of 7899·17 such miles, or, neglecting the ellipticity, which is only one 290th part of the mean of these diameters—nearly that of a globe whose diameter (the mean of these extremes) is 7912·41 statute miles. Calculating on this *datum*, we find that its superficial area (sea and land both included) is about 197 millions of *square*, and its solid contents above 259 thousand millions of *cubic* statute miles. Its average density, as collected from a mean of several independent determinations, differing much less *inter se* than the evident difficulty of such an inquiry would lead us to expect, may be taken at $5\frac{1}{2}$ times that of pure water, which is fully double that of the average material of the earths and rocks of which its surface consists. And hence we may compute its absolute weight, which is about 5842 trillions (5842×10^{18}) of tons; while at the same time we conclude either that the interior portions of it are to some considerable extent metallic; or, which is more probable, condensed by the immense pressure they have to sustain, some conception of which may be formed from this—that if a channel, only three-quarters of a square mile in sectional area, were opened from the bottom of the sea to the centre of the earth, the whole ocean would flow into it—taking, that is to say, the increase of density of water (according to the experiments of Perkins) at 0·474 per cent. for every additional 100 atmospheres of pressure, and *supposing the same ratio to hold good under all pressures.*. This, of course, cannot be supposed to be really the case. One of two things must happen, either the water would be compressed into solidity, or must be sustained from so doing by an increased elasticity, the effect of an exceedingly high temperature.

(6.) This, indeed, we have every reason to believe, really exists within the earth. Not only is it a general fact that the thermometric temperature of the ground does increase in descending, in all regions of the globe wher-

ever deep mines have been sunk, or borings executed, at an average rate of about 1° Fahr. for every 90 feet of depth; and not only do the phenomena of volcanoes and hot springs indicate unmistakeably the still further increase of heat beyond the reach of artificial excavation, but the fact itself, that the mean density of the globe is so small as $5\frac{1}{2}$, must be held conclusive evidence of an excessive internal temperature. It is not by solidifying that fluids can escape from further condensation. Solids, as well as fluids, are compressible; even the densest metals increase in density by hammering; and though the rate of compressibility of matter in the solid state is vastly smaller than in the fluid, it is not conceivable that, under a pressure of 300,000 atmospheres, much that we usually look upon as very solid substance would not be reduced to a small fraction of its bulk. Nor will it avail to look to the support of the upper strata by the spherically vaulted form of the lower, so as to relieve the internal portions of their load. The lateral thrust, in an equilibrated arch or vault, vastly exceeds the weight laid upon it; so that nohow can the conclusion be evaded that the internal portions of the earth, whether fluid or solid, actually do sustain this almost inconceivable force, and we can look to no power but the expansive force of heat which can counteract its condensing effect.

(7.) Whatever be the intensity of that heat, and whether the central portions of the globe be solid or fluid, there can be no doubt that the density of the materials of which it consists in proceeding downwards, must follow an increasing progression. ASTRONOMY, grounding its conclusion on some observed facts in the moon's motion, otherwise inexplicable, assures us that, as a matter of fact, it does so. This being the case in the absence of any cause to produce disturbance (and we can perceive none of power enough to act at *great* depths,[1] so as to produce upward currents), the lower strata must preserve their level, and the whole interior of the earth, considered on the great scale, must be in a state of absolute quiescence, enough so at least, at all events, to prevent the central heat from being carried to the surface by the material transfer of heated and molten matter. Under such circumstances, we learn from THERMOTICS (see HEAT), that the escape of heat from the interior, through the external shell of the earth out into the air, and free space, must be of most inconceivable slowness—so much so, that no appretiable share in producing or maintaining the warmth of the *surface*, can be attributed to it, and that the difference of climates and local temperature is the result entirely of external influences, which it belongs to METEOROLOGY to develope. (See our article on that subject.)

(8.) From the principles of DYNAMICS, we learn that the deviation of one 290th from exact sphericity in the earth's figure, is a consequence of its rotation on its axis, and is essential to the maintenance of the equilibrium of the ocean, so that a shifting of the axis would entail the submersion of the existing land; but from the same source we learn that from natural causes (as known to us), no such shifting ever can have taken place, or ever will; and this deduction from theory is confirmed by Astronomy, which shews that the latitude of places, as determined by the most delicate observation, are absolutely invariable. Were the earth a sphere, this might be drawn into an argument against its internal fluidity, since the external shell, floating on an ocean of fluid, might at first sight be supposed capable of drifting at random from its relative place, without a displacement of the general axis of rotation. But (even were the conclusion a valid one, which it is not), the rigidity of the elliptic shell which can only *fit* the elliptic (though fluid) supporting nucleus in one position, will act as a retaining force, and prevent any, the smallest deviation; since, to disturb the whole external shell on the whole internal fluid, would be in effect to change the figure of the latter, and call into action all the antagonistic forces which resist such change.

(9.) If then, as GEOLOGY assures us, the continents can be proved by unmistakeable evidence to have been submerged, and the ocean-bed laid dry, not once only, but repeatedly, nay, that the process is actually going on, though slowly, under our eyes, we must look elsewhere than to a change in the axis of rotation for the causes of such a fact. Yet more, we learn from dynamical principles, that all the influences exterior to the earth, by which the waters of the sea are kept in agitation, act through the intervention of these waters in antagonism to the existence of the continents for the time being, and perpetually tend to degrade and destroy them, and to spread their materials over the bed of the sea, filling up its hollows and doing their best to bring on a state of perfect smoothness, in which the whole earth would be covered with sea, having a dead level for its bed. The land, then, is maintained in its elevated position by internal force, locally exerted, and varying its locality from age to age, according to laws which belong to the domain of geological, rather than geographical science. Whatever be the nature and ultimate origin of that force, it is manifested to us in action from time to time in the volcano and the earthquake, which thus we learn to regard as very far from purely destructive arrangements in the great scheme of nature; since, without the agency of which they are part and parcel, there would by this time have been no dry land whatever. The fact that all our present continents consist of beds or strata, which have resulted from the destruction of former ones, and the distribution of their materials at the bottom of the sea, and of granitic masses forcibly thrust up through those strata, disturbing and dislocating them, leads direct to the conclusion that, had the primeval world been constructed as it now exists, time enough has elapsed, and force enough, directed to that end, been in activity, to have long ago destroyed every vestige of land, but for the reproductive efficacy of these internal forces bringing up continually new lands to replace the old.

(10.) Hence, then, we come to perceive that the actual configuration of our continents and islands, the coast-lines of our maps, the direction and elevation of our mountain chains, the courses of our rivers and the soundings of our oceans, are not things primordially arranged in the construction of our globe, but results of successive and complex actions on a former state of things; *that* again, of similar actions on another still more remote; and so on till the original and really primeval state is pushed altogether out of sight and beyond the reach even of imagination; while, on the other hand, a similar, and, so far as we can see, an interminable vista is opened out for the future, by which the habitability of our planet is secured amid the total abolition on it of the present theatres of terrestrial life.

(11.) But the revelations of geology do not stop here. They assure us, further, that in each of those successive submersions and reconstructions of the continents, fresh corresponding races of animals, and a new and different clothing of vegetation have been introduced—the one perishing off as the others have come into existence; nay, that even the denizens of the ocean itself have had no exemption from this great law of change—which, however,

[1] Such as exceed 100 miles, for instance.

has not operated either by a gradually progressive variation of species, nor by a sudden and total abolition of one race, and introduction of another entirely new, but by a series of overlappings, having the last portion of each in co-existence with the earlier members of the newer series. Higher forms of being, moreover, appear at every stage of the process, up to the final and culminating point of humanity, and the existing order of things. And by the indications afforded by the exhumed remains of these successive creations, the geologist finds himself enabled to co-ordinate the succession of strata, and to assign to each its epoch in the past history of the world.

(12.) From METEOROLOGY we learn to refer the great system of aquatic circulation, which transfers the waters of every one region of the ocean, in the course of time, to every other, to the action of our Trade-winds, and their compensating currents, the Anti-trades; themselves the results of solar action in combination with the earth's rotation on its axis. By the oceanic currents thus arising, the material carried down by rivers, or abraded by the action of the waves (increased in their efficiency by the extent of sloping beach, produced by the rise and fall of the tides), is carried off and dispersed abroad, or, it may be, collected by subsidence in deep and comparatively motionless hollows, or in eddy-pools. There are features in the outlines of our continents on the great scale which bear obvious reference to some such process. Thus, the excavation of the Gulf of Mexico and the Caribbean Sea is an evident effect of the continued and powerful action of the Gulf Stream, or rather of the general set of the great South Atlantic current on that part of the American coast which issues thence at present in the concentrated form of the Gulf Stream, and which, unless counteracted by other causes, must sooner or later cut through the Isthmus of Darien, leaving a chain of islands like those which, on a larger scale, serve to keep up an ideal connection of the continent of Asia with the great mass of Australia, which thus we may be led to consider as forming the same sort of southern appendage, past or future, to the eastern part of the great Europo-Asiatic continent which Africa does to its western, and which South America does to North. Looking only at the land in great masses; regarding Africa as South Europe, and Australia as South Asia, we may still form a tolerably general conception of the distribution of land and sea by regarding the land as chiefly collected in the northern hemisphere in a mass which, but for the narrow interval of Behring's Strait (not more than 40 miles across), would be continuous, and which sends down three great lobes into the southern, where they appear as three projecting apexes pointing towards the south pole, which they approach by not very unequal degrees of remoteness, and surround at not very unequal intervals of longitude; much as the thumb and two first fingers of the hand in the attempt to grasp with them a globe of a couple of inches in diameter.

(13.) But although the southern hemisphere, as compared with the northern, is more aquatic, yet, if we would divide the globe into two hemispheres, the one of which shall contain the greatest quantity of land, and the other of water, it must be cut by a plane perpendicular—not to the axis of rotation, but (singularly enough) to the diameter passing through the south-west corner of England. A chart of the two hemispheres projected on the horizon of this point (or, which comes very nearly to the same thing, on the horizon of London) exhibits the one containing all the great continental masses, except Australia and the small tapering extremity of South America, while, with these exceptions, and those of the great islands of Sumatra, Borneo, and New Guinea, the other is nearly all occupied by water. The fact is instructive, as it proves the force by which the continents are sustained to be one of *tumefaction*, inasmuch as it indicates a situation of the centre of gravity of the total mass of the earth somewhat excentric, relatively to that of the spheroidal figure of the ocean-surface—the excentricity lying in the direction of our antipodes; and is therefore a proof of the comparative *lightness* of the materials of the terrestrial hemisphere.

(14.) As regards, then, the general configuration of the land and its distribution over the surface of the globe, in referring it to the causes above indicated, we have done all that is possible in the present state of geological knowledge. It must be accepted as part and parcel of the arbitrary *data* of our subject. Not that speculation has been wanting as to the ultimate origin of that configuration. The globe has been likened to a great crystal, formed by cooling from fusion—its angles and edges cropping out from the general spherical surface—its great mountain chains, and the deep clefts of its sea-valleys to the corrugations on the surface of a molten mass formed in the act of setting, by crossing systems of crystallization. And more recently[1] a suggestion has been put forth, attributing the forms of the continents, not to any effect of crystallization, but to the contraction of dimension due to the cooling of a homogeneous fluid nucleus, modified by the resistance of the surface already solidified to a further change of dimension; in a word, to a crumpling or shrivelling of the exterior crust arising from the withdrawal of support from within. It is not easy, however, to see (though the author cited thinks otherwise) how such a cause, acting on a homogeneous spheroid, equably invested in every part, could result in anything other than a further flattening inward of the already flattened polar portions, *i. e.*, in an increase of external ellipticity, or, in other words, in the production of an annular equatorial continent—and to suppose an original difference of resistance (from which, no doubt, undulated forms, both of meridians and parallels, might so arise) is only to shift what is arbitrary in the assumption a step farther away; since by properly assuming the law of resistance to flexure, any given form of crumpled surface might arise. Although, then, it is certain that such a cause, acting under any conditions, must produce *some* protuberances, and, under fitting ones, *might* produce those actually existing, we are still as far from a rational explanation of the *observed* forms on this, as on any other supposition.

(15.) There are, however, local peculiarities in the outlines of the land where the effect of causes now in action is distinctly traceable, as we shall hereafter take occasion to shew when speaking of Deltas, Sand-spits, and some other features of coast lines, evidently originating in tidal action combined with that of currents, and, in one or two instances (as in the Spit of Arabat), of winds. There are other peculiarities also, of which no such account can be rendered, but which yet, being of frequent occurrence, would seem to point to some general cause, determining the direction of those movements by which the rise of the land from the sea-bed has been effected. We allude to the very evident tendency of the outlines of coasts to run out into peninsular projections, having a meridional direction, or a near approach to such. Not to speak of the three great prolongations of the northern continents into the southern hemisphere, we may instance as cases in point the peninsula of Hindostan, and on a smaller scale those of Cambodia and Carpentaria, the Malayan, Corean,

[1] "Discours sur la condition Physique de la Terre." Par M. Jean Reynaud.

and Kamschatkan peninsulas, and those of California and Florida. Nay, even the more continental masses of Greenland and Scandinavia (including Sweden, Norway, and Lapland) may be cited as coming under this law.

(16.) *Of the Atmosphere.*—We must refer our readers to our article on METEOROLOGY for an account of the nature and constitution of the atmosphere, and the general laws which regulate its movements, and the circulation of heat and moisture operated by them over the surface of the globe. The effects of these movements in producing the modifications of climate prevailing in different regions, belong, however, to the proper object of this essay, but must be deferred until we have brought the reader acquainted with those features in the arrangement of the land and water upon which these modifications depend. There are, however, one or two points which it is right to mention here, and first, as to the total mass of the atmosphere. It is stated in the article referred to as being one 180,000,000th part of the total mass of the earth. This requires correction; the true proportion is one 1,125,000th. The absolute weight there set down (11⅜ trillions of pounds avoirdupois) is, however, correctly computed. 2dly, We have to regret the omission of all mention in that article of Lieutenant Maury's most valuable and important works,—*The Wind and Current Charts*, and *Sailing Directions*. Neither those works, nor his more recent one on *The Physical Geography of the Sea*, had then reached us. Though compelled, as we shall hereafter find ourselves, to dissent from several of the philosophical views put forward in the last-mentioned work, we do so with the most grateful recognition of the zeal and indefatigable industry he has exhibited in the collection and arrangement of a vast mass of facts, and the ability and success with which he has been able to combine them for practical use. The *Wind Charts*, now in process of publication by the Board of Trade, are founded entirely on the numerical data so collected and arranged, and will exhibit, on simple inspection, the prevalent wind, and its average deviations, both in direction and intensity, for each quarter of the year, in every area of 10° in longitude and latitude over every part of the sea, and in particular regions, where necessary, in closer detail.

OF THE SEA.

(17.) *Extent, Mean Depth, entire Content, and Mass of the Sea.*—From a careful measurement of its extent, as laid down in charts, it has been concluded that the dry land occupies about 49,800,000 square statute miles. This does not include the recently-discovered tracts of land in the vicinity of the Poles, and allowing for yet undiscovered land (which, however, can only exist in small quantity), if we assign 51 millions to the land, there will remain about 146 millions of square miles for the extent of surface occupied by the ocean. Its mean depth cannot, of course, be stated with any certainty. There are phenomena in the formation and progress of the tide-wave, and of certain other great undulatory movements, which are incompatible with an average depth under four or five miles. *See* art. 80. Most of the soundings which have been taken far from land, and in deep water, fall, however, far short of these limits; but as some have attained the higher of them, and as there are numerous instances where 20, 30, 40, and even 50 thousand feet of line run out have failed to give distinct evidence of the bottom having been reached, a *mean* depth of four miles may be taken as one quite as likely to be beyond the truth as within it; the more so, as a great proportion of the vast area of the Pacific is so abundantly bestrewn with islands as to authorize a reasonable suspicion that its average depth is less than that of the Atlantic, where islands are comparatively rare, and of which the depth has been ascertained over no inconsiderable portion of its whole extent. Calculating on these data, we find for the total cubic contents of the sea, 788 millions of cubic miles, and for its mass or weight (taking the specific gravity of sea-water under a pressure of two miles 1·0151) 3,270,600 billions of tons, or one 1786th part of the total mass of the globe.

(18.) The most remarkable general feature which the sea presents to the physical geographer is its *continuity*. With exception of the Caspian Sea, the little Sea of Aral, and a few other quite trifling salt-water lakes (trifling, that is, in comparison with the whole amount of water), the ocean is one and undivided, throwing its arms round the globe in such a way as to justify the notion and description of it by the ancient tragedian, "*περι πασαν ειλισσομενος χθον' ακοιμητῳ ῥευματι.*" Even the most closed and the deepest indentations which it makes into the land—the Mediterranean and the Red Sea—have deep water at their entrance, and a sufficient breadth of opening to admit a free communication with the general area.

(19). *Composition of Sea Water.*—The sea consists wholly of salt water; and it is this continuity of all its parts, conjoined with the system of circulation of its waters in currents, caused by the regular and perpetual action of the winds, which ensures the uniformity, or near approach to uniformity, of its saltness in every part. As the sea continually receives the drainage of all the land, besides having, in the course of countless ages, washed over and over again the disintegrated materials of successive continents, it must of course hold in solution all the saline ingredients capable of being separated and taken up by such lixiviation in cold water; in fact, in greater or less quantity, every soluble substance in nature—such, at least, whose existences in extremely dilute solution are not incompatible. By far the larger proportion, however, consists of chloride of sodium (common salt), after which occur chlorides and sulphates of magnesia and lime in some considerable abundance. And in much more minute, but yet appretiable quantity, occur salts of potash and ammonia, the iodide and bromide of sodium, carbonate of lime, silica, and other matters too numerous to mention. The sulphate and carbonate of lime, and the silica, however minute the percentage of the two latter, are yet of vast importance in the economy of animated nature, as furnishing all the lime and silica out of which the shells of Mollusca, the structures of the coral and other similar insects, and the shells and carapaces of the siliceous infusoria, &c., are derived. But besides these saline and earthy ingredients, metallic salts in excessively minute quantity have been shewn to exist in sea-water. Thus, copper is present to such an extent, that clean and polished iron dragged in the wake of a ship, during even a short voyage, has been observed to come up with a film of that metal precipitated on it.[1] Silver also is found in combination with the old and worn coppering of ships to such amount as to make it worth while to extract it. It has been computed from some analyses of such copper, compared with the total distance run through by the ship, and the time of its remaining attached, that at least two millions of tons of silver are thus held in solution in the whole ocean.

(20.) The mean specific gravity of sea water taken up at a small depth (a few feet) below the surface (so as to be out of reach of the *immediate* influence of *recent* rain), reduced to 62° Fahr., may be stated at 1·0275, which

[1] Query, whether iron so dragged in a ship's wake might not take up a portion of the copper dissolved off the ship's bottom.

experiment shows to correspond to a *total* percentage of saline contents, irrespective of the difference of the ingredients, of about 3·505, so that it is incorrect to state, as some have done, that the saline contents do not add to the bulk. This of course is to be understood of water taken up in open sea, out of reach of the influence of rivers, icebergs, &c., which produce local variations to which we shall presently recur. Beyond such influences, however, there are meteorological causes in action which produce a perceptible deviation, dependent on geographical situation, from the exact average. Thus, in those portions of the ocean, on either side of the equator, swept by the trade-winds, especially towards their northern and southern limits, the saltness of the surface water may be expected to be, and is in fact found, somewhat in excess of what prevails either on the equator on the one hand, or beyond the tropics on the other. For these winds arrive from higher latitudes deficient both in heat and moisture (METEOROLOGY, art. 111), and take up both in their progress towards the equator, while they return little or none of the fresh water so taken up, in the form of rain, till their arrival at and near the equator itself. There, however, they at once precipitate a large proportion of the water so absorbed, a process which, being in constant operation, must in some degree freshen the surface. Thus, Captain King, in his South American Survey in 1829-30, found the maxima of specific gravity in the Atlantic to occur in latitudes 27° N. and 20° S., the mean result for both being 1·02808 at 62° F., while in the equatorial region, from 5° N. to 5° S., the mean of his results is only 1·02723. Ruschenberger and Porter, as reported by Maury, found the Atlantic maxima in 17° N. and 17° S., and in 20° N. and 17° S. respectively. The mean of all gives 18° N. and S. So also, in the Pacific, Captain Beechey, in his survey of Behring's Straits in the Blossom (1825-8), found the maxima to occur in latitudes 22° N. and 20° S., their mean being 1·02937 (reduced to 62°),[1] that of the equatorial zone being 1·02791. On the other hand, beyond these limits in the ultra-tropical regions, where the anti-trade winds prevail, the whole of their residual moisture is discharged in rain or snow, while at the same time, owing to the habitually lower temperature of these regions, evaporation from the sea-surface is very much diminished. And, accordingly, the results of both King and Beechey indicate a slight though very perceptible progressive diminution of specific gravity in proceeding towards either pole—the mean of Captain Beechey's results between 55° and 60° of both north and south latitudes in the Pacific giving 1·02580, and those of Captain King, in the corresponding region of the South Atlantic, 1·02551—results on the whole in excellent accordance with each other, and which leave no room for doubt as to the general fact in question.

(21.) At the mouths of great rivers the sea is often superficially freshened to a considerable distance from shore. This is the case with the Amazon River to such an extent, that fresh water may be taken up from the sea surface when out of sight of land, and the sea itself is rendered sensibly less saline at two or three hundred miles from its mouth. At the time of the inundations of the Nile also, the water is perceptibly freshened out of sight of land.

(22.) In the Euxine, and still more in the Sea of Azof, the supply of fresh water from the rivers feeding them is greater than their waste by evaporation, and their communication with the Mediterranean being restricted by the long and narrow channels of the Bosphorus and the Dardanelles, out of which a current always sets in calm weather, they have become materially fresher than the general average. The Euxine water has a specific gravity of 1·01410; and the Sea of Azof, which is shallow and of small extent, and receives a considerable river (the Don), probably less. So also in the Baltic, which is a shallow sea communicating with the main ocean by a shallow and obstructed channel, the specific gravity varies from 1·00476 at Tunaberg, to 1·020437 off the Scaw Point, at the entrance of the Cattegat—[Thomson].

(23.) With respect to the Mediterranean, it has been held, on the authority of Halley, that its evaporation is materially greater than the extra supply from its rivers, and that, therefore, it must be increasing in saltness by the continual indraught of sea water from the Atlantic, unless relieved (as has also been supposed) by an undercurrent of salter and heavier water flowing outwards. This opinion has recently been called in question by an authority entitled to every respect; but from the best consideration we have been able to give the subject, we feel compelled to acquiesce in Halley's conclusion. A few words will suffice to explain the grounds of our conviction on this point. The total area of the Mediterranean, Euxine, and Azof seas, amounts to 1,150,000 square miles, and may be regarded nearly enough for the purpose of such a calculation, as traversed medially by the isotherm of 63°. Now, this is the mean temperature of July at Tottenham, at which, for that month, the observations of Howard assign an average evaporation of 4·111 inches, which, continued over the year, would give 49·33 inches. Dalton's determination for Liverpool for the same month is 5·11 in., corresponding to 61·33 in. per annum. The observed annual evaporation at Marseilles exceeds 85 Paris inches (*Kamtz*, i. 446). So that we shall be quite within limits in taking 50 inches per annum as the average evaporation over the whole surface in question. As regards the quantity restored by rain, Palermo,[2] as an insular station, well situated about the middle breadth of the Mediterranean, gives 22·3 in. for the fall of rain, which may be taken as the average supply from that source, leaving 27·7 in., or in round numbers, 28 in. for the excess of evaporation. This, computed as extending over the whole area, gives 508 cubic miles of fresh water annually abstracted.

(24.) The Nile delivers into the sea 101,000 cubic feet of water per second (Talabot) on the average of the whole year, which gives an annual contribution of fresh water from this river alone = 21·653 cubic miles. So that, even on the extravagant supposition that each of the other principal rivers (the Danube, Dnieper, Don, Rhone, Dniester, Ebro, and Po) contribute as much as the Nile, we should still have only 173 cubic miles of river supply, leaving 335 to be furnished from the Atlantic.

(25.) In point of fact, the current which sets in at the Straits (estimated by Admiral Smyth[3] as 4 miles in breadth, with an average velocity of 2½ miles per hour) would carry in, supposing it to extend 30 fathoms only in depth, 2986 cubic miles per annum, of which it is therefore past a doubt that at least 2000 must flow out again in the form of an under-current (no regular lateral return currents being observed to exist). This enormous interchange of water is sufficient perfectly to account for the observed fact that the Mediterranean is not sensibly salter than the ocean, and not materially so at great depths than at the surface, though, on arranging the results

[1] Captain Beechey's results (where reduced by him) are given for 60°, and are corrected by — 0·00020 to bring them to 62°.
[2] A mean of eleven stations at points surrounding the whole of the Mediterranean, as reported by Admiral Smyth, gives 23·05 inches
[3] Mediterranean, p. 160.

recorded by the last-named eminent hygrographer in groups according to depth, a very perceptible increase is apparent. Thus we find (setting apart the last result as anomalous, and as a case in which, by bare possibility, a submarine brine spring may have been struck upon)—

At depths from	[illegible]	By
0 to 8 fathoms	1 0271	2 observations.

(26.) The disproportion between evaporation and fresh-water supply is carried to its maximum in the Red Sea, where rain scarcely ever falls, into which no rivers run, and throughout whose whole extent an excessive temperature always prevails. The evaporation has been computed at 165 cubic miles per annum, so that but for an interchange of water with the Persian Gulf, similar to that which takes place between the Mediterranean and the Atlantic, only more intense, it could not fail to be speedily reduced to the condition of an almost saturated brine.

(27.) In several places in the Mediterranean, springs of fresh water, nay, even subterraneous rivers, well up to the surface from considerable depths. Many such are enumerated by Admiral Smyth; but the most remarkable is Anàvolo, in the Sinus Argolicus, between Kiveri and Astros, where a body of fresh water fifty feet in diameter rises with such force at a quarter of a mile from the shore, as to produce a visible convexity of surface, and to disturb the sea for several hundred feet round.—(Leake, *Travels in the Morea*, ii. 480). In the Gulf of Xagua, south-west of the Port of Batabano, on the south coast of Cuba, a similar instance occurs (Humboldt, *Aspects*, p. 233), and others are said to exist in the Pacific, among the Sandwich Islands.

(28.) In the Polar Seas, too, there are extensive regions where large accretions of fresh ice, from snow or glaciers melting in summer, render the surface-water comparatively fresh. But these are too obvious exceptions to the general fact to need more than a passing notice.

(29.) The following is given by M. Regnault (*Chim.* ii. 193) as a mean result of the analysis of sea water. Under the head of "loss" may be comprised the various ingredients which exist in too small quantity for distinct separation, except in operations conducted on a very large scale.

Water		96·470
Saline ingredients = 3.505.	Chloride of Sodium	2 700
	„ Magnesium	0 360
	„ Potassium	0·070
	Sulphate of Lime	0 140
	„ Magnesia	0·230
	Carbonate of Lime	0 003
	Bromide of Magnesium	0·002
Loss (including Iodides, Silica, &c.)		0 025

(30.) *Colour and Phosphorescence of the Sea.*—The sea is only purely blue in the open ocean, or in very deep water, out of the fouling influence of rivers, the washing of coasts, or such currents as drift along mud and impurities. When clear of all such causes of discoloration, a white object, as a plate thrown overboard, is seen to become bluer and bluer as it sinks. The light illuminating the Grotto of Capri, in the Bay of Naples, which is mainly derived from reflexion at the bottom of the water, and which has traversed many yards of sea-water, is very blue. This colour is common to the sea and to lakes of pure fresh water. In the little lake of Chede (now filled up by the fall of a mountain), the blue colour of the water used to be very apparent at a few yards in depth. So also of the water in the Grotto of Vaucluse. It will hardly be contended that in these instances the colour is owing either to salt, which is insisted on by some as the cause of the colour of the ocean, or by cuprate of ammonia, which, on the strength of the discovery of copper in sea water, has recently been suggested. The intense blue colour of the Rhone, where it issues from the Lake of Geneva (far surpassing that of the bluest sea), is alone sufficient to negative both these explanations. Like the blue colour of the sky, the explanation is yet to seek, unless we are content with the very simple, but somewhat doubtful one, that in both cases it is an absorptive colour proper to either element.

(31.) In this view of the subject, wherever the sea is otherwise than fully and purely blue, we may be sure it is by reason of *solid* matter held in *suspension*. In many instances this is obviously the case. The surface water both in the Indian and Pacific Oceans is frequently coloured in patches as far as the eye can reach, of red, brown, or white, the water of which, when taken up and carefully examined, is found to be full of animalculæ of the colours in question. On the shores of the Red Sea a red matter is thrown up, which Ehrenberg has found to be of vegetable origin. Along the coast of China, and especially in the Yellow Sea, spots of that colour are said to be not unfrequent. Captain Kingman, in lat. 8° 46′ S., lon. 105° 30′ E., passed through a tract of water 23 miles in breadth and of unknown length, so full of minute (and some not very minute) phosphorescent animal organisms, as to present the aspect (at night) of a boundless plain covered with snow. Some of these animals were "serpents" of six inches in length, of transparent gelatinous consistency, and very luminous. Such tracts by daylight appear white, not by reason of light emitted from the insects, but of the sun's light reflected by their filmy and all but aqueous substance. (*Cf.* Buist, *Naut. Mag.* 1854.)

(32.) *The Phosphorescence of the Ocean* is a phenomenon which strikes all who witness it with wonder and admiration. It prevails largely through the whole extent of the tropical seas, and proceeds from a great variety of marine organisms—some soft and gelatinous, some minute crustacea, &c., of the genera Cancer and others. They mostly shine when excited by a blow, or by agitation of the water, as when a fish darts along, or oar dashes, or in the wake of a ship as the water closes on its track. In the latter case are often seen what appear to be large lamps of light rising from under the keel, and floating out to the surface, apparently of many inches in diameter. These we have never succeeded in catching, though we feel assured to have seen them enter the net (of Urling's patent lace) dragged along for them, so that the light must have emanated from a creature small enough to escape through the meshes. One of the most remarkable of these luminous creatures is a species of pyrosoma, a tough cartilaginous bag or muff-shaped body, of more than an inch in length, which, when thrown down on deck, bursts into a glow so strong as to appear like a lump of white-hot iron.

(33.) One of the most curious phases of phosphorescence which we have witnessed (and which we have not met with elsewhere described) is the appearance on the surface of calm or but little agitated water, of luminous spaces of several square feet in area, *shining fitfully, and bounded by rectilinear, or nearly rectilinear, outlines*, presenting angular forms, across which the light flashes as if propagated rapidly along the surface.

(34.) *Depth and Form of the Bottom of the Sea.*—Of the *average* depth of the ocean we have already spoken. Of particular districts in the great ocean, nothing very distinct can be stated, except in respect of the North Atlantic, or the Atlantic basin, in which soundings enough have been

obtained to enable something like a rude chart of level lines to be constructed, and of which a summary account may be stated as follows. We shall suppose level lines corresponding to depths of 1000, 2000, 3000, 4000, and 5000 fathoms to be laid down, which will therefore trace out what would be the coast lines of continents and islands, were the sea to sink in level, successively by these several quantities. The first of these lines (that of 1000 fathoms) corresponds pretty closely in its general form with the existing coast line, or rather with what that coast line would be, supposing on the American side the Caribbean Sea and the Gulf of Mexico filled in, so as to carry the continent out to the extreme verge of the Bahamas and Caribbee Islands; and supposing the irregularities of the North American coast smoothed off by carrying out the coast line clear round Nova Scotia, to include Newfoundland with the Great Bank; and supposing, on the European and African side, the Bay of Biscay and the British and Irish Channels also filled in. From the coast lines so arising, the first level line in question hardly anywhere deviates more than 120 geographical miles, (60 to the degree). Nor does it appear that the sea-line so altered would give rise to any considerable new masses of land, but only a very moderate extension of the Azores, and a very trifling one of Madeira, the Canaries, and the Cape Verde Islands.

(35.) The level line of 2000 fathoms along the east coast also conforms very nearly to the outline of the European and African continents, taking in the Canary and Cape Verde Islands, never departing more than about 250 geographical miles from the present coast, except in the case of the last-named islands, but clinging closer to it along the European than the African coast. On the western side this level line, from 10° of south latitude northwards, accompanies the coast (modified as above) for the most part considerably within the same limit of distance as on the eastern (the descent being most precipitous at the edge of the Caribbean Sea), until we reach a point about lat. 43° N., long. 43° W.,[1] where it quits the neighbourhood of the existing coasts, and suddenly turns southwards, running in a meridional direction for 16° of latitude, and forming so much of the western boundary of a great submarine table-land which fills nearly the whole bed of the northern part of the Atlantic basin, and of which, if laid dry, the peak of the Azores would be the culminating point. Were that the case, we should see a lobe of land, (following, singularly enough, the general tendency of configuration pointed out in art. 15, not very unlike Italy in form, extending southward to the tropic of Cancer, leaving a channel of sea of about 500 miles broad between it and the eastern continent, and connected at its south-western extremity with a great triangular mass like Sicily in shape, two sides of the triangle having a general conformity to the present outline of the American continents, so as to leave a channel of about 800 or 900 miles in breadth on that side, separating it from the coast of the United States.

(36.) It is this submarine continent or plateau which, happily for the communication between the old and new world, appears as if provided to receive the lines of telegraphic wire which will one day bring America into intellectual contact with Europe.[2] From Cape Race, in Newfoundland, to Cape Clear, in Ireland, it has been ascertained to form a continuous platform of nearly 400 miles in breadth, at the depth of about 2000 fathoms, which has been sounded and surveyed for that purpose Its surface is covered with broken shells of foraminated and diatomic organisms, among which the cable might find secure lodgment, and in all probability become ultimately incrusted and imbedded in their mass.

(37.) Were the Atlantic to sink another thousand fathoms (to the 3000 fathoms level line), the whole of the European and African side of its bed would be laid dry. The table-land spoken of would form an extension of the European continent. The British Islands, and the north of Europe, would become united with the Labrador coast, and nothing would remain of the ocean but a comparatively narrow channel, following at no great distance the present line of the American continent—reduced to very slender dimensions at the Caribbees, and thence opening out into a bay or great salt lake, occupying that part of the area opposite the United States, and extending between Bermuda and the southern edge of the Bank of Newfoundland. The central and deepest part of this lake would seem to be a long valley running nearly east and west from about 46° to 67° west longitude, along which a depth of from 25,000 to 30,000 feet at present exists.

(38.) By the first step in the subsidence of the ocean we have been supposing, the Baltic would be laid dry—its depth nowhere exceeding 1100 feet—as would also the German Ocean, the British and Irish Channels, and the Bay of Biscay; but the Mediterranean would remain as a great salt lake, a bar extending across the Gut of Gibraltar, at about 900 feet in depth, inside of which the water deepens so rapidly, that between Gibraltar and Ceuta, where the breadth of the channel does not exceed 12 miles, the depth is already 6000 feet; 90 miles east of Malta, we find a depth of 15,000; between Rhodes and Alexandria, 9900; and between the latter part and Candia, 10,200; so that the next step in our ideal descent of the general sea level would lay the whole bed of the Mediterranean dry. We see, then, that the Mediterranean fills an immensely deep and comparatively a precipitous chasm, which would almost seem to have been the effect of subsidence towards the south, contemporaneous with and complementary to the upheaval of the great line of mountainous tracts which run along the whole extent of south Europe.

(39.) The depth of the Arctic Ocean is probably not great. From Baron Wrangel's explorations we learn that over very extensive tracts of the northern coast of East Siberia the water shoals so gradually, that at upwards of 150 miles from land the depth is only fourteen or fifteen fathoms, and the broken character of the northern coast of America, with its labyrinth of islands, and tortuous channels, affords a similar indication. In the axis of Baffin's Bay, however, a few days' sail from Finskernaes, in Greenland, Dr Kane found 1900 fathoms.

(40.) Of the Pacific, too little is known to afford any ground for forming even the most general notion of the form of the level lines of its bottom. The islands scattered over it spring up, for the most part, from very deep water, and soundings are said to have been obtained of enormous depth, even greater than five miles. The deepest recorded by Maury was obtained by Lieutenant Brooke, (with a deep-sea sounding apparatus of peculiar and simple construction, *bringing up specimens of the bottom*), in 58° 46′ N., 168° 18′ E., being 2700 fathoms. The greater interest therefore attaches to an estimate of its average depth in the section across its whole breadth from Simolo, in Japan, to San Francisco, in California, along the parallel of 34° N. latitude, derived by Professor Bache (*Report of Superintendent of the U. S. Coast Survey*, 1855, p. 346), from observations which can certainly be depended upon of the time taken to traverse it by the great waves of December 23, 1854, caused by the terrible earthquake

[1] All our longitudes reckon from Greenwich.

[2] The thing is done! (Aug. 1858)

which ravaged Japan on that day. Several of these waves were propagated all across the Pacific, and were recorded on the self-registering tide-gauges of San Diego and San Francisco, on the Californian coast. A comparison of the observed times of arrival so recorded with the times at which the waves took place in Japan, leads to the conclusion that a wave 217 miles in breadth can be propagated across the interval in question (4527 miles) at an average rate of $6^m 1$ per minute, from which, by the theory of waves, Professor Bache concludes a mean depth of 2365 fathoms, or 14,190 feet.

(41.) In the "Coral Sea," 13 S., 162 E., a depth of 2150 fathoms, with a specimen of the bottom, was obtained by Lieutenant Brooke. The same ingenious officer reports a sounding of 7040 fathoms in the Indian Ocean (42,240 feet, or exactly eight miles!), but under circumstances authorizing considerable doubt as to the correctness of the result. It deserves remark, that off the mouth of the Hoogly river, in the Bay of Bengal, there exists a sudden and deep depression in the ocean bed called "The Bottomless Pit," an epithet, however, relative only to the ordinary "deep-sea lines" of the old merchant vessels, yet of importance as occurring just where the lighter part of the sediment of the Ganges is carried out to sea, and for which it serves as a receptacle.

(42.) Among the most interesting results of the mode of sounding adopted by Lieutenant Brooke, may be considered the evidence procured by it of the nature of the deposits in actual process of formation in the tranquil depths of the ocean, from a microscopic examination of the specimens procured. Thus, the specimens brought up in the Coral Sea are found to consist chiefly of the siliceous spiculæ of sponges, with a few other siliceous and some calcareous infusorial shells; while over the basin of the North Atlantic, over the whole extent of the telegraph plateau, and the wide area covered by the expansion of the Gulf Stream, the bottom appears to consist exclusively of the remains of delicate calcareous exuviæ of animalcules of the foraminiferous family, in a state of such perfect preservation as proves them to have suffered no abrasion, but to have been quietly deposited, on the death of the animals, from the surface-water which served them for a habitat during life. Thus we see here going on the formation of a cretaceous deposit exactly analogous to our own chalk formations, which the researches of Ehrenberg and others have also found to consist almost exclusively of the shells, and fragments of shells, of minute infusoriæ. In some places, too, volcanic ashes and pumice, in fine powder, are found—the product, doubtless, of wind-drifted ashes bestrewing the surface.

(43.) *Subdivisions of the Sea.*—The ocean separates the globe into two principal continental masses, which our insular position between them entitles us to designate as the Eastern and Western Continents. They are separated on one side by the Atlantic Ocean, which extends north and south, in all probability, from pole to pole, and which is continued across the north pole, and through the Arctic Ocean or north polar basin, from which it is hardly separated by any well-defined line of demarcation, the interval between the Greenland coast and that of Norway alone being nearly 500 miles, not to speak of the channel communications leading out of Davis' Strait—while to and probably over the south pole it presents nothing but open sea. The separation of the continents on the other side is effected by the Pacific Ocean, which, but for the narrow communication with the Arctic Sea by Behring's Strait, would come to be considered as a great bay, bounded on the eastern side by the whole coast line of North and South America, and on the western by that of Asia, considered as prolonged by a chain of great islands to the Australian continent. Narrow and shallow as this channel of communication is—not exceeding 30 miles in breadth where narrowest, and 25 fathoms in its deepest channel—it is yet important in the economy of nature, inasmuch as it allows a portion of the circulating water from a warmer region to find its way into the polar basin, aiding thereby not only to mitigate the extreme rigour of the polar cold, but to prevent, in all probability, a continual accretion of ice, which else might rise to a mountainous height. Nothing, indeed, can be more remarkable than the way in which all direct equatorial circulation is barred by the Isthmuses of Darien and Suez on the one hand, while on the other the polar communication is left free. One of the reasons adduced in support of the early, but erroneous, opinion that the figure of the earth is that of an oblong spheroid, was drawn from a crude notion of the continued accumulation of ice and snow over the polar regions, which it was argued must result in an indefinite prolongation of the earth's polar axis. The actual form of the continent, however, prevents any such consequence from taking place, and it is probable that the melting of the ice where it rests on the sea, together with the bodily drifting away of detached masses, form, in the long average, a compensation to the effect of continued precipitation from the atmosphere.[1]

(44.) Another such vast bay or gulf, but without any northern outlet (the Red Sea and Persian Gulf being barred), is the Indian Ocean, limited westwards by the African and Arabian coasts, northwards by the south coast of Asia—the peninsula of Hindostan breaking it into two deep and nearly symmetrical indentations—and eastwards by the broken masses of Sumatra, Java, and the Indian Archipelago, and by the west coast of Australia.

(45.) Each of these great bodies of water communicates without any natural barrier-line with the Southern Ocean, which probably extends across the pole beneath the great icy barrier discovered by Sir James Ross. If, therefore, we would distinguish between them, we must assume arbitrary lines of demarcation. On the north, the arctic circle, which passes within a degree of the narrowest part of Behring's Strait, forms a very appropriate limit to the "Arctic Ocean." The Antarctic Ocean has no such natural limit, but under the wider designation of the "Southern Ocean" may be taken to embrace all the area limited by great circles drawn between Cape Hoorn, the Cape of Good Hope, and Bass' Strait, so as to constitute these localities the southern termini of the Atlantic, Pacific, and Indian Oceans. This appears a simpler division than that which runs meridians up from the three capes (the two last named and Cape Pillar) to the Antarctic Circle, so as to form a purely imaginary Antarctic Ocean, and to constitute a Southern Ocean, equally imaginary as to its limits, between the Indian and Antarctic.

(46.) Each of the three principal oceans has subordinate seas, specially marked out by distinguishing features. Besides the Mediterranean and the Baltic, on the European side, the Atlantic opens out, on the American, into the great bays which bear the names of Baffin and Hudson, both heavily encumbered with ice; the former of which communicates by a labyrinth of intricate and ice-obstructed passages with the Polar Sea, and is the source from whence are continually drifting southwards those

[1] On land, the penetration of the central, or volcanic, and local heat of the globe *may* assist in limiting its increase. Dr Kane describes the Mary Minturn River, in lat. 78° 54′ N., as issuing in a roaring and tumultuous torrent, three quarters of a mile broad, from beneath a glacier Kane Lake, near Etah (78° 17′ N.), is fed by a glacier stream, never ceasing to flow summer or winter.

floating icebergs which form one of the chief dangers of Atlantic navigation. On the other hand, the deep indentation of the Gulf of Mexico and the Caribbean Sea, nearly land-locked by the peninsula of Florida and the long chain of the West India Islands, forms a basin of hot water, having a higher mean temperature than any other oceanic district.

(47.) The mass of islands which sketches out the connection between the Asiatic and Australian continents, is continued northward along the west coast of the Pacific, forming a loose and broken barrier between the main ocean and the east coast of Asia, and breaking it up into compartments more or less land-locked by them, and by the singular system of meridional peninsulas (of Kamtschatka, Corea, Cambodia, and Malaya) known as the seas of Ochotsck and Japan, the Yellow Sea, and the China Sea. The difference in character in this respect between the western coasts in the two oceans is extremely remarkable.

(48.) On the other hand, their eastern coasts are both characterized by an equally striking absence of features of this nature. With exception of the Gulf of California, there is no approach to any deep and extensive land-locked indentation along the whole line of western America, nor does any exist on that of west Africa, or along the European coast from the Gut of Gibraltar to the British Channel.

(49.) *Temperature of the Sea.*—The mean temperature of the sea surface, when undisturbed by currents transferring water from a hotter to a colder zone, or *vice versa*, is of course nearly that of the air above it; but on descending below the surface, a most remarkable law prevails. In very deep water all over the globe a uniform temperature of 39° Fahr. is found to prevail, while above the level when that temperature is first reached, the ocean may be considered as divided into three great regions or zones—an equatorial and two polar. In the former of these, warmer, in the latter colder, water is found at the surface. The lines of demarcation are of course the two isotherms of 39° mean annual temperature. The depth at which this temperature is found is about 7200 feet at the equator, and 4500 in the highest accessible latitudes. The medial line of maximum surface temperature is far from following the exact line of the equator, being deflected by the effect of currents, and in the case of the Indian Ocean by the proximity of heated land, as the following tabulated trace of its course, indicating its greatest deviations from, and intersections with, or near approach to the equator, will shew for each of the three great oceanic regions.

Atlantic.			Pacific.			Indian Ocean.		
Longitude	Latitude	Temperature.	Longitude	Latitude.	Temperature	Longitude	Latitude.	Temperature
Deg	Deg.		Deg	Deg		Deg	Deg	
9 E.	0	80	82 W.	2 N.	84·7	120 E.	8 S.	84·6

			130 E.	0	...			
			125 E.	8 S.	84·7			

(50.) Universally, the temperature of the sea surface, for the reasons explained in METEOROLOGY, is far less variable than on land, and there exist vast regions (as may be seen on inspection of the above table) over which an almost absolute uniformity in this respect prevails. The determination of the mean temperature of these regions *to the extreme of precision*, is a practical problem of the highest importance.

(51.) *Currents of the Ocean.*—Every wind that sweeps the ocean drives along before it the surface-water. The impulse given is horizontal, and proportional to, or at least increasing, in some ratio of the *relative* motion of the air, a ratio probably higher than that of the simple difference of absolute motions, by reason of the universal roughness of surface consequent on the action of the wind. If the difference of motion be due to an excess of diurnal rotation on the part of the sea, it is the water which (driven against the air) gives out momentum to the latter; if that of the air be in excess, it receives it from that element. In either case, the effect is the same; the two are brought nearer to a community of direction and velocity by their mutual friction.

(52.) The trade-winds occupy two belts on the earth's surface on either side of the equator, which are limited on the equatorial side by a belt of calm air (the movement of which is upward, and in which no prevailing tendency, east or west, is perceivable). On the polar they are limited by two belts of comparative calm, with uncertain and variable winds, which for our present purpose we may consider as nearly coincident with the tropics. Over the belt of equatorial calms, the N.E. and S.E. trades, *reduced to meridional directions by the eastward frictional impulse of the earth's rotation* (Basil Hall, *Fragments of Voyages and Travels*, 2d Series, i. 162), meet, and to a certain small extent perhaps commingle, in their upward movement, which, however, can only be the case with those portions of air which actually attain the medial line, or approach very near it; for, as the region of calms extends to four or five degrees on either side of that line, the greater part by far of either indraft will rise on its own side, and must of necessity be turned over towards the pole of its own denomination, and return, as an upper current, by a tract precisely the reverse of that of its arrival.[2] On the other hand, over the region of tropical calms, a portion of the descending air of the upper current, where it first strikes the earth, is dragged back into the tropical circulation, while the rest goes forward to form the Antitrades (or S.W. and N.W. winds) of the temperate and polar zones, which, as prevalent winds, with more or less frequent interruptions, according to local circumstances, occupy both the extra-tropical regions.

(53.) In obedience to the trade-winds, a drift of the intertropical surface-water is produced, which tends to carry it in a S.W. and N.W. direction respectively towards the equator, where the meridional components of the two drifts neutralize each other, and their westerly components conspire to produce an equatorial current setting westwards, the borders of which will be stronger than the medial line, because the existing cause is there most energetic. The general current resulting from the concentration of the drift will therefore bifurcate where it meets or nears the land, the northern portion turning northward, and the southern southward.

(54.) In the Atlantic, this bifurcation takes place somewhat south of the equator, off Cape St. Roque. The equatorial current is there not very powerful; but in its progress along the north-east coast of South America, it

[1] In the Gulf of Mexico, off New Orleans; it is evident that this is an exceptional result.

[2] Such, at least, is the ordinary, and, as appears to us, the correct dynamical view of the subject, and this is one of the points on which we have the misfortune to differ from Lieutenant Maury, who conceives that the south-east and north-east trades cross as they near the equator, and pursue their course in the upper regions of the atmosphere towards the poles of *contrary* denominations The point is irrelevant to the matter actually in hand, but it will be necessary to recur to it when we come to speak of the distribution of moisture.

is reinforced by the whole amount of S. W. drift setting towards that shore from the North Atlantic, and is thereby forced into the Caribbean Sea and through the Channel of Yucatan; and having made the circuit of the Gulf of Mexico, issues through the Straits of Florida, clinging close in shore round Cape Florida, whence it issues as the Gulf Stream in a majestic current upwards of 30 miles broad, 2200 feet deep, with an average velocity of four miles an hour, and a temperature of 86° Fahr. It is to the continual scouring of this recess, by so vast a torrent of perfectly pure water from the main ocean, that the extreme and crystalline transparency and intensely blue colour of the Caribbean Sea is owing—a transparency such as to allow every object at the bottom to be clearly seen in 30 fathom water.

(55.) From its issue through the "Narrows" off Cape Florida it is darted off into the main ocean, where it takes up a course (as Lieut. Maury has well pointed out) conformable (in a general way) to the easterly impulse given by its excess of diurnal rotation, in passing from a lower to a higher latitude, and which drives it away from the American coast in an almost direct N.E. direction *towards* the opening of the Arctic Sea, between Spitzbergen and Norway. Arriving in colder water, it becomes relatively buoyant, and thins off in depth (which has been, by a strange perversion of language, called "running up hill"), spreading itself gradually in width, until its motion at length, conspiring with that of the south-west Antitrades of the extra-tropical latitudes, it is swept on, partly by what may yet remain of its original impulse, but mainly by their aid, as a drift-current (*Stark*) of moderately warm water (51°), into the North Sea. There can be little doubt that a portion of this warm stream enters the Arctic Ocean, and, sweeping round its basin, reissues in the form of a cold current between Spitzbergen and Greenland; after skirting the coast of which latter, it unites with a similar current, also running southward, through Baffin's Bay (and which probably conveys the whole of the water entering at Behring's Strait), and forms a cold stream, which descends along the Labrador coast, and that of the United States, till it becomes extinct, or re-enters the circulation at the point where the Gulf Stream quits the coast.

(56.) It is about the 42d or 43d parallel of N. latitude that this process of thinning off and superficial extension may be said to have *dispersed, and, in fact, destroyed, the Gulf Stream as such*, since at this point, or rather over this region, a large portion of its water, strongly marked by excess of temperature (79°-73°), curves round to the eastward, and is then again deflected southward, forming an eddy or return current, which follows the bend of the great northern protuberance of Africa, but at some distance from the coast, till it again rejoins the equatorial waters. In the interior of this vast circuit, about the tropic of Cancer, and forming a floating island of an elongated oval form, between the 20th and 65th degree of W. long., and the 18th and 28th of N. lat., occurs that extraordinary accumulation of rootless sea-weed, known as the gulf-weed, or Sargasso, consisting almost entirely of the *Fucus natans* and *Macrocystis pyrifera*, and affording a home to myriads of molluscs and crustacea.

(57.) The dynamics of the Gulf Stream have of late, in the work of Lieut. Maury already mentioned, been made a subject of much (we cannot but think misplaced) wonder, as if there could be any possible ground for doubting that it owes its origin *entirely* to the trade-winds. A few words on this point, therefore, will not be superfluous. *First*, then, if there were no atmosphere, there would be no Gulf Stream, or any other considerable oceanic current (as distinguished from a mere surface drift) whatever. By the action of the sun's rays, the *surface* of the ocean becomes *most* heated, and the heated water will, therefore, neither directly tend to *ascend* (which it could not do without leaving the sea) nor to *descend*, which it cannot do, being rendered buoyant, nor to move laterally, no lateral impulse being given, and which it could only do by reason of a general declivity of surface—the dilated portion occupying a higher level. Let us see what this declivity would amount to. The equatorial surface-water has a temperature of 84°. At 7200 feet depth the temperature is 39°, the level of which temperature rises (art. 49) to the surface in lat. 56°. Taking the dilatability of sea-water the same as that of fresh, a uniform increase of temperature, from 39° to 84° Fahr., would dilate a column of 7200 feet by 10 feet,[1] at which height, therefore, above the spheroid of equilibrium (or above the sea-level in lat. 56°), the equatorial surface is actually raised by this dilatation. An arc of 56° on the earth's surface measures 3360 geographical miles, so that we have a slope of one 28th of an inch per geographical mile, or one 32d of an inch per statute mile for the water so raised to run down. As the accelerating force, corresponding to such a slope (of one-tenth of a second 0·1"), is less than one two-millionth part of gravity, we may dismiss this, as a cause capable of creating only a very trifling surface drift, and not worth considering, even were it in the proper direction to form, by concentration, a current from east to west; *which it would not be, but the very reverse.*

(58.) *Secondly.*—Whatever the difference of equatorial and polar temperatures in the surface-water, or, were there no difference at all, the actually existing trade-winds must of necessity act on the surface-water in the manner described in art. 51. Their action is in the nature of a *vera causa*, which cannot be ignored or set aside. The easterly momentum communicated to *the whole mass of air constituting the trade-wind has*, on its arrival on the equator, been abstracted from the surface-water. The surface-water *has* lost that easterly momentum, which is equivalent to saying that it *has* acquired an equal westerly amount, relatively to the dry land. It is for those who deny or under-rate the power of the winds to produce currents to dispose of this momentum otherwise.

(59.) *3dly and lastly.*—Sea water, by evaporation, acquires additional saltness and density, and by dilution with rain, the reverse qualities. In this fact we have a *vera causa*, though a very feeble one, for the production of an indraft on both sides *towards the lines of maximum evaporation and minimum precipitation.* These lines (as we have seen, art. 20) are not very remote from the tropics, being somewhat nearer the equator, it is true, but not so much so as to make it worth while to distinguish them for our present purpose. The diurnal rotation, then, will modify the directions of this indraft. Water coming in to the northern tropic, for instance, from the north side, will arrive in a south-westerly direction, and from the south in a north-easterly. The indrawn waters, then, will meet from opposite sides point blank on the tropic, and destroy each other's impulse. They will simply replace the volume of evaporated water while the denser water subsides vertically. The rain, moreover, which descends on the equator, has, on its arrival at the sea level, no tendency either eastward or westward. It opposes no resistance to being swept in the latter direction by the wind, and thus carried into the general circulation as part of the equatorial current.

[1] 9·971 feet, calculating on Dr Young's formula for the dilatation of water. Lect. ii. 392.

(60.) We ought here to observe, too, that it is by no means necessary, in accounting for the Gulf Stream or other ocean current, to assume or prove the existence of what is called "a head of water." Such currents do not of necessity run from a higher to a lower level. Indeed, such a condition (as a general one) is incompatible with the notion of *circulation.* A circulation in a closed area, produced by an impulse acting horizontally on the surface-water, may perfectly well co-exist with a truly level course of each molecule. A billiard ball runs along a level table by an impulse from the cue quite as naturally as if it rolled on an inclined plane by its weight. The notion of a "head of water," as a necessary condition, is a fundamental misconception in most of the received theories of oceanic currents, though such a head may be produced if a current be resisted or deflected.

(61.) The equatorial current of the Atlantic, as we have stated, bifurcates off Cape St Roque, and a branch called the Brazil current runs southwards—inferior in volume to the Gulf Stream. The projection of the South American coast, and the absence of any deep hollow like the Gulf of Mexico, affording no focus of concentration, a small portion only of it coasts along at about 300 or 350 miles from shore up to the extremity of the Continent, while the main body performs in the South Atlantic much the same sort of evolution as the offset of the Gulf Stream in the north. The further progress of this stream is by no means well made out. It is no doubt swept round in an eddy in some respects analogous to that in the North Atlantic basin, so as to form what is called the "connecting current of the South Atlantic," which runs nearly due east about the 33d parallel of south latitude; but in what way it is returned into the equatorial circulation, or whether so at all, does not clearly appear. It has been considered as finding its way at the Cape into the Southern Ocean. More probably a portion returns to the equator, and a portion escapes into the Southern Ocean, giving the Cape of Good Hope, however, a wide berth.

(62.) The equatorial current of the Pacific preserves a steady course, from its origin on the west coast of America across the whole Pacific basin, until it nears the Asiatic coast, where (as in the Atlantic) it bifurcates—the larger portion, however, being carried southwards through the broken channels between Borneo and New Guinea, to sweep the northern and western coasts of Australia, while the smaller branch, under the name of the Japan current, skirts the outside of the island barrier of the eastern Asiatic coast, imitating in the North Pacific, as nearly as the form of its basin and the narrowness of its opening into the Arctic Sea will permit, the course of the Gulf Stream in the North Atlantic. For it sends only a small shoot north-easterly up to the straits, while the main body, curving round, takes a great sweep along the Californian coast till nearly off the entrance of the Gulf of California, where it turns to the west, and regains the equatorial circulation. For nearly half the year (December-April) it is partially prolonged along the Mexican coast by the "Mexican coast current"—an alternating drift produced by monsoons setting along that coast.

(63.) In the North Pacific, in the latitude of Owyhee, and over an area of nearly 50° of longitude to the eastward of that island, that is to say, within the area encircled by the great eddying stream above traced, occurs a somewhat anomalous counter-current, or system of currents, running eastward, which in all probability result from peculiarities in the configuration of the bottom of the ocean—perhaps to shallows or to submarine coral elevations, which entangle and deflect a portion of the equatorial current. This and some other of the North Pacific currents are as yet far from well understood.

(64.) To understand the currents of the South Pacific, we must remember, that while the northern portion of the great equatorial drift merely eddies round the closed North Pacific basin, its southern waters find an escape, and enter the general circulation of the world through the Indian Seas. The Pacific, then, would be drained of its waters were it not replenished from the southern ocean, and we find accordingly that it is so. But this condition implies a northward direction given to the water drifted by the north-west Antitrades, which, combined with the movement to the south-east those winds alone would tend to impress, overcomes the southerly element of that motion, and leaves the east outstanding. Thus originate two leading currents known as the Antarctic drift current (of cold water bearing icebergs), and the South Pacific current, both setting into the concavity of the South American west coast (the latter prolonged into what is known by the name of the Mentor drift current), together with a general drift of cold water to the southward of both these, which takes the form of a bifurcating current about 45° S. lat., nearly opposite the isle of Chiloe, and about 600 geographical miles from the coast. One portion proceeds to, and rounds Cape Hoorn, as the "Cape Hoorn current;" the other skirts the whole western coast of South America, as the "Peruvian or Humboldt's current" (attention being first drawn to it by that celebrated traveller), interposing itself between the Mentor drift and the coast, till off Payta, in latitude about 4° S., it turns westward, and joins in the south equatorial circulation.

(65.) The currents of the Indian Ocean north of the equator are complicated by the monsoons, caused (see METEOROLOGY) by the proximity of the Asiatic coast, and it is only over the region of the S. E. trades, and about the 20th parallel of south latitude, that a general and steady westward set of water takes place. This follows, *mutatis mutandis*, the same laws as in the Pacific, the ocean being open to the south. It bifurcates about the 75th degree of east longitude, one portion taking its course north of Madagascar, and then curving southward as the Mozambique current along the African east coast, the other passing Madagascar on the east side, and pursuing a direct course towards the Cape of Good Hope, where the two branches rejoin; a portion only of the stream so produced shoots southwards past the Cape as a warm current, but the greater part is suddenly deflected and driven back in an eddy or counter-current, running nearly eastward, by the cold water setting in from the south (bearing icebergs), to supply (just as in the case of the Pacific) the deficit of water, and carrying out precisely the same system of reaction as in that ocean. The drift produced by the prevalent north-west winds beyond the southern tropic, has the southerly portion of its momentum destroyed by the general equatorial indrift, and overcome by this cause, the easterly subsisting, and the result is a north-easterly stream bifurcating off Cape Leewin about 105° E. long., and sweeping the western and southern coasts of Australia, the former portion (just as in the case of the corresponding portion of the Pacific supply current) reverting west, and joining in the equatorial circulation, the other going forwards in part supply of the Pacific deficit. We have been perhaps more diffuse on the subject of the oceanic currents than the nature of this article may seem to justify; but some such detail seemed necessary to vindicate to the winds their supremacy in the production of currents, without calling in the feeble and ineffective aid of heated water, or the still more insignificant[1] in-

[1] Insignificant for such a purpose, but not for some others, when its accumulated effect in long periods of time is regarded.

fluence of insect secretion, which has been pressed into the service as a cause of buoyancy in the regions occupied by coral formations.

(66.) *Tides and Waves.*—The tides are in the nature of forced oscillations (*i.e.*, such as are maintained against continued resistance and unconformable oscillatory tendencies in the system of waters subjected to them) maintained by the sun and moon, each of which produces and maintains such an oscillation, which, in virtue of the law of superposition of small motions, co-exists with the other, and either conspires with, or contradicts it, according to the phases in which they happen to be at a given time and place. The action of either luminary consists in a difference of attractive force exerted by it on the solid nucleus of the globe, and the covering ocean, whence arise disturbing forces analogous to those by which the motions of the moon are affected by the sun's attraction. If the disturbing luminary maintained a constant position with respect to the earth, the effect would be to produce a distortion of figure in the ocean surface, surrounding the whole globe (or which would so surround it, if entirely covered with water), having the form of a slightly elongated ellipsoid, the two vertices of which, were the waters instantly to assume a form of equilibrium under the acting forces, would be the one precisely under, the other precisely opposite to, the points at which the luminary is vertical. This, however, is not the case, the forces shifting their point of action before the ellipsoid has time to form. Thus a wave is produced, which pursues the luminary round the globe.

(67.) The height of the wave thus produced by the moon is to that produced by the sun as 100 to 38. Their mean periods of revolution about the globe are also unequal, being respectively the lunar day of 24h. 54m., and the solar day of 24h. They conspire, and have a common vertex when the sun and moon are in conjunction or opposition (*i. e.*, at new and full moon); in which case the joint tide is the sum of the separate ones, and is called spring-tide. From these points the lunar lags behind the solar wave until the quadratures of the moon, when the high water of the moon coincides with the low water of the sun, and the joint tide is the difference of the separate ones, and is called neap-tide. And it is therefore by assiduous observations of the heights of the tide at the conjunctions and quadratures that, the sum and difference becoming known, the proportions of the two are ascertained (as above), the rise and fall of the spring and neap being as 138 to 62, or nearly as 7 to 3. The greatest tides occur when the luminaries are nearest, and pass most nearly vertically over the place of observation.

(68.) The depth of the sea varies so much, and the form of its basin, taken as a whole, is so interrupted by the land, that it may be doubted whether, were the action of the luminaries at once suspended, their tide waves would perform even a single revolution with any sort of regularity, and in the course of two or three, would be so broken up and confused by reflexion to and fro, as to destroy all vestige of a tide. Hence it follows, that the tides for the time being may be considered as *almost* completely commanded by the then actual position and proximities of the luminaries, the free oscillations of the sea in its bed being quite subordinate to the forced wave generating them. In consequence (as is always the case in forced oscillations), every periodicity in the action of the forcing cause is propagated into the oscillations, and records itself in the recorded height of the tide on every point of every coast, but at each point, at a greater or less interval from the culmination of the luminary, according to its local position and the more or less circuitous course taken by the tide-wave to reach it, and which special observation can alone determine. This interval is called the *establishment* of the place.

(69.) The motion of the water in the tide-wave is totally unlike that in an ordinary surface-wave, such as the wind produces. When a narrow wave of this latter kind, or a succession of such waves of equal breadths and heights, is formed in deep water, a light floating body, as a cork, revolves either in a vertical circle, or an ellipse not very different from one, having the longer axis vertical. But in the tide-wave the movement of each particle may be regarded as performed in an excessively elongated ellipse, the *shorter* axis of which is vertical. The breadth of the tide-wave from crest to crest, supposing all the earth covered, would be half the earth's circumference, or 12,500 miles, in comparison of which the depth of the sea is insignificant; and the slightest consideration suffices to shew that as all the water which goes to form the elevated portion must be brought from that depressed, this can only take place by a lateral approach of the vertical sections of the sea when the water is rising, and their recess from each other when falling—*i.e.*, over a quadrant of the globe in either case, which is only another way of expressing an alternating forward and backward horizontal current at any given place—with this especial peculiarity, viz., that these currents (the flow and ebb current) run *most rapidly* at the moments of high and low water; the instants of *most rapid rise and fall* being those of "slack water," or no current one way or other. In fact, it is obvious that the surface must be rising most rapidly when water is *setting in equally both ways to*, and sinking most rapidly when setting *out equally both ways from* the place; in neither of which cases can there be any current *at* the place.

(70.) The tide-wave differs also from a wind-wave in another very remarkable point. It affects the whole depth of the ocean equally, from the bottom to the surface, while the wind-waves, even in the most violent storms, agitate it to a very trifling depth. For the force which acts to produce the former, which is what in the lunar theory is termed the *tangential* element of the disturbing force, is exerted equally in every portion of the vertical extent of the water, while those producing the latter are strictly confined to the surface. Hence it would at first sight seem that the tidal action must be very violent at the bottom of the sea: and in shallow seas it is so, but not in deep water. A tide-wave of four feet in total height (between high and low water), which is that of the tide at the Atolls of the Indian Ocean, advancing over a sea 30,000 feet deep, implies in each particle an alternate advance and recess of 2800 feet in its total extent; but this movement, being spread over 6 hours either way, is nowhere very rapid.

(71.) In shallow seas, however, the actual movement to and fro is more rapid in the inverse ratio of the depth of water, and this is seen in many remarkable instances, as, for example, in the Race of Alderney, and the seas in the island channels of the Orkneys, and the celebrated Maelstrom off the Norwegian coast, as well as in the rapid streams which flow all round our own coasts, and are familiar to every seaman. It is this which gives the tides their drifting and abrading power on the materials of the coast.

(72.) Both the sun and moon, on a general average, are vertical over the equator, where, therefore, if the sea covered the globe, would be the region of highest tides, and round which zone they would circulate uniformly; but the equatorial sea being broken up into three great basins, and open water existing only to the southward of the three great continental masses, the phenomena of the tides are complicated in a very singular way. In each of

these basins the equatorial tide has to take a fresh start from the eastern side, with every fresh upper and lower transit of the producing luminary, and is destroyed or confused by reflexion on the western coast before the creation of a new wave, while in the open part of the Southern Ocean the tide-wave circulates unimpeded, and spreads in to the three oceans, up which it runs as a free wave from south-east to north-west, overtaking in its progress, and amalgamating with, the partial equatorial tides or forced waves proper to either ocean, and their reflected portions. In spite of all the complications so induced, however, and of those additional ones which arise from the shoaling of seas and the narrowing of channels, as a general fact two high and two low waters occur everywhere in the course of a lunar day of 24 h. 54 m., the solar and lunar tides never contradicting each other so far as to produce a double maximum in their combined wave. The day and hour of occurrence of the highest spring-tide next following the conjunction of the luminaries being observed, informs us not only of the "establishment" of the place, but also of the *age* of the tide, or that particular original tide-wave, of which any one circuitously arriving at a place, may be a branch. Thus the age of the tide in the port of London is two days, and on the coast of Spain, thirty-six hours. By determining these particulars at a series of points along all the coast lines, it becomes possible to construct a chart of *cotidal* lines, or those of contemporaneous arrival of the same tide, however subdivided, as has been done with extraordinary perseverance and success by Dr. Whewell. From his researches we learn,

(73.) 1*st*. That whereas the forced equatorial tide in a continuous sea would run round the globe in 24 h., and therefore with a mean velocity of 900 geographical miles = 1050 statute miles per hour, it requires 12 h. to run up the Atlantic from 50° S. to 50° N. lat., giving an average rate of about 500 geographical miles per hour. In the Atlantic, then, it is more in the nature of a free than of a forced wave.

(74.) 2*dly*. That its rate of advance is mainly determined by the depth of water. When it enters the Atlantic its front runs nearly from N.E. to S.W., but in its progress it becomes curved and convex northwards, till it approaches the southern tropic, where its progress is retarded again in the interval from thence to the equator, just where the appearance of islands (St Helena and Ascension) afford an indication of less depth. From the equator northwards, its progress again becomes rapid, and the increasing convexity of the lines of successive hours marks as clearly as soundings (since obtained) would do, the deepest channel. Thus the cotidal line corresponding to the eleventh hour of its progress, which at its eastern extremity rests on Cape Blanco (lat. 21° N.), and at its western on Porto Rico (19° N.) has its front advanced to the north nearly to the bank of Newfoundland (46° N.), and the point of its farthest advance precisely on that part of the sea where (as we have seen in art. 37) the great submarine cross valley of the North Atlantic is situate. Advancing further north, the cotidal lines of the successive hours close up, in correspondence with the diminishing depth of the North Sea, and round the Irish coast, indicate a velocity not exceeding 150 miles per hour, while in the channels the wave advances still slower, and they are crowded still closer.

(75.) Further and very remarkable corroborations of the same theoretically demonstrable law appear wherever the advancing front of the tide-wave stretches across the opening of any great bay or recess of the coast line. Such is the case in the hollow of the South American coast off Patagonia, between the River La Plata and Cape Horn; and again in the Indian Ocean, in the Arabian Gulf, and the Bay of Bengal, in which last, as the rate of advance of the wave diminishes, the extent and force (as a necessary consequence) of the aquatic movement increases, both the height and the ebb and flow current are exaggerated, and result in the phenomena of a *Bore*, or sudden and violent wave rushing up the Hooghly River with such impetuosity as to sweep everything before it. The same thing takes place in many other estuaries, or gradually expanding mouths of rivers, which receive and concentrate the tide; as, for instance, in the Garonne, and in our own Severn, where the spring-tides at Chepstow (which in mid-ocean, as at St Helena and Ascension, do not exceed three feet) rise to forty, and where at such times a bore nine feet in height runs up stream. The bore of the Chinese river Tsientang advances up that river at Hangchau like a wall of water, extended across the river, thirty feet in height, and advancing at the rate of twenty-five miles per hour, sweeping all before it. In the Amazon River, at the equinoxes (when the equatorial tide is at its maximum), during three consecutive days, bores of twelve or fifteen feet high rush up the river with each high water; so that, along the course of the stream, up which for 200 miles from its mouth no less than eight tide waves are simultaneously advancing, as many as five bores are sometimes at once in progress.

(76.) The effect of concentration, by the gradual approach of the shores, and the shoaling of the bottom, is nowhere so strongly exemplified as in the Bay of Fundy, where the tide not uncommonly rises fifty feet, and, as is said, on some occasions to more than double this height. The whole of the tide-wave between Halifax and Charleston is made to converge by the shore of Nova Scotia on one side, and the United States on the other, to the entrance of this bay; a ship has been known to strike and remain fixed on a sunken rock at high water there during the night, and at daybreak the crew have been astonished to find themselves looking down a precipice into water far below.

(77.) The tide which flows round the British Islands, on the west side, bends round the north of Scotland, and enters the German Ocean from the north, after traversing which, it meets the tide of twelve hours' earlier origin which has entered by St George's Channel. Hence arises a singular complication; the former tide mainly clinging to the British, and the latter to the Continental coast, and producing a revolving wave and nodes of undulation; and, in consequence, there is a point in the North Sea whose existence was pointed out *a priori* by Dr Whewell, and verified by observation, where the rise and fall of the tide is *nil*.

(78.) The tides of the Pacific are but ill understood. In some parts of it (as in the Atlantic) they are of very small magnitude, as far as rise and fall is concerned, so that at some points, as at the Sandwich Islands, they may be said to be entirely masked by the effect of the land and sea breezes, and the diurnal variation of the pressure of the air: and a single feeble tide, at fixed hours in the day and night, occurs in place of the usual double rise and fall at hours continually varying. At Singapore, also at the Keeling Islands, and at Petropaulovski, similar phenomena occur due to local peculiarities. At Tonquin also (at Batschan) there is only a single tide; but this is explained by the interference of tides which reach it at the same time in different phases, and by different channels, combined with the "diurnal inequality" of the two high waters (a very generally observed phenomenon), which annihilates one of them, but leaves a portion of the other outstanding.

(79.) Wind-waves are small at their first origin, com-

mencing with a mere ripple, or, as the sailors term it, "a cat's paw," on the water—"darkening like water in the breeze." But each wavelet, as it advances, acquires increased height by the continued pressure of the wind, according to a law which has been clearly deduced from strict dynamical principles by Mr Airy, in a very remarkable paper on Tides and Waves, forming part of the *Encyclop. Metropol.* Hence it is that the larger waves are not developed in narrow seas, or when the wind blows off the land; they require breadth of water and continued pressure *a tergo*, for their formation. The greatest waves known are those off the Cape of Good Hope, under the influence of a north-west gale (the storm-wind of that region), which drifts the swell round the Cape, after traversing obliquely the vast area of the South Atlantic. In such gales, waves are there met with of forty feet in height, so that two ships in the trough of the sea, with such a wave between them, lose sight of one another from their decks. Off Cape Hoorn, also, waves of thirty-two feet from crest to trough have been observed. In our own seas the waves rarely exceed eight or nine feet in height.

(80.) There exists a relation between the breadth of a wave, its velocity of progress, and the depth of the water on which it travels, which has been embodied by Mr Airy in the following table:—

Depth of the Water in Feet.	Breadth of the Wave in Feet.							
	1.	10.	100.	1000.	10,000.	100,000.	1,000,000.	10,000,000
	Corresponding Velocity of Wave per Second in Feet.							
1	2·262	5·320	5·667	5·671	5·671	5·671	5·671	5·671
10	2·262	7·154	16·883	17·921	17·933	17·933	17·933	17·933
100	2·262	7·154	22·264	53·390	56 672	56 710	56·710	56·710
1000	2·262	Do.	22·264	71·543	168·83	179 21	179·33	179·33
10,000	2·262	Do.	Do.	71·543	226 24	533 90	566 72	567·10
100,000	2·262	Do.	Do.	Do.	226·24	715·43	1688·3	1793·3

The conclusion of Professor Bache respecting the depth of the Pacific, noticed in art. 40, is founded on this Table. And by a similar principle of calculation, grounded on the progress of the tide-wave (regarded as a free-wave) running up the Atlantic (art. 73), viz., that a wave 6000 geographical miles in breadth from crest to crest travels its own breadth in twelve hours, we find for the *mean* depth of the whole Atlantic from 50° south lat. to 50° N. 22,157 feet, a result perfectly in accordance with what we know from numerous soundings of its northern basin, and what may reasonably be concluded from the comparatively few obtained in its southern.

(81.) As the wind, supposed to blow off shore, continues to act on a wave, it increases both in length and breadth, and the water deepening, its velocity of progress increases rapidly. The depth of water to which the agitation of a wave extends perceptibly, never bears a very large proportion to the dimensions of the wave, either in breadth or height, the motion diminishing in geometrical progression, as the depth below the surface increases in arithmetical, and at a depth equal to the breadth of the wave, the motion is diminished to one 534th part of that at the surface. In the case of a wave, then, a quarter of a mile in breadth, and forty feet in height, the displacement of the water at a depth of 1320 feet, in its passage over it would be less than an inch, and would be incapable of disturbing the smallest grain of sand.

(82.) When waves cross each other, they are simply superposed, and in place of dividing the water into parallel ridges, they break it into lozenges. In this case, the motion of each particle of the surface-water, besides that of rising and falling, is one of circulation in a horizontal plane, and a small portion of the surface changes its inclination to the horizon in what is called a vorticose manner, a perpendicular to the surface (as the mast of a ship floating on it) revolving conically, by a combination of pitching and rolling distressing to the passengers, and trying to the vessel. This crossing of waves, especially when more than two series cross one another, forms what is called "a chopping sea." Such seas occur, 1*st*, when a series of waves, rolling into an extensive bay, meet, at oblique angles, the waves reflected from its shores, as is very frequently the case in the Bay of Biscay. 2*dly*, When the wind, after blowing long and fiercely in one direction, veers suddenly to another, which happens especially in those hurricanes called cyclones, or revolving gales, which produce waves travelling at once towards all points of the compass, the combination of which, near the centre of the whirlwind, produces a sea of the most fearful description. 3*dly*, When a storm in one direction acts on a sea in which there exists already a long rolling swell setting in from a great distance in another, called a "ground swell," the consequence of a far remote storm which has never made itself sensible in any other way at the place of the ship.

(83.) By far the largest waves, however, are those which owe their origin to earthquakes. On such occasions, great tracts of the ocean-bed are often suddenly uplifted or depressed, and the result is necessarily a vast wave running out from the spot in all directions. One such wave has already been mentioned. In the earthquake which destroyed Lisbon in 1755, a portion of the coast-line suddenly sank to a depth of 600 feet, and the result was a wave of 60 feet in height, which swept over the land, ravaged the whole coast of Portugal, and was propagated seaward quite across the Atlantic to the West Indies. At Madeira it rose and fell 12 feet.

(84.) When a wave runs forward into shoal water, the friction retards the movement of the lower particles, those of the upper continuing. The circle described by the water molecules gradually passes into a more and more flattened ellipse (Weber, *Wellenlehre*), and at length the wave *breaks:* its crest curls over, and precipitates itself forward on the shore, up which it rushes, the under-water at the same time racing back, and tearing up the beach in its backward course. Hence the abrading and destructive action of the surf on a sea-beach. Certain coasts are particularly infested with a heavy surf, such as that off Madras, where the surf habitually breaks at such a distance from the beach as to render landing always difficult and dangerous, and sometimes impossible. The great waves which roll in from the Indian Ocean sometimes break there in nine fathoms water, and at a distance of four miles from land.

(85.) The force of waves, when breaking against an

obstacle, is enormous. Their effective pressure during violent storms has been estimated as high as 6000 lbs. per square foot. The waves breaking against the base of the Eddystone lighthouse, have been known to dash up above its top to 150 feet above the sea-level, and descend like a cataract on its summit. In the great Barbadoes hurricane of 1780, cannon, which had been long lying sunk, were washed far up on shore, and found high and dry on the subsidence of the storm.

(86.) *Coral Formations, Atolls, Reefs, Lagunes.*—A very large area of the tropical seas, both in the Indian and Pacific Oceans, is dotted over with islands, the upper portions at least of which are the work of those singular organisms of the genera astræa, meandrina, and caryophyllia, which secrete from the sea-water the *nidus* which they inhabit in the form of continuous rocky masses, perforated according to regular patterns, and known by the name of coral. The animals themselves live and work only within certain very moderate limits of depth, not exceeding ninety fathoms; and whether those now living are to be considered as successors or prolongations (by a process of gemmation) of those which have perished *in situ*, does not seem well made out.

(87.) The coral formations are chiefly confined to the Indian and Pacific Oceans, between the parallels of 30° north and south. The Arabian and Persian Gulfs, and the Red Sea, are full of them, and between the coasts of Madagascar and Malabar, the whole ocean may be considered as a great coral sea. Along the east coast of Australia, and stretching thence to New Guinea, they form barrier reefs of the most dangerous character, which prevent all access to the coast, except through narrow channels occurring only at rare intervals. The "Great Barrier Reef" extends from Breaksea Spit, in lat. 24° 36′ S., to Bristow Island, 9° 15′ S., a mean breadth of 30 miles, a length of 1100, and an area of 33,000 square miles. But the most curious and striking peculiarity of the coral formations is their tendency to crown every summit rising up from deep water, and to form, upon sunken rocks, circular basins or lagunes, a *fleu de l'eau*, called Atolls, surrounded on every side with water of unfathomed depth, and shelving off in the most precipitous manner. Of these, the most remarkable instances in the Indian Ocean, is the chain of islands, or rather groups of islands, running directly south across the equator from the western extremity of the peninsula of India, the Laccadive, Maldive,[1] and Chagos Isles. These consist of "a series of circular assemblages of islands, the larger groups being 40 or 50 miles in their longest diameter. On the outside of each circle, or atoll, are coral reefs extending to a distance of two or three miles, beyond which are no soundings at immense depths. But in the centre of each is a lagune from 15 to 20 fathoms deep." It has been considered, with great probability, that these atolls crown the craters of extinct and submerged volcanos; and from the excessively sudden and precipitous manner in which many of them in the Pacific spring up from deep water, the lower portions being formed of *dead* coral (for the animal lives and works only at or near the surface), an argument almost irresistible has been drawn by Mr Darwin in favour of a slow but continual subsidence of the bottom of the ocean in which they occur, the animals constantly raising the summit to the surface as the base subsides. The upper portion of their work is battered by the sea, which heaps up the broken fragments on the windward side, leaving generally an opening into the lagune to leeward, and thus forming, as it were, harbours of refuge of great security, with free access at all times. This peculiarity has been insisted on by Sir C. Lyell as an additional and very cogent argument for their gradual subsidence, as it is difficult to imagine any other cause by which the leeward opening could constantly be kept unobstructed.

(88.) In the Pacific, the most remarkable coral formations are those of the Caroline Islands, a vast assemblage of coral groups, extending over more than 20° in longitude, and 5° in latitude, the Society Isles, and the so-called Dangerous Archipelago. Indeed, every island yet examined in the wide district termed Eastern Oceania, consists either of volcanic rocks, or coral limestones.

(89.) It is one of the peculiarities of these Zoophytes, that they always build perpendicularly upwards. This, while it serves to explain the precipitous character of the external wall of their lagunes, may serve, in conjunction with the great depth from which they rise, to give some idea of the duration of the period in which the subsidence of their foundation has been in progress—such steepness being of extreme rarity on coasts where no coral exists, and where the usual action of the sea, except on the hardest granite, invariably shoals the water into a more or less gradual declivity.

(90.) *Phenomena of the Polar Seas.—Floating Ice—Icebergs.*—Beyond the 56th parallels of latitude, as we have seen, the temperature of the water is lower at the surface, and rises as the thermometer descends, till the level of 39° is reached. The sea then, even in deep water, becomes frozen at the surface in the winter months, or rather through all that portion of the year which intervenes between the beginning of September and the latter end of June—July and August being, in high latitudes, the only open months. Sea-water freezes at a lower temperature than fresh ($28\frac{1}{2}$° Fahr.), but its ice, like that of fresh-water, floats, and nearly with the same buoyancy. It may, indeed, be doubted whether salt-water ice be really anything else than fresh, with a portion of concentrated brine entangled in its pores. Snow falling and floating on water of 28°, does not of course melt, so that the Polar Seas become coated with a stratum of perfectly fresh ice over very extensive tracts. The broken masses detached from the coasts, also, around which the ice accumulates in the long winters into cliffs and glaciers of vast height, and hundreds of miles in extent, and which, when set afloat, drift along as icebergs, by the effect of currents, are necessarily fresh. In estimating the magnitude of these masses, it must always be borne in mind that the specific gravity of ice being only 0·9, only about one-tenth of its bulk projects above the surface.

(91.) There can be very little doubt that, in the winter time, the surface of the ocean at both poles is entirely frozen; but at the North Pole, it is probable, from many indications, that open water exists over a very large area of the central polar basin, during a considerable portion of the warmer months. Although the northern coasts of Europe and Asia, from Nova Zembla to the extremity of Siberia, are always lined with ice, yet, in advancing out to sea-ward in sledges, from Kotelnoi Island and the mouth of the Kolyma River, in lat. N. 76° and 72°, Lieut. Anjou and Baron Wrangel found open ocean as far as the eye could reach; and the same has been observed by Inglefield and Kane (the latter viewing it from "Cape Constitution," 540 ft. in altitude), in lat. 81° 22′ N., in Kennedy Channel, at the north end of Smith's Sound. In the land-locked and intricate channels between Greenland and the north coast of America, the obstruction very frequently continues, however, during the whole summer, and even several successive ones, as the annals of Arctic exploration only too emphatically witness.

[1] See Moresby and Powell's beautiful charts of the Maldive Atolls.

(92.) When, under the influence of the advancing season, the "field-ice" of the general surface breaks, it becomes heaped together in sheets piled on each other into what is called an "ice-pack," showing in lines the thickness of the sheets, which often extends to 30 or 40 feet. The wild confusion which a storm creates in such a "pack," is more easily imagined than described. When extensive ice-fields meet, which they often do, under the influence of opposing winds and currents, their enormous momentum crushes together the edges in contact, breaks them up, and drives them one over the other into ridges. Occasionally these floating fields come into collision with icebergs, which are making their way under the influence of the current, by which (on account of the great depth and volume of the submerged portion) they are entirely commanded, while the "floes" drift at the mercy of the winds, when an awful scene of destruction takes place, the floes, of course, giving way, tearing up, and flying to pieces in all directions.

(93.) To give an idea of the quantity of ice which is carried out of the polar regions, independent of the icebergs, and drifted into warmer temperatures, we need only instance the case of the Resolute, exploring-ship, which, having been abandoned by reason of its getting inextricably engaged in a vast field of ice in Melville's Straits, was found afterwards in Baffin's Bay, having been carried 1000 miles from its former position by the drift of an ice-field 300,000 square miles in extent, and 7 feet thick. A similar occurrence carried Captain De Haven, of the U. S. Navy, in a mass of frozen sea-water an equal distance south of his position in the mid-channel of Wellington Straits.

(94.) Little of the *floe*, or surface-ice, however, escapes unmelted from Baffin's Bay: it is speedily broken up and destroyed by the waves in open water, and it is only the great detached masses which float to any considerable distance from either polar circle into the temperate zones. In the Atlantic they are seldom met with below 40° N. lat., being destroyed by encountering the Gulf Stream. In the North Pacific, their access from the Polar Basin being barred, they do not occur. In the Southern Ocean they attain as far as 40° S., and are very often met with in rounding the Cape of Good Hope, at some distance from land.

(95.) These bergs, from the mode of their formation, being detached by fracture from glaciers projecting into the sea, and from barrier lines of ice cliff, and being afterwards subjected to the melting influence of the air, assume the most uncouth and extraordinary forms, sometimes picturesque with towering pinnacles and overhanging cliffs, and always grand and awful. They have been seen as much as 600 feet in height, but when met with at sea are seldom more than 200 or 300. They spread a sensible degree of cold in the air, accompanied with fog, for great distances round them, and form one of the chief dangers in navigating the North Atlantic.

(96.) Many of the bergs which drift out to sea, having been the extremities of glaciers while in attachment to the coast, are loaded with broken fragments of rock and other materials, which have been heaped on them by casualties of weather, and the fall of rocks during their gradual descent to the sea level. These they carry with them wherever they may drift, and ultimately deposit at the bottom of the sea on melting. Icebergs have been encountered in the North Sea, covered or interstratified with ancient soil, among which were the bones of mammoths and other extinct animals.

(97. Around the south pole a sea, open (at least so far as land is concerned) or nearly open, extends all round it, except between the meridians of 160° and 170° E. longitude, and the parallels of 70° and 80° S. latitude, which is occupied by the coast of Victoria Land, discovered in 1841 by Sir J. C. Ross. From the southernmost accessible point of this coast, in lat. 78° 15′, extends for 450 miles to the eastward an unbroken vertical cliff of ice, being 180 feet above the water, and therefore about 1000 feet in thickness—floating in water 280 fathoms in depth (1680 feet), though probably connected to the south with an extension of Victoria Land. With exception of this, and some similar masses also connected with land, the Antarctic Sea is less unbrokenly coated with field ice than might be expected, the swell from the great oceans with which it is connected breaking the fields up into floes of no great magnitude. But, on the other hand, the "packed ice," which results from the fracture and piling up of the field ice, accumulates in immense quantities. Sir J. C. Ross, in the daring voyage of the Erebus and Terror, had to force his way through 1000 miles of such obstructions.

(98.) In consequence of the intense cold of the icy surface, contrasted, as it sometimes is in summer, with the warmth of the air, the phenomena of atmospheric refraction are exaggerated in these regions in a most extraordinary manner—the forms of icebergs, rocks, &c., are seen drawn up in vertical altitude, and spread out on their apparent summits laterally, so as to present no resemblance to their real form. One of the beneficial consequences of the great amount of refraction is the earlier appearance of the sun above the horizon, and its later disappearance, by which the dreary polar winters are shortened by several days.

(99.) Another phenomenon, which is witnessed in its highest perfection in the polar seas, and, in general, in high north and south latitudes, is the Aurora. The magnificence of its displays, as recorded by those who have witnessed them in the arctic regions, is such as those who have seen it only in our latitudes can hardly conceive. It is described as an immense curtain, waving its folds like the canopy of an ample tent agitated by the wind, and fringed with a border of light of the richest colours and vivid brilliancy. The impossibility of wintering in very high southern latitudes cuts off the most advantageous opportunities of observing auroral exhibitions.

(100.) THE LAND.—*Its Coast-lines, Harbours, Sea-cliffs, Beaches, Shingle-drifts, Tidal abrasion, Estuaries, Deltas.*—We have mentioned in arts. 12, 15, the more general features of the coast-lines of the great masses of land; but it is their minor local irregularities of outline which, in the magnitude and convenience of harbours, estuaries, and river mouths, accessible at all seasons, and the protection and facility of communication with the interior these afford, constitute a feature of the last importance to the well-being and commercial intercourse of the countries they border. In this respect there is a marked and vast difference between the several regions of the land, which has exercised, and must ever continue to exercise, a most powerful influence in determining the relative degree of civilization of nations, and, what is of greater importance, the more or less cosmopolitan character of that civilization. In this respect Europe, and the eastern coasts of North America, stand pre-eminent. It is true that the great Archipelago of the east affords innumerable and excellent positions of this nature; but their very multitude and disconnection fit them rather for nests of piracy, or for dependent emporia of commerce *in transitu*, than for the seats of great, compact, and united communities.

(101.) The capacity of any region of the globe for external communication may, to a certain degree, be very fairly estimated by a comparison of the extent of its coast-line with its superficial area. Europe, for instance, with an area

Physical Geography.

of 3,400,000 square statute miles, has 20,000 statute miles of coast-line, being at the average rate of a mile of coast for every 170 square miles of surface, and of which only about 3000 miles is of difficult access. Asia, with 17,600,000 square miles of surface, has 33,000 miles of coast (or one to 533), nearly a fourth part of which is arctic, and all but inaccessible. Africa, with 11,300,000 miles of surface, has a coast of 16,500 (1 to 420), singularly destitute, in every part of its outline, of good harbourage, and with some of its great rivers barred, and others pestiferous. On the other hand, the area of North America being 7,200,000 miles, has a coast-line (1 to 260), of 28,000, of which, however, nearly a third being arctic, is useless as a seabord. South America, with an area of 6,800,000 miles, and a coast-line of 16,500 (1 to 420), presents a remarkable contrast between its eastern and western coasts, not so much in respect of indentation by good harbours, of which it has little to boast, as on account of the vast rivers which flow into the Atlantic, and afford a power of penetrating into the interior, *ab extra*, unexampled except in North America and China. Our own islands, Ireland in particular, are more richly supplied in this respect than any other territory of equal extent, with exception of Norway, the whole coast of which is one continuous chain of deep indentations, or fiords, but whose rugged and precipitous character, and difficulty of accessibility on the land-side, owing to the rude and mountainous nature of the country, go far to neutralize this great natural advantage. The least-favoured region in this respect is Australia,—a mass of 3,500,000 square miles in area, but lying compactly within a very rounded general outline, having a coast but little indented, and nearly, in a very large portion of its eastern sea-bord, rendered unapproachable, except through particular channels, by the great barrier coral reef noticed in art. 87. Nevertheless, it possesses in Sydney perhaps the most perfect and magnificent harbour in the world, and one in which all its united navies might float in security.

(102.) One of the greatest advantages a harbour can possess is that of having, at some little distance off its opening, and in the direction from which tempestuous weather chiefly comes, an island to act as a natural breakwater, according to Virgil's description :—

> "Insula portum
> Efficit objectu laterum, quibus omnis ab alto
> Frangitur, inque sinus scindit sese unda reductos."

Such is the security and ready lateral accessibility on either side afforded to Portsmouth by the Isle of Wight, and to New York by Long Island. Table Bay owes what little security it may be considered to possess, in like manner, to the proximity of Robben Island. Where such natural breakwaters are wanting, or insufficient, artificial ones have often to be constructed, at vast expense, as at Plymouth and Cherbourg.

(103.) A sea-beach is a more or less gently sloping area, on which the breakers do their work of grinding to powder, and carrying out to sea, the fallen fragments of cliffs undermined by their action during high tides and storms, or precipitated by landslips. Such a slope, rising at a small angle (smaller in proportion to the fineness of the detritus of which it consists), surmounted usually by a somewhat steeper bank of shingle (loose stone not yet battered to powder), and backed to landward by a vertical or very precipitous escarpment, marking the limit so far attained by the encroaching ocean, and hollowed into caverns by its waves, is the almost invariable character of a coast line, except when (as in Norway, and on the west coast of Scotland) its material consists of the harder crystalline rocks, in which case there is often deep water close to the cliff, or rugged rocks in every stage of progressive destruction, forming a *talus* rising above the waves. It is therefore perfectly easy to recognize by these marks, when we find them in the interior of a country beyond the present reach of the waves, the existence of what was once a sea-beach, and thence to conclude the action, since that epoch, of elevating forces. Innumerable instances are met with in every part of the world of such ancient sea-beaches elevated at various heights above the actual sea-level—for example, at Plymouth, at New Quay, near Falmouth, in many parts of Wales and Scotland (as in the celebrated parallel roads of Glenroy, clearly shewn by Captain Hall to be ancient sea-beaches); from Alten Bay to Hammerfest in Finmark (Bravais), in the Val di Noto in Sicily (Lyell), in the Morea, as described by Boblaye, and still more remarkably in South America, in the valley of Lima, near Baños del Puyo (Cruickshank), 700 feet above the present sea, and at Coquimbo (Hall). Lately a succession of raised beaches, like a vast flight of 41 terraced steps, 480 feet in total height, has been described by Dr Kane as occurring along the coast of Kennedy Channel, separating Greenland from the land to westward, commencing at 76° N. lat., and continued to "the Great Glacier," and the north of Grinnell Land, or North Victoria. This, then, is one of many cases in which the study of what is actually going on educates the eye and the intellect to discern what has passed; and it is thus that we recognize, in the escarpment of our chalk formations, the cliffs bounding that sea which has denuded of its chalky covering the whole of our Wealden country, and conclude the continued levelling action of the ocean wherever we find a hilly country, cut down by such escarpments, abutting on an extent of comparatively level ground.

(104.) The material so pulverized and washed down into deep water is transported by the tide-current to great distances. In the peculiar nature of the tidal undulation described in arts. 69, 70, we perceive the great transporting and distributing agency by which new strata are formed from the destruction of old ones. But the full effect of this power is only to be appretiated when we contemplate the rounded forms of hills, and the branching and sinuous valleys of a very large portion of the surface of the land where the action of the existing rivers, or of any conceivable amount of atmospheric precipitation, is quite inadequate to have performed the work of excavation, and where there is no evidence of sudden and violent convulsion. Witness our own chalk downs, much of our Wealden swells and slopes, and the gentle undulations which everywhere cover the surface of the lower lands in all countries—

> "Qua se subducere colles
> Incipiunt, mollique jugum demittere clivo;"

and which can be referable to no other agency than tide-washing during a period of prolonged submersion in shallow seas. A large portion of the surface of France is one continued exemplification of this agency.

(105.) Loaded with the material so abraded, the tide-currents sweep along the coast a vast quantity of matter which they deposit in eddies, and thus alter the outlines of the coasts, silt up harbours, form sand-banks, shingle-drifts, land-spits, and other appendages to coast lines (of which we have examples in the great shingle-drift of Dungeness Point and the Chesil Bank), and are active in producing one of the greatest impediments to navigation in the form of bars at the mouths of rivers, of which notable instances occur in the Rangoon River, the Meinam, the Senegal River, the Quilimane or Zambesi, and the Canton River, where there are two bars, Port Natal, and most of the harbours on the South African coast. Such bars are chiefly formed where the opening of the river

to the sea is narrow, and not spread out into an estuary, which the tide tends rather to scour than to silt up.

(106.) Besides the material worn off from the coast by the action of the sea, a vast quantity is brought down by rivers, which accumulates at their mouths, forming deltas, the forms of which are greatly modified by tides and currents. The Ganges has been computed to deliver, on an average, into the sea annually 534,600,000 tons of solid matter; the Mississippi 292,700,000; and the Irawadi 102,500,000. No wonder, then, that in the course of ages deltas should accumulate. That of the Ganges extends across a space of 160 miles, and it has nearly the form of an equilateral triangle, considered as filling the area included by the Hooghly branch, and the innumerable smaller streams which cross like a net work over its surface. The delta of the Nile, like that of the Ganges, is formed in a fork of the river, about 90 geographical miles from the sea (though doubtless the sea, at some former period, occupied the whole space between the branches), and forms on the sea-bord a segment of a circle, having a chord of about 170 geographical miles, the outline being rounded off by the action of the currents, sweeping the drift to the eastward, and bordered with a chain of salt or brackish lakes, separated from the sea by narrow sand lines. That of the Rhine, or rather the united delta of the Rhine, Meuse, and Moselle, constitutes the whole of Holland, and offers, in its northern part, the same phenomenon of a rounded outline and chain of low drift banks (Texel, Vlieland, Schelling, and Ameland), enclosing a shallow expanse of water (the Zuyder Sea), the rivers entering the sea by innumerable outlets to the south. On the other hand, the deltas of the Mississippi and the Lena carry out the rivers to great distances, and form very projecting points; that of the Mississippi, in particular, which is singularly ramified, and in which the main channel prolongs itself, on land of its own formation, like the claw of some web-footed bird, far into the Gulf of Mexico, being increased by immense quantities of drifted trees, which meet together, and form a vast floating mass—the "Raft of Atchefalaya," which, in 1816, contained upwards of 250,000,000 cubic feet of timber, accumulated, in consequence of some local obstruction, in only 38 years, and has been increasing ever since.

(107.) THE LAND, *continued.—Law of Distribution of its Materials—Geological Relations.*—One of the first things which travel teaches us is, that the materials of which the earth consists are not scattered chaotically, and at random, over its surface. Particular sorts of earth and rock occur largely and almost exclusively over some districts, and are wanting in others, and it is the business of geological science to furnish a clue to the intricacies of their distribution, and to point out the relations which subsist between adjacent districts in respect of material composition, and the conditions which have determined the form and extent of each.

(108.) A very superficial observation of the escarpments of cliffs, and other features of a country which lay bare some considerable depth of the ground, suffices to shew that a very large portion of the earth's surface consists of successive layers or beds of different material, or of the same with marking lines of separation, or thin layers of others interposed, while other portions exhibit no such character. Hence a division into *stratified* and *unstratified.* If these layers were strictly horizontal, and of equal thickness, the slope of every hill, and the face of every cliff, would exhibit a series of horizontal belts, running level lines around their contour, and defining the extent over which each would form the surface soil; their superficial breadth being determined simply by the more or less gradual slope of the ground, and the thicknesses of the strata so intersected or "out-cropping." But this is found to be rarely the case; the strata are inclined to the horizon, and some more, some less so; and being intersected by or "out-cropping" at the surface, and that surface being an uneven one, the belts which they form on it neither follow level lines, nor are bounded by parallel outlines. It is therefore to the thickness, inclination, and *order*, if any, *of superposition of the strata*, that we have to look for a key to the extent, configuration, and order of arrangement, side by side, of mineralogical and agricultural districts.

(109.) So long as mineralogical characters only were referred to as distinctive of a "formation," it could never be positively asserted that any definite order of succession existed. The same kind of rock, a limestone for instance, might be found bordering in area, or superposed in level, on many different kinds of rock. But when the attention of geologists came to be directed to the fossil remains of animals and vegetables imbedded in them, it was found possible to assign to each formation characters so definite, drawn from these its fossil contents, as to admit of an unbroken order of succession being recognized, not in one county or district, but over the whole surface of the globe. It is this grand generalization which, worked out to its full extent by modern geologists (the hint being furnished by a countryman of our own, William Smith, with a long array of British names, many of them those of our contemporaries, standing pre-eminent in the list), has led to the full establishment of those magnificent views of the history of our globe which are embodied in our articles 9 and 10.

(110.) In traversing a country in a direction always perpendicular to the lines of demarcation of its geological districts, then, it is found, as a general fact, that we always come upon the strata in a determinate order of succession, which, taken in one direction, leads ultimately up to a district or mass of unstratified rock, through a series whose fossils differ more and more from the existing organisms; or, on the other, to one bearing evident marks of recent origin, the fossils it contains imbedded being the remains of organized beings now existing, and the material wanting in that solidity and cohesion which indicate age and pressure. The series of stratified rocks, then, *reposes on* the unstratified, and to this no exceptions are found (or extremely rare ones), except in cases where volcanic action has poured out liquid matter over or among the others, which has cooled into rocky masses.

(111.) Assuming the horizontal deposition of each stratum in its origin, inclination is in itself evidence of subsequent disturbance; and when we find, as a general rule, that the lower the stratum in the order of superposition, the greater the disturbance of this kind it has undergone, those in the immediate vicinity of the unstratified rocks being often vertical, much shattered and contorted, and even, in some few cases, actually overturned or doubled back, and that upon the broken edges of these, others have been deposited horizontally, and these again disturbed, though in a less degree; the conclusion is irresistible, that it is to the intrusion from below, and forcible upheaval, at successive intervals, with intervening periods of repose, of the unstratified masses, that the disturbance has been owing, and the whole series raised from the ocean bed, not merely to its present level, but to such a level as to admit of the upper portions of the upheaved strata being subsequently degraded and carried away, so as to leave the land as we now find it. Were it not for the evidence these facts of universal occurrence afford, and for the additional proofs afforded by the corroborative one, that in every case where a section can be observed or concluded on *both* sides of a central

mass of this kind, the strata succeed one another in the same order outward, and "dip" everywhere *from* the central line, we might hesitate to accept, so far as these rocks are concerned, the position of their upheaval. But when we come to look upon them, not, indeed, as the *prima mobilia*, but at least as the instruments, the levers and wedges with which the real *primum mobile*, the central heat, does its rough work on the crust of our globe, they lose their claim to this ideal permanence, and come to be considered as, in fact, *newer* than the rocks they penetrate and displace.

(112.) We must refer to our article on Geology, and to works especially treating of that subject, for an enumeration of the long series of strata interposed between the granitic and other unstratified rocks, and the last-deposited alluvium, as well as for an account of their characteristic fossils, in detail. There is probably no part of the world in which all, or even the major part of these strata, exist actually superposed. The series is for the most part broken by the absence of many of its members; necessarily so, indeed, since what was covered with water during one epoch, and therefore a receptacle for the deposit proper to it, became dry land during another, and therefore ceased to receive such as were then elsewhere in process of formation. But the order is never inverted. The beginning, middle, and end of each form of organic life can be traced, one form, indeed, overlapping another, but once extinct, never reappearing in the formations of a later epoch. By a singular felicity, which has influenced more than anything the progress of geology, the British Islands afford, condensed into a small compass, the nearest approach to a complete series of the strata which probably exists anywhere, and within their area (active volcanic agency excepted) there is hardly any form of geological upheaval and dislocation which is not exemplified, the Isle of Wight being especially remarkable as an instance.

(113.) Without going into detail, however, it will be advisable to give here a very brief summary of the principal *groups* into which geologists divide the strata, and their distribution. Here are—1*st*, The older Igneous formations, consisting of Granite and Granitoid rocks, such as Syenites, Porphyries, &c., in which no trace of any schistose or stratified structure is discernible. 2*d*, The Crystalline Schists or Metamorphic Rocks, such as Gneiss, Mica slate, Quartzite, Serpentine, &c., in which a tendency to cleavage, or to a fibrous structure, is for the most part perceptible—arising, as Professors Tyndall and Sorbey have rendered very probable, from pressure, prior to consolidation, giving parallel directions to particles of mica, and which cause has certainly produced the "slaty cleavage" in the true slates. These rocks contain no fossils, and, as Sir C. Lyell supposes, have been subjected to a heat so near to fusion, as to obliterate any vestiges of organic life they may have once contained. 3*d*, The Lower Palæozoic or Silurian system of Sir R. Murchison, in which the stratification is evident, and the earliest vestiges of life are found—mainly fishes, molluscs, and zoophytes. In these, too, and in the metamorphic rocks, the principal metallic deposits occur. 4*th*, The Upper Palæozoic, subdivided into the Devonian or Old Red Sandstone, the Carboniferous and Mountain Limestone, and the Permian or Magnesian Limestone, with the Lower New Red Sandstone. In this series fossils are abundant, and it derives immense importance from being the seat of the coal measures in every part of the world. 5*th*, The Mesozoic group, comprising the Lias and Oolites, the Muschelkalk and Keuper, the Jura Limestone, and the Chalk, comprehending, as their highest member (or the lowest of the next succeeding group, according to more recent authorities), the Nummulite Limestone. 6*th*, The Tertiary deposits, divided by Sir C. Lyell into Eocene, Meiocene, and Pleiocene, as indicating three stages of progress towards the now existing species of organized beings. 7*th*, The Alluvial and Boulder formation, consisting of modern detritus and erratic matter. 8*th, and lastly*, The Volcanic or Newer Igneous formations, trap, basalt, &c., which occur indifferently in every part of the series.

(114.) The proportions in which these several "formations" occupy the area of the existing land, is very different. The older igneous rocks, granite, syenite, &c., occupy but a comparatively small aliquot part of the whole surface, and in masses of little continuity, as might naturally be expected, when it is considered that it is only when actually thrust through the whole series, so as to tower above them all (as in some of the highest peaks of Mont Blanc), they would of themselves come into view, and that in all other cases they would only be laid bare by the destruction of the whole superincumbent series. In only a few districts in Europe are any extensive continuous granitic formations disclosed; such as in the north-west of Portugal and the south-west of Spain (if the whole of what is laid down as such in maps be really granite)—in the interval between the Bug and Dnieper (in Volhynia, Kiew, Podolia, and Cherson)—between Dresden and Görlitz—in the Grampian mountains in Scotland—the Lofoden Isles on the coast of Norway—in Corsica and Sardinia, &c. The southern chain of the Ural Mountains is also granitic; and across France, the district running south-west from St Malo and Ushant towards Avignon, the granite occurs in frequent masses, their line of direction, when continued, passing through Corsica and Sardinia. Indeed, there is hardly any extensive region of the globe in which, here and there, a granitic mass does not break forth. Along the east coast of Brazil there is a continuous granitic band from Rio to the mouth of the San Francisco River.

(115.) It is otherwise with the Metamorphic group, comprising the gneiss, mica slate, &c. These cover large and continuous districts, as, for instance, in Europe, nearly the whole extent of Sweden, Lapland, and Finland, except a narrow belt on the Baltic coast; almost the whole coast of Norway; nearly all the northern half of Scotland, from Perth northwards; nearly all the higher Alpine district of Switzerland and Tyrol, from Grenoble to Gratz; all the crest line of the Ural chain of mountains; probably the whole of Greenland, Labrador, and all the land north of Hudson's Bay; all the southern portion of Canada and the British North American possessions, up to the chain of lakes; and the Arctic sea-coast, as far as the Coppermine River; the whole of Russian America, as well as the eastern corner of Asia, as far as the river Kolyma. Proceeding southwards, we find nearly the whole of Tartary, a great part of China, the Malayan and much of the Cambodian peninsula; the southern part of the peninsulas of India and Arabia; nearly all that is known of Southern Africa, up to the Deserts, with exception of the Cape Colony; and in South America nearly all Brazil, Guiana, and a considerable portion of Venezuela, on the eastern side, and the chain of the Andes on the western, occupied with this most widely distributed and important formation, which, in effect, includes within its range almost all the highest mountains and most elevated country in the globe. Nearly two-thirds of the interior of Australia, also, would appear, so far as our information goes, to be occupied by it—so that at least one third of the total surface of the land consists of this formation.

(116.) The next formation in point of extent, as it is in order, is what has been termed the Transition Series, com-

prehending the whole of the Silurian, and the lower portion of the fourth or Upper Palæozoic group, as far as the carboniferous limestone. Its greatest development is in the northern portions of the continents, extending over the major part of European Russia up to the Ural, over the basins of the upper Irtisch and Yenesei, north of the Baikal Lake, together with the district occupied by the Stanovoi, Ourakantsha, and Altai Mountains, in which the Kolyma and Indigirka rivers take their rise. The comparatively small portion of Norway which is not occupied by metamorphic rocks is filled with these strata. In our own islands they have considerable development, as well as in Portugal. In North America, they divide, with the metamorphic rocks, the whole of that immense territory east of the Rocky Mountains, with exception of a comparatively small district west of the Missouri, while in South America they skirt the whole line of the Andes on the east side, spreading over Bolivia, and forming a belt bordering La Plata and Patagonia on the west, along their whole extent. In Australia, likewise, they occupy two such belts, parallel to one another, running along the whole east coast from the northern to the southern extremity.

(117.) The Secondary Formation, comprising the series from the Permian beds upwards, and including the chalk, viz. the Upper Sandstone, Lias, Oolite, Greensands Chalk, and Nummulite limestone, is very much more limited in its range. It is represented in England by the chalk-beds and other deposits in the south-east of the island, cut off by a line running from the mouth of the Tees to Exeter; on the eastern side by a broad belt of no great continuity, being often overlaid by the tertiary beds, but in which it is impossible not to trace a certain unity, continuing the east Anglican formation, in a direction from N.W. to S.E., over the whole of the south of Europe and the north of Africa, down to Egypt on the one hand, and over much of Asia Minor, through Arabia and Persia, into the Indian peninsula. Thence the belt (with larger interruptions) takes a northern direction, reappearing in Thibet, and again in China, in the districts of Setchuan and Hoo Quang. Again tending northwards, it reappears along the whole eastern coast of the Sea of Japan, and the western of that of Ochotzk, forming the sea-bord of the Kamschatkan peninsula. In the western continent it is much more sparingly represented, the states of Kansas and Nebraska being the only portion of North America occupied by it, while in South America it has as yet hardly been traced at all, with exception of a small district on the Orinoco River, at the northern extremity of that continent.

(118.) One of the most remarkable features of this vast formation (of its cretaceous members, that is to say), is the astonishing fact disclosed by microscopic examination, of its consisting almost entirely of the exuviæ of minute animalcules. In the Chalk, properly so called, they exist in such abundance, and of such minuteness, that millions have been reckoned to the cubic inch; and in the Nummulite limestone, so called from the shells of that name it imbeds, which forms nearly the whole of the south European and African portions of the formation (attaining, in some parts of its distribution, a thickness of many thousand feet) it consists entirely of minute foraminiferous shells, whole or in fragments; and it may be added, that the green and ferruginous sands which present themselves interposed between and underlying these deposits, have also been discovered by Ehrenberg to consist of *casts* of such shells, the shells themselves having disappeared. We have seen that in the North Atlantic, the process of the formation of such beds is still in progress, and from the bottom of the Gulf of Mexico, and the Gulf Stream, such casts, *together with* living specimens, have been brought up in sounding (Carpenter, *R. Inst. Proceedings*, March 12, 1858.)

(119.) We may here recall what has been stated respecting the extensive formations of calcareous submarine masses by the labours of the coral insect. Such facts would be utterly incredible but for what we know of the astonishing rapidity of multiplication of these minute forms of animal life. Dr Carpenter computes the progeny of a pair of aphides, if allowed to accumulate, at the end of one year, at a *trillion*. Granting the reproduction of marine animalcules to be *a thousand billion times less rapid* than that of aphides—granting that each of them, during its lifetime (supposed not interfered with, and food supplied), secreted only a ten-millionth part of a cubic inch of indestructible calcareous matter—we should find accumulated, in less than a quarter of a century, a globe of such material, whose diameter would exceed the distance travelled by light since the ordinarily received epoch of the creation (4004 B. C.), and the surface of the globe, supposed to continue increasing at the same rate, would then be swelling out into space a great many thousand times faster than the speed of light. There needs, then, only a residual immunity for a very small percentage of those produced to afford scope for the production of all the calcareous formations existing; and the same may be said of all those geological formations, such as the Polishing Slate of Bilin (40,000,000 to the cubic inch!), the Infusorial formations in Holland, &c., which microscopic examination has shewn to consist of infusorial and other exuviæ.

(120.) The Tertiary formations occupy a very large portion of the whole surface of the land. They are found (as the circumstances of their deposition necessitate) occupying the intervals and hollows of all the other formations, and that, too, occasionally at such considerable elevations above the actual sea-level, as suffice to shew the enormous period which must have elapsed since their deposition. Thus, in Chile we find them at 1500 feet, in the Isle of Ischia at an elevation of 2000 feet, and in the Niti Pass, in Thibet, at an elevation of no less than 17,000 feet. In England they are not largely developed, but on the continent they form a broad belt, extending all across Europe from the Baltic to the Black Sea, and including nearly the whole of Belgium, the Netherlands, Denmark, Hanover, Prussia, Poland, great part of Austria, including nearly the whole course of the lower Danube, the southern provinces of European Russia down to the Black Sea; thence entering Asia across the Sea of Azof, they occupy the whole of the Caucasian district between that sea and the Caspian, together with the depressed basin occupied by the latter and the Sea of Aral, and nearly the whole of Western Tartary. Thence sweeping upward to the north, they cover an immense area, extending to the Gulf of Obi in length, and in breadth from the Obi to the Yenesei, that is to say, nearly the whole of Western Siberia. Southward, the Great Desert of Northern Africa would seem to belong to these formations, as well as the bulk of Arabia, Persia, and Upper India; the deserts of Gobi and Shamo are also considered as being perhaps referable to the same geological district.

(121.) In the American continent the disposal of these strata is very remarkable. In the northern continent they form a broad belt, running west of the Rocky Mountains from the Polar Sea to the head of the Gulf of California; while in the southern they follow all the sinuosities of the coast line, in a band of from 300 to 600 miles in breadth, on the eastern side of the slope of the Andes, and separated from them by the secondary belt already mentioned. The central portions of Australia, too, are probably occupied by members of this series.

(122.) Taken together, then, the Metamorphic and Tertiary strata occupy the lion's share of all the existing continents, the intermediate formations having been, for the most part, denuded from the former, while they must be assumed still to exist underlying the latter, which, from all the phenomena of their occurrence, there is little reason to doubt have been formed of the immediate detritus of adjacent land during the countless ages which have been occupied in its upheaval.

(123.) The Volcanic or newer Igneous formations are distributed over the globe in a manner wonderfully indicative of the universality of those deep-seated causes which have produced them. They break through every other formation, not excepting the granite itself, as in the case of the Auvergne volcanoes, which, over a large district, divide the surface of the country with granite, every other formation being wanting, and whose scoriæ are found enveloping masses of feldspathic granite, torn up by them in the act of their ejection.

(124.) *Volcanoes* are either extinct or active, and either subaerial or submarine. In the former case they usually consist of cones of ashes and scoriæ (lava thrown up into the air, melted, and falling as stone in various broken and contorted forms), with a funnel-shaped depression called the crater, from which (frequently from a deep break in one part or other of the rim) lava streams have issued, coating the older layers of ashes, and binding the whole together as a mass, often intersected with dykes or vertical walls of lava. When lofty, the lava frequently breaks out laterally, and when such outbreaks are accompanied with ejections of scoriæ, lateral cones are formed, of which Vesuvius, and especially Etna, exhibit striking examples. Some volcanoes habitually pour forth torrents of lava during their eruptions, as Hecla, Vesuvius, Etna; others chiefly scoriæ and volcanic dust, as those of Sumatra, Java, &c.; others mud, as often happens in the eruptions of the South American volcanoes, and one (the double crater of Mowna Roa and Kirauia in Owyhee) offers the phenomenon of two perpetual seething cauldrons of liquid and red-hot lava, occasionally overflowing, but never ejected with violence. The lavas of modern volcanoes differ much in character, but are seldom or never columnar or basaltic.

(125.) Extinct volcanoes often exhibit every appearance of active ones, except their activity. In Auvergne, and the adjacent volcanic districts of France, we find cones (as that of Ayzac) which, but for the trees growing in the crater, might have been supposed in eruption not many years ago, pouring out lavas beautifully columnar; others, as the Puys of Clermont, with the craters more or less rounded off by weather, but still quite distinct, and the lava currents flooding the surrounding country; others, again, (as that of Agde), water-washed heaps of scoriæ. Over many vast tracts of country deluges of lava (as in the Vivarais, and Cantal, in France) have flowed, taking a perfectly level surface, like a sea, and, therefore, evidently from a subaërial source; in others (as in the valley of Fassa in Tyrol), vast subterranean upwellings of augitic lava of inky blackness have upheaved whole provinces of pure white limestone, and, by some process of sublimation, while splintering them into the most picturesque pinnacles, have, at the same time, impregnated them with magnesia, converting the limestone into dolomite. Others, again, have broken out, and still occasionally break out, as at Santorino, Pantellaria, Sabrina (Azores), beneath the sea, and have either, after a brief appearance, been washed over and obliterated, or remain as permanent insular craters, of which innumerable instances occur—Teneriffe, Mowna Roa, Jan Mayen's Island, the Peak of the Azores (El Pico), the Isle of Bourbon, &c.

(126.) The quantity of material ejected by volcanoes in eruption is sometimes very enormous. In those of Tomboro, in Sumbawa, in 1815, ashes and scoriæ were thrown out sufficient to form three mountains equal to Mont Blanc, or to cover the whole of Germany two feet deep. The lava which streamed, in 1783, from the Skaptar Jokul, in Iceland, has been computed on Sir C. Lyell's data (Geol. i. 375) at 21 cubic miles, a quantity equal in volume to the whole of the water poured by the Nile into the sea in a year.

(127.) The most striking features connected with the exhibition of active volcanoes, are 1st., *Their tendency to a linear arrangement when insular*. Of this, there are many very striking examples. Thus, in the Aleutian Islands, from the extremity of the Peninsula of Aliaska to the Island of Ostrova Semisopothnie, 23 active volcanoes lie almost precisely in a right line, 900 geographical miles in length. The disposition of eleven active vents, which, with many extinct ones, form the Kurile Islands, 600 geographical miles from the extremity of Kamschatka to Yesso, is also almost an exact right line, which might be prolonged 540 geographical miles northward, by taking in those of Kamschatka, which are obviously a continuation of them. Those of the Ladrone Islands, again, form a straight line, 420 geographical miles in length; and the linear arrangement of those of Java, Sumbawa, and Floris, over a length of 1080 geographical miles, is not less exact and characteristic. 2*dly*, *Their constant association with coast-lines*, which is so marked a character, that hardly more than one or two tolerably well authenticated instances have been produced (and those in regions never visited by European travellers) of volcanoes habitually active, occurring at a distance greater than 300 miles from the sea. These are the volcanoes of Peshan and Ho-tcheou, in the Thian Shan Mountains, which the Chinese annals (cited by Humboldt) describe as having been so within the period they embrace; and one on Lake Alakul, whose activity within the memory of man has been rendered very questionable by the recent explorations of Mr Atkinson (*Oriental and Western Siberia*, p. 562). Mount Demawend, in Persia, indeed, is considerably more remote from the ocean; but it is on the borders of the Caspian Sea, in the prolongation of the great Mediterranean fissure, and at the very extremity of a broad belt of volcanic activity, now for the most part extinct, which, commencing with Iceland, extends through Britain, France, Southern Europe, and Asia Minor, skirting the Mediterranean, the Euxine, and the Sea of Azof, which, there is every reason to believe, at no very remote period, to have been connected with the Caspian.

(128.) The number of volcanoes certainly known to have been in activity within the last 160 years amounts, according to Humboldt, to 225, and the total number of volcanic vents, extinct and active, to 407; but the real number is probably much greater. M. Junghuhn enumerates 19 volcanoes in Sumatra, and 45 in Java; and according to M. Laugel (*Rev. des Deux Mondes*, xiii. 353), there are no less than 900 in the vast archipelago extending round Borneo from the Nicobar Islands to the Philippines.

(129.) Besides volcanoes ejecting scoriæ and lava, there occur, sometimes separate, sometimes associated with the former class, mountains evidently of igneous origin, but of which the material (trachyte, domite, etc.) has apparently issued from the earth in so imperfect a state of fluidity as *not to run*, but to form rounded masses, sometimes of great height. The Puy de Sarcouy, in the

chain of volcanoes at Clermont, is a very characteristic specimen; and the Puy de Dôme itself consists of this material, and does not appear ever to have been, properly speaking, *in eruption.*

(130.) By far the greater number of volcanoes, and of the active ones an immense majority, occur upon the coast-line of the Pacific, regarded as prolonged by the chain of islands and the Australian coast down to Van Diemen's Land and New Zealand, and even to the active volcanoes of Mount Erebus, and the extinct one (?) of Mount Terror, in South Victoria. Thus viewed, indeed, the Pacific may be considered as bordered by an almost continuous line of recent and extinct volcanoes, and of igneous rocks, clearly owing their origin to volcanic action. Along the whole chain of the Andes, in Central America, and in Mexico, almost all the loftiest peaks are volcanic or trachytic, and the earthquake and eruption are normal, and not exceptional events. Along the north-west coast of the American continent, the chain of newer igneous formations is almost continuous, and in Oregon attains an immense development; nor are active volcanoes of great magnitude wanting, *but only those parts of the volcanic zone which lie upon the coast-line* contain such, viz., Mounts Regnier and St Helens, at the mouth of the Columbia river. The line is continued along the coast of Russian America by the Cerra de Buontempo, or Mount Fairweather (14,732 feet), Mount St Elias (17,850 feet), and Wrangel's Volcano (N. lat. 62°), in Russian America. From almost the extreme west point of the American continent, on the Aliaskan peninsula (which is igneous), the chain is continued to Kamschatka by the Aleutian Isles, where eruptions are frequent, and a new island rose in 1814, and thence, in almost unbroken succession, by the Kurile and Japanese Islands (where outbreaks are frequent, and of excessive violence) through Formosa and the Philippines down to the Indian Archipelago, where Sumatra, Java, Sumbawa, and Floris, exhibit a perfect rookery of volcanoes, the scene of one of the most dreadful eruptions of modern times (that of Tomboro above noticed).

(131.) The east coast of Australia offers no active volcano, but it is marked along its whole extent, from north to south, with evidences of former igneous activity, occurring (in striking resemblance with what prevails on the opposite coast in South America) among the crystalline and transition rocks which constitute the general seabord. But the subterranean fires would seem here to have shifted their ground, and taken up a new line of action to seaward, at an interval of from 1000 to 1200 geographical miles from the coast, but still conforming to its curvature, prolonging the series through the Solomon Islands, New Hebrides, and Friendly Isles, to New Zealand.

(132.) It seems impossible to disconnect this obviously systematic arrangement with the general evidence we have, from other sources, of the tendency to continued elevation of the coast line of the Andes, and, indeed, of the whole continent of South America, on the one hand, and of depression over a large portion of the bed of the Pacific, on the other—alterations which would naturally result from a change in the incidence of pressure on the general substratum of liquefied matter which supports the whole. The bed of an ocean supported on a yielding substratum may be depressed without a corresponding depression of its surface, by the simple laying on of material, whether abraded from the land or chemically abstracted from the sea itself. That matter *is* in process of abrasion and transportation from the land into the ocean at every instant, and along every coast line, we know as a matter of fact. We know, too, that all existing strata, however enormous their thickness, *have* been formed at the bottom of the sea, and it is therefore no hypothesis, but a perfectly legitimate assumption, that the same process is still in progress, no matter how slowly, from this cause, at least in the vicinity of coast lines; and when we look at the vast amount of organized exuviæ which constitute so large a portion of many of the secondary and tertiary beds—the secretions of mollusca, infusoria, and zoophytes—and bearing in mind the large proportion of continental substance which has been so formed, look to the evidence afforded by deep-sea soundings (42), and by coral formations (87), that the same process is going forward in open sea, far out of the reach of coast washing and river deposit (the material being *taken up chemically* by the river and coast waters, and *chemically extracted from them,* when diffused by currents, by the processes of organic life), we shall at once perceive that any amount of pressure on the one hand, and relief on the other, which the geologist can possibly require to work out his problem, and any law of distribution of that relief and that pressure, is available without calling in the aid of unknown causes.

(133.) Rocks of igneous origin border the west coast of Greenland: and the chain of the Ural, along its eastern side, offers evidence, in the intermixture of newer igneous with granitic and metamorphic rocks, of having been, at some very ancient period, a line of volcanic activity. The only other great systems of igneous rock, referable either to subaërial or submarine volcanoes, are those which occupy the Mysore country in the peninsula of Hindostan, and a great area in the centre of Africa, of which, however, our present information is extremely scanty.

(134.) "Craters of elevation" are supposed by Von Buch to have originated in a general swelling and upheaving of the strata, by the action of subterranean fire or expansive vapour, round a central point, either without, or antecedent to, actual eruption. In some cases the central portion is supposed to have fallen in, and to have subsequently become a habitual volcanic vent, as in the case of Teneriffe and Vesuvius, where the remains of the old crater or broken dome still exist, partially surrounding and inclosing the modern cone.

(135.) *Mean elevation of the Continents, Level Lines, Lines of greatest and least Declivity, Valleys and Ridges, Lakes, Drainage Basins.*—Barometrical observations, both stationary and itinerant, assisted of late by that very useful and portable form of the barometer called the aneroid, which can be read off in a carriage or on horseback, have been now so far extended over the whole accessible surface of the globe, as to afford ground for a reasonable conclusion respecting the average elevation of the surface of the land above the sea-level, and a very accurate one as to those of mountain chains and summits. The conclusion arrived at is not a little remarkable, and quite contradictory to former impressions. The mean height of the surface of the dry land most probably does not exceed one-fifteenth of the mean depth of the bed of the ocean. The following are given by Humboldt as the approximate heights of the centres of gravity of the continents above the sea level, viz., Europe 671 feet, Asia 1132, North America 748, South America 1151; from which it follows that the mean elevations of their *surfaces* (the doubles of these) are respectively 1342, 2264, 1496, and 2302 feet. Africa, from what we know of its interior, with the additional light lately thrown on it by Dr Livingstone, is probably intermediate between Europe and Asia, and its mean height may therefore be reckoned at 1800 feet, so that a general average of the whole would give about this last-named height for the mean height above the sea-level of the surface of the whole land. A rise of the ocean level, therefore, to this extent would submerge at least

three-fourths of the existing area of the land. It is remarkable for how moderate an item the great mountain masses of the world figure in the general result. The Alps, spread equally over the surface of Europe, would raise the general level no more than 21 feet (Humboldt); and the vast mountain chains of Asia, so treated, would afford a superstratum of only 150 feet thick over that continent (Ansted), the elevated desert of Gobi, 128, and the whole plateau of Thibet, with its flanking chains, 358.

(136.) If we suppose a series of level lines marking out elevations above the sea, rising progressively by steps of 100 feet, these of course would be the coast-lines of the land left outstanding were the sea to rise by such successive degrees; and if we suppose the same continued below the sea-level we should in like manner obtain the depressed coast-lines. Thus we should cover our chart of the world with a series of re-entering curves or ovals, more or less complicated, each summit and each cavity being surrounded by a series of its own—the one series expressing a mountain, the other a basin. Where the same level line makes a loop by crossing itself (at what may be termed a jugal point [*jugum*]), we have a *col* [*collum*] or mountain-pass, *across* which lies the lowest, shortest, and steepest course by which it is possible to pass out of one basin into another, or from one branch of a basin to another branch, and *along* which the shortest, highest, and least inclined path from summit to summit.

(137.) Two descriptions of lines intersect the level-lines of a country at right angles, viz., lines of watershed (wasser-scheide,[1] separation of the waters) or ridge-lines, and valleys or river-courses. The former, in proceeding downwards from a summit, intersect the level-lines at their convexities or greatest horizontal distances from the summit, and are, consequently, the paths of gentlest declivity, or the longest lines of descent from a higher to a lower level. The latter intersect them in their concavities, or least distances, and are the lines of greatest steepness or swiftest descent, and, of course, those chosen by streams whose erosive action is perpetually deepening them. Where the bottom of a basin lies above the sea-level, or, if lower, is separated from the sea by inclosing ridge lines, it becomes filled, wholly or in part, with water, and constitutes a lake, with or without an outlet. If wholly, the water finds a vent at the lowest jugal point or lip, and the lake becomes a feeder of a river, or in some cases of several, issuing by distinct outlets, as in the instance of the Lake of Yojoa in Honduras (Squier). In this case its supply exceeds its evaporation. In the contrary case, the area occupied by the water adjusts itself so as to effect an equilibrium between the evaporation and supply. The former case is that of infinitely the most common occurrence, and lakes thus fed from a number of upland sources, to which they serve as reservoirs, issue in rivers, or, if above the limit of perpetual snow, they become "neves" in glaciers. The latter case can never happen in moist climates, since, however large the basin, and however high the lip, it must at length become filled, and overflow; but in arid regions, especially in very elevated districts, in which the habitual siccity of the upper atmosphere (see METEOROLOGY, art. 88) comes in aid of otherwise favourable local circumstances, it is not uncommon, as, for instance, in the Lake of Titicaca, on the lofty plateau of the Desaguadero in Bolivia, upwards of 12,000 feet above the sea; in the Salt Lake of Utah, on the elevated region north of Mexico; in the Lakes Tchad, 'Ngami, and Nyassi, in Africa, &c. But the most remarkable instance of such a "continental basin," or one in which all the waters run inwards, terminating in inland seas and salt lakes (for, owing to the perpetual concentration of the drainage water by evaporation, such inland collections of water are of necessity more or less salt), is to be found in the great continental basin of Central Asia, an area of nearly 3,000,000 square miles, which includes the Caspian Sea, the Sea of Aral, and a vast multitude of inland rivers of all magnitudes which feed them, and innumerable other salt lakes, such as the Lakes Van and Urumiah in Armenia, the Lakes of Balkasch, Issikul (or Touz), Alakul, and Kezilbasch, in Turkistan, the Lake Lob or Loph in Upper Tartary, &c. &c. Of these, some are situated on elevated plateaus, but the Caspian and Aral Seas are situated in an extensive depression, an area of several hundred thousand square miles in extent, actually below the sea-level, the surface of the Caspian itself being 84 feet below the Black Sea.

(138.) A still more remarkable instance of depression below the sea-level, and consequent internal drainage, resulting in a lake of almost saturated brine (which is also the case with that of Utah), is that of the Dead Sea, in Palestine, fed by the River Jordan, the level of whose surface has been satisfactorily proved to be no less than 1312 feet below the Mediterranean, from which it is separated only by a narrow belt of land, occupied by the chain of Mount Lebanon, about fifty miles in breadth. There can be little doubt that the Jordan at some former period flowed into the Gulf of Akabah, in the Red Sea, and its course being depressed into a deeper valley, or the connexion cut off, by some geological change elevating the southern part of the valley, the sea-water continued to occupy this basin, which, when the gulf in question filled the valley, extended to the Lake of Tiberias, the surface of which being 983 feet above the Dead Sea, its salt water has been all washed down into the latter by the river flowing through it. Such a barrier once in existence, the increasing specific gravity of the water would counteract the effect of subterranean percolation from the Mediterranean (Fox). The waters of the Dead Sea have a specific gravity of 1·24 (Marcet), so that were a narrow channel of communication opened at a depth of about 7670 feet below the surface of the Mediterranean, the two seas would remain *in equilibrio* by equality of hydrostatic pressure.

(139.) In the upheaval of any extensive tract of land from the sea, hollows fitted for lake basins cannot fail to be left. If the upheaval be rude and paroxysmal, resulting in the formation of mountain chains, and accompanied with fracture and dislocation of the strata, such hollows will be deep, precipitous, and narrow in proportion to their length. Such is the general character of the lakes in mountainous regions—of the Swiss lakes, for instance, those of North Italy, of Cumberland, Westmoreland, and Scotland, &c. On the other hand, where the upheaving forces have acted more gently and gradually, and have raised the country with more uniformity, producing extensive plains and low steppes, lakes will not only be more numerous, by reason of the less erosive power of running water to drain them by deepening their outlets, but will affect more rounded forms, and cover the country with shallow pools or ponds void of all picturesque beauty, as we see exemplified in Poland, and in the districts between the Gulf of Finland and the White Sea, which are almost connected by a great chain of shallow lakes, some of them (as those of Onega and Ladoga) very extensive. Occasionally, too, lake basins come to be created by what may be called accidents, as by volcanic ejections barring the courses of rivers, as in the instance of the

[1] This word is used in a wrong sense in METEOROLOGY. Art. 93.

Lake of Aidat, near Clermont in France, produced in this manner by the lava of the Puy de la Vache damming the river Sioule.

(140). Every line of watershed continued downwards terminates either in a lake or in the sea, and always (of necessity) in a promontory, or more or less projecting tongue of land, or salient point of coast line. The area, bounded on the land side by one continuous line of watershed, and to the seaward by the sea itself, constitutes the drainage basin of whatever river flows into the sea between its extreme promontories.

(141.) The river courses and watershed lines then form a double system of allineations, the one branching out from the lowest cavities or pits, for the most part concealed below the sea; the other from the mountain summits. As the river branches can never be traced up beyond a certain degree of minuteness, nor the ridge lines below the sea level, these two systems have no common points, the fibres of one being always interposed between those of the other, so that, in the absence of one system of lines on a chart, it can always be approximately traced if the other be correctly mapped; and thus the limits of basins of drainage admit of being assigned, and the area of a country divided among its several rivers, the courses of rivers being generally much better laid down than the mountain system of a country. For a list of the superficial extent of the basins of the principal rivers of the world, according to the best authorities, as at present known, and the lengths of their main streams, see Appendix.

(142.) *General Distribution of Mountains.*—When we cast our eyes on a complete and well-executed set of charts of the mountain systems of the world, such for instance as those in the Physical Atlas of Mr Keith Johnston, it is impossible not to be struck with the contrast exhibited between those of the New and Old World. In the former, besides a general direction of the great mountain chains approximating to a meridional one, we find a continuity, unbroken except in a few small intervals in the narrow isthmus connecting the two Americas, of a vast and extremely precipitous line of very elevated mountains, running from the Arctic Ocean almost to the extremity of Patagonia, including 120° of latitude, or 7200 geographical miles (8280 statute miles), skirting along the western coast of that immense continent, closely following all its flexures in the southern half; and in the northern, opening out somewhat more, it is true, in breadth, and decreasing in average height, but still preserving the same general character of a lofty mountainous western border to a vast expanse of eastern lowlands. And throughout the whole extent of this border, we perceive a most distinct and unmistakeable tendency to a system of double or triple ridges nearly or exactly parallel, not here and there for short distances, but extending for hundreds of miles in succession, and resumed again and again when interrupted. In the Old World, on the other hand, we find no single well-defined continuous chain running throughout, much less following the coast line, but a broad belt of mountainous country traversing the whole mass of land in a general direction, nearly at right angles to the meridians, and carried through the heart of the continents, from the extremity of Europe and North Africa across to the western shores of the Pacific. In the European portion of this system, linear prolongation, except in the Pyrenees, is very far from distinctly indicated. On the contrary, divarication and embranchment are there the dominant features, as they are especially so in the north-eastern region of Asia; and it requires some determination in tracing connections, to follow out a leading line through the Pyrenees, the higher Alps, the Caucasus, and the mountains of Elbrouz, through the Hindu Koh, up to the great system of Asiatic mountains which enclose the plateau of Thibet. Neither is the principle of parallel association carried out with anything like the same precision and sequence in the old as in the new continent. Along the Caucasian and Elbrouz range, and as far as the termination of the Hindu Koh, this principle is pretty clearly maintained; but from the point in Little Thibet, where this last-mentioned system forks out into the two great chains of the Himalaya and the Kuen Lun, which enclose the table-land of Thibet Proper, a greater degree of interlacement and confusion prevails, and beyond the termination of these ranges in Assam and on the Chinese frontier, the mountain system of China and south-eastern Asia spreads out like an immense fan, in some of whose ranges a high degree of parallelism is preserved among contiguous members, while in others the branching character prevails quite as conspicuously.

(143.) *Mountain Systems of America.*—In describing more particularly the several partial systems of which these great subdivisions consist, we shall begin with the more simple—that of the New World. Commencing with the very extremity of the southern continent, or what may be considered its natural prolongation, the Terra del Fuego, we find already a most rugged country, with lofty peaks, and glaciers descending from them, one of which, "Mount Sarmiento," attains the elevation of 6900 feet. On the main land, though it can hardly be said that a continuous mountain chain borders the whole of Patagonia, we find lofty single peaks, such as "Mount Stokes" (6400 feet), a country generally mountainous, and an excessively rough and broken coast, full of fiords like those of Norway, of immense depth, fed by glaciers descending from the high lands above—the perpetual snow-line here descending as low as 3000 feet above the sea-level. This, however, does not prevent a great luxuriance of vegetation below that limit, the extreme humidity of the climate favouring the growth of forest trees, which clothe the mountains from the coast upwards. What may properly be called the Cordilleras, commence in latitude 47½°, about the Gulf of Penas, and extend thence close to the coast line to Mount Llebecan (latitude 41°-45°), including volcanic peaks such as Yanteles (8030 feet), Corcobado (7510), and Minchinmadava (8000), already entitled to be regarded as lofty mountains. At this point the broken coast line and its complicated insular barrier ceases with the Isle of Chiloe, or rather the same system of formation is continued on the main land by the addition of a bordering belt between the Andes and the sea, terminated in a granitic rocky barrier skirting the Chilian coast. Here the Patagonian Andes terminate, and the Chilian commence; and from this point we find, interposed between the cordillera and the sea, a slope of land continued up to the equator, nowhere exceeding 120 geographical miles in breadth from the coast to the actual ridge. Hence, too, the chain itself gains a great accession of height. Already at Valparaiso occurs the gigantic porphyritic peak of Aconcagua, the loftiest of the whole chain (23,910 feet); but the chain continues single (with a slight appearance of lateral parallels in the Sierra de Velasco, and the Pamatina ridge, at 75 and 100 geographical miles respectively distant eastward from the main chain) till it reaches the 20th parallel of S. lat., where the Chilian Andes terminate, and the Bolivian commence. Along their whole extent the former range attain and surpass the snow-line, which rises rather suddenly from 8000 feet at Valdivia, in lat. 40° S. to 12,780 at Valparaiso (33° N.), between which, about the parallel of Concepcion (36° 40′ S.), a corresponding change of climate from extreme moisture

to excessive dryness (a consequence of the change of prevalent winds), takes place, and furnishes a satisfactory explanation of the phenomenon.

(144.) About the 20th parallel, near a point marked by the lofty volcanoes of Gualatieri (21,960 feet), and Sahama (22,350), the chain which had so far followed a precise meridional direction, deflects to the N.W., still accompanying the coast line; but it is now flanked eastward by a great parallel chain, the Cordillera Real, commencing at Potosi, the highest city in the world (being 13,350 feet above the sea), and near which, at a level of 16,150 feet, is one of the richest silver mines known. These chains include between them the Plateau of Bolivia, a great table-land upwards of 130,000 square miles in extent, and 12,700 feet above the sea level, forming the internal drainage-basin of the Desaguadero, in which is placed the lake of Titicaca, already mentioned, and which is part and parcel of a considerably more extensive "continental basin," of which more hereafter. The chain of the Cordillera Real is also extremely lofty, and full of high peaks and ridges, among which the non-volcanic mountain of Illimani attains an elevation of 21,150, and that of Sorate 21,290 feet. It pursues its parallelism with the main chain (in which alone the great volcanoes and domelike trachytic igneous mountain-masses occur, and in which are the active volcanoes of Arequipas (20,320 feet), Uvinas (16,000) Viejo (20,500), and Chipicani (19,745), up to the knot of Pasco, a great ganglion, as it were, of the system, in lat. 10° 42′ S., and excessively rich in silver mines, from which point springs a third chain, preserving, like the other two, a strict parallelism with the coast line, from which it is distant 450 geographical miles, and running N.W. for about the same distance, the three being known as the eastern, central, and western Cordilleras of Peru.

(145.) From the termination of this triple arrangement to the equator, and somewhat beyond, the Cordillera is continued in a double line, or rather in a series of pairs of parallel ridges about thirty miles asunder, separated by cross ridges, and placed exactly conterminous; in the northern part of which are situated the great volcanoes of Chimborazo (21,424 feet), Cotopaxi (18,875), Antisana (19,137), Pichincha (15,924), and Tunguragua (16,424), a group unequalled in the world. These enclose the elevated valley of Quito, about 200 miles in length, with a mean elevation of 10,000 feet. The city itself is 9543 feet above the sea, and contains, or once did contain, 70,000 inhabitants.

(146.) The equator passes across the Nevada of Coyambé, a beautiful snow-clad cone, not volcanic (at least not active), of 19,535 feet in height, and immediately north of it, the phenomenon of a triple, and nearly parallel mountain-chain is resumed—those of the eastern, central, and western Cordilleras of Peru. In the *central* Cordillera occur the great volcanoes of Puracé (17,034 feet), and Tolima (18,020).

(147.) It deserves especial remark, that the most westerly of these chains does not continue as a lofty mountain-range into the isthmus of Panama, but dies out in a succession of low, nearly parallel ridges; while the eastern, deserting its parallelism, curves round, with a circular sweep, to the eastward, and forms the littoral chain of Venezuela, terminating in the peninsula of Paria, or prolonged into the Isle of Trinidad. The Sierra Nevada of Santa Marta, near Cape St Juan, on the Caribbean Sea, 19,000 feet in altitude, may be considered as an outlying prolongation of the middle chain. Whatever the forces which have elevated this vast mountain system, and however they may stand in connection with those which, probably at a much earlier period, have raised the chains north of the isthmus, there is evidently a breach of continuity, or at least a diversion of activity at this point.

(148.) The Andes, from their very commencement in Patagonia, slope rapidly, but not precipitously, to the eastward by a series of terraces consisting of secondary strata, which run out to no very great distance from the chains themselves, and terminate in the vast expanse of low country occupied by the tertiary formations, and by the alluvia marking the lower courses of the great South American rivers. The closed area or continental basin spoken of in art. 144, extends on the east side of the loftiest chain, from lat. 14° 10′ to 30° 40′ S., or about 1600 geographical miles in length, with an average breadth of 120 geographical miles, comprising an area of nearly 200,000 square geographical miles, and contains, besides the lake of Titicaca, several other smaller lakes, which are salt. This basin may be considered as occupying two distinct levels; the surface of Titicaca being more than 12,000 feet above the sea, while the southern portion of the basin (if indeed it be really such, which seems a little doubtful) has a much lower altitude.

(149.) The *mean* elevation of the South American Andes, according to Humboldt, is 11,830 feet, and the extent of surface covered by their bases is 531,000 square geographical miles. They present the extraordinary phenomenon of great communities of men, subsisting in wealth and comfort, at an elevation at which the inhabitant of the plains finds respiration difficult. Besides Quito, the city of Cuzco, on the outer and northern edge of the Bolivian plateau, at an elevation of 11,384 feet, and once the capital of the Incas, and the seat of an early and high degree of civilization, still contains 50,000 inhabitants; and the silver mines of Pasco, at an elevation little inferior to those of Potosi, attract into their neighbourhood a numerous and active population.

(150.) The narrow isthmus which connects the two continents, under the general appellation of Central America, preserves the character of precipitous descent to the sea on its west side, and is studded along the coast of the Pacific with volcanic mountains broken into groups, and intermixed with masses of disconnected table-land. The principal of these groups are those of Costa Rica, known as the groups of Uragua and Salamanca, succeeded by a great chain of volcanoes along the west coast of Honduras, Nicaragua, and Guatimala, among which are those of Agua, 15,000 feet in height, and Cosiguina, which, though less lofty, became in 1835 the focus of a frightful eruption, the ashes of which were carried even to Jamaica.

(151.) Entering upon the North American expansion of the isthmus, we find in Mexico a singular volcanic group extending almost precisely east and west, and from sea to sea, consisting of very elevated mountains, viz.—Colima (12,000 feet), Toluca (15,542), Popocatepetl (17,717), Iztacihuatl (15,705), Orizaba (17,374), and Tuxtla. With these the active volcanic series seems to terminate, and what may be called the regular mountain system of North America to commence. Indeed this line of volcanoes seems scarcely to belong to the coast chain, but to be of later origin, cutting, as it does, across its direction almost at a right angle, and finding its prolongation in the Antilles.

(152.) To understand the mountain system of North-Western America, we must conceive two coast lines similar to that which bounds the southern continent—an eastern and a western, the latter of posterior elevation to the former, and having between them the broad tertiary area noticed in art. 121. The former of these is marked out by a system of mountain chains, running generally northward, but converging towards a central knot or ganglion, about the 40th parallel of latitude, near

the sources of the Arkansas river, and at a point at present of some political interest, as affording almost the only practicable access from the east by rugged and difficult passes to the Mormonite settlement of Utah. These branches, of which the principal are the Cordillera of Cohahuela and San Luis de Potosi on the one side, and the Sierra Madre prolonged into the Sierra de S. Juan and the Sierra Verde on the other, enclose and sustain between them the high table-land of Mexico, from 6000 to 8000 feet above the sea (Mexico itself is 7482 feet), and on the eastern side slope down to the flat country by two great terraces of 4000 and 2500 feet average respective elevation, occupying the eastern portions of Texas and Kansas, a country of exceedingly sterile and uninviting character. From this knot or ganglion, marked by high elevations, lately become known as Long's Peak and Pike's Peak, and by the broken ranges of the Bow Medicine mountains, between and across which the direct railway route to California from the east may one day come to be traced, the main chain of the Rocky or Chippewyan Mountains is continued in a N. W. direction in a straight and almost unbroken course to the mouth of the Mackenzie River in the Arctic Ocean. It is generally lofty, and contains several very high peaks, such as Fremont's peak (13,568 feet), "Mount Hooker" (15,700), and "Mount Brown" (15,990) respectively, in altitude. Above the 45th parallel, however, the chain forks out and sends out a lower branch into the Columbian territory, which runs generally parallel to the main chain as far as 60° N., and between the 50th and 60th degrees is again accompanied by another parallel chain above 300 miles in length, which divides the interval between the coast line and the former chain almost equally. The distance between the eastern range of this great barrier of mountains and the Pacific varies from 300 geographical miles at its two extremities to 800, where it recedes farthest inland in 40° N., and encloses the basin of Utah.

(153.) The western coast-range commences northward with Mount St Elias (17,850 feet) in 60° N. lat., and Mount Fairweather (Cerra di Buon Tempo) (14,782), and follows the coast-line with as much fidelity as the southern Andes, never receding from it more than 150 geographical miles; and is continued under the name of the Cascade Mountains, and the Sierra Nevada, down to and along the whole Californian peninsula. In latitude 35° N., nearly opposite Point Concepcion, it sends off a branch northwards, running between the main chain and the coast mountains, about 450 miles in length, repeating strikingly the phenomenon of parallelism of which the Andes have afforded so many instances.

(154.) Between these two barriers lies a plateau of elevated land, comprising two remarkable districts—the Oregon territory, in which a vast development of volcanic activity appears, at some remote period, to have subsisted, and the great saline plateau, or inland basin of Utah, whose elevation is from 4000 to 5000 feet, and the waters of which, having no outlet, form a series of salt lakes, one of which, lying close to the settlement so called, is of considerable extent, and almost saturated with salt.

(155.) Neither the northern coasts of America nor the interior of the continent carry those outward and visible signs of violent and paroxysmal upheaval the western mountains suggest; nor do any extensive mountain ranges exist in the northern, except in the immediate vicinity of the eastern sea-bord, along the coasts of the United States. Here we find the St Lawrence delivered into the Atlantic along a wide valley skirted on the north by the Watshisch Mountains, a range of no great elevation, extending from the north-east extremity of Labrador to the Mistassin Lake, and terracing down by two subordinate parallel ranges to the valley, and on the south by the Nôtre Dame, the Green, the White, and the Adironbeck Mountains—a series of low interrupted parallel ranges of hills, among which are some which rise to the dignity of mountains, as Mount Washington (6428 feet), and Mount Katahdin (5360 feet) in Maine, which stands out apart from the general range. These hills are separated from the more important system of the Appalachian and Alleghany Mountains by the Valley of the Hudson River, which cuts across them, and which, doubtless, at some earlier period, extended up to the Gulf of St Lawrence, cutting off New England, New Brunswick, and Nova Scotia from the main-land.

(156.) On the southern side of the Hudson commence the mountain ranges of the Alleghanies, or the Appalachian system, a series of several closely parallel chains, much cut across by transverse valleys, affording outlets to numerous rivers, running through the states of Pennsylvania and Virginia, and dividing the Carolinas from Kentucky, running south as far as the 33d parallel of latitude, and forming a belt of about 120 geographical miles in breadth, and nearly 800 in length. The slope of these hills to the sea-bord comprise some of the finest districts, and the most fertile and diversified country in the United States. The ranges themselves have a mean elevation of 2556 feet, and in few places exceed 3000 or 4000 in height, and appear to have no central dominant axis of elevation, but to form an excellent exemplification of Mr Hopkins' views of the action of upheaving force, extending over an area much longer than its breadth, which he has shewn to have a tendency to produce parallel longitudinal fissures, cut across by others at right angles to them.

(157.) The Alleghany mountain system belongs chiefly to the older and newer Palæozoic, the Silurian, and Devonian groups of rocks, being flanked on both sides along its whole length by bands of the carboniferous series, which on the west expand into a vast territory full of coal measures, the source of immense present and future national prosperity. Further eastward, below the carboniferous limestone, crop out belts of metamorphic and crystalline formation, preserving a parallelism with the crests of the mountain ridge on the one hand, and with the general direction of the coast on the other.

(158.) The mountain systems of the east side of South America differ from those of the northern continent, in consisting almost entirely of metamorphic and crystalline rocks; and from that of the western coast in exhibiting little of that systematic tendency to parallel arrangement (except along the coast of Brazil) which is so conspicuous a feature of the latter. They form two distinct systems, that of Parimé and that of Brazil.

(159.) The mountain system of Parimé occupies an area from a little north of the equator to about 8½° N. latitude, and from the 50th to the 60th meridian of west longitude, comprising the whole district of Guiana between the mouths of the Amazon and Orinoco, and forming the watershed between the lower portions of the basins of other great rivers. It consists of a plateau of from 1500 to 2000 feet in height, of granite and crystalline rocks, and rises to a series of mountain chains variously directed; those known as the Sierras of Imaraca, Pacaraimo, and the long southern boundary of the district (Sierra de Acaray, Triputa, or Tamucarague), running nearly east and west, while the more westerly members of the group (the Parimé and Maigualida Sierras) affect a meridional direction. The whole system rises like an island (as no doubt at some earlier epoch it was) from a vast tertiary district, which completely surrounds it, being, however, very narrow on the coast side, but developed inland over an immense tract. There are

only two mountains in the whole formation which rise to any great elevation—that of Duida (7149 feet) at the western extremity, and Roraima (7450), near the centre of the district.

(160.) The Brazilian mountain system occupies a coast line of nearly 27° of latitude, from the most easterly projection of the continent nearly to the mouth of the La Plata, and extends its ramifications 1800 geographical miles inland, separating the waters of the Amazon River from those of the La Plata. The coast line for nearly the whole extent of this system is granitic, and a mountain barrier (under the names of the Sierras of Espinhaço, Pedade, Frios, Gran Mogol, Almas, Chapada, and Muribeca), consisting principally of crystalline rock other than granitic, upheaved by the protrusion of the latter, runs from Rio Janeiro in a north-east direction, at an interval of about 200 geographical miles from the coast, separating the coast rivers from the basin of the San Francisco River, which runs parallel to them till it escapes through a break between the Sierras Muribeca and Caryris, between which latter and the Atlantic run two other chains, preserving an exact parallelism with it. The line of mountains is continued, as the Sierra Vermelha, diverging somewhat from the sea line, to the north-east coast near the mouth of the Paranahyba River. The mountains of this principal barrier line are pretty lofty, attaining in the Peaks of Itambe 5960 feet (lat. 18° 40′ S.) and Itacolumi (5750 feet) (lat. 20° 25′ S.) (which gives its name to the mineral Itacolumite) and Itabira (5250 feet). The mountains of the Corcovado and the Organos, near Rio Janeiro, are remarkable for their picturesque beauty and the rich development of vegetable forms which adorn them, and indeed the whole of this region, and clothe their ridges to the summit.

(161.) The interior of this mountain district constitutes a plateau of vast extent, whose mean elevation is about 3200 feet. It is intersected with chains running in very various directions. The Cordillera Grande runs for 400 geographical miles from north to south, precisely along the 50th meridian, and that of the Montes Pyreneos for 150 exactly east and west. The diamond mines of Brazil are situated on the slopes of the Espinhaço range, and the ruby, topaz, and emerald are also the produce of the Brazilian mountains. Gold is washed down from the mountain by almost all the Brazilian rivers, but it is chiefly in the province of Minas Geraes that the richest gold deposits and the finest precious stones are found.

(162.) *European Mountains.*—The mountains of Europe have been divided into six principal groups, or systems—the British, the Iberian or Spanish, the Alpine, the Scandinavian, and the Sarmatian. The mean height of the surface of Europe, as we have seen, is 1342 feet, so that an elevation of the sea level of 1000 feet would submerge by far the larger portion of it. In fact, such an elevation would insulate Scandinavia, and cover at least two-thirds of France, the whole of Belgium, Holland, Denmark, North Germany, Prussia, and Poland, together with the whole of Russia, up to the Ural Mountains and down to the Black Sea, with exception of that small and insignificant group of low hills which, under the name of the Valdai, constitute the "Sarmatian System," and which suffice to afford a watershed line to the basins of the Dwina and Neva, which deliver their waters into the White Sea and the Gulf of Finland, and to determine the south-west course of those of the Dnieper and Volga.

(163.) The British system is no way remarkable for height, the highest summits in its several compartments being Ben Nevis in Inverness-shire, Scotland (4368 feet), and Ben Wyvis in Ross-shire, Cross Fell in Cumberland (3383), Snowdon in Wales (3557), and Curran, or Cairn Tual in Kerry, Ireland (3410). Only along the western coast-line in England and Wales is there any considerable tract attaining 1000 feet above the sea level, and scarcely any point of the eastern or midland counties reaches that elevation. The north-western part of Scotland beyond Loch Ness is, generally speaking, above that level; and the chain of the Grampians, which stretches across the country from N.E. to S.W., has numerous ridges from 2000 to 3500 feet in height. In Ireland there are but few points which exceed 1000 feet, and those, as in England, chiefly along the west coast.

(164.) The general direction of the Scotch mountains (which consist chiefly of crystalline rocks, with here and there, in the Grampians, true granite), as well as of the deep cleft of Loch Ness, which cuts across the country from sea to sea, and the exceedingly rectilinear character of this, and of the strike of the formations of the whole of Scotland, and especially of a great belt of trappean and basaltic formation which crosses it, from the Friths of Forth and Tay across the channel to Antrim in Ireland (where it is developed in the magnificent colonnades of the Giant's Causeway), is not among its least remarkable features. The rugged nature of the country affords, both in the west of Scotland and the north-western counties of England, lakes and other scenery of exquisite beauty. The same character of a general north-eastern strike of the geological formations, which is supplanted in the northern counties of England and in Wales by a meridional direction of the leading eminences, re-appears over its southern and eastern portions, as well as in the great contraction of breadth in the island between the estuaries of the Severn and the Welland.

(165.) *The Scandinavian* mountain system has the same general north-eastern direction. It consists mainly in a series of lofty and broad plateaus, intersected by deep valleys cutting them down to the sea, where they form a coast-line of excessively rugged character (art. 103). The chain extends along the whole western coast of Norway, from end to end, upwards of a thousand miles, under the names of Hard-angar, of the Langefield, the Dovrefield, or Doffrines, and the Kiolen Mountains; the highest summits of which are the Schneehutten (7520 feet), in lat. 62° N., and the Sulitelma (6200), in lat. 67° 20′ N. The greatest part of them rise above the limit of perpetual snow. A considerable portion of this range consists of silurian rocks.

(166.) The *Iberian Mountain System* consists of a great rectilinear barrier (the Pyrenees), of the Permian, Carboniferous, and Devonian strata, with some granitic masses (especially towards the eastern part of the chain), extending from the farthest western point of the peninsula (Cape Finisterre) to Cape Creux, the farthest east. It is very lofty—no less than 7970 feet in mean elevation, and has several peaks exceeding 10,000 feet in height, viz., the Malahite or Nethou (11,168 feet), Mont Perdu (10,994), the Cylinder of Malore (10,899), the Maladetta (10,886), and the Vignemale (10,820). Spain itself is generally high land, having a central plateau of nearly 2000 feet in elevation. Besides the Pyrenees, it has several other mountain chains—the granitic chain of the Sierra de Guadarama (prolonged into Portugal by the Sierra Gredos, which rises to a height of 10,552 feet, and the mountains of Gata, to the S. d'Estrella)—the Toledo chain, which culminates at Guadaloupe, and the Sierra Nevada, which skirts the south coast, and rises, in the peak of Mulhaçen, south-east of Granada, to the height of 11,664 feet.

(167.) The mountain system of North Africa belongs, obviously, to judge from its general parallel direction and elevation, to the Spanish group of the European formation. It consists of three subdivisions, the most extensive

and loftiest of which is the most southern, and runs generally parallel to the Mediterranean coast, at a distance of from 100 to 180 geographical miles, following the curvature of the Atlantic sea-bord outside the Straits of Gibraltar, through Morocco, where it rises to the height of 13,000 feet, or above the line of perpetual snow. This chain continues eastward to the Gulf of Cabes at the confines of Tripoli and Tunis, and would seem to be a continuation of the Apennines through Sicily. The middle range, or rather succession of terraced heights and table-lands, interspersed with mountains rising from the lesser or coast range to the interior and higher, comprises the best and most habitable part of North Africa, including Algeria, while the lesser, commencing opposite Gibraltar as an offset from the great chain, and rising there to a very considerable altitude, runs first inland, then returns to the coast about Oran, and continues along it as far as Tripoli.

(168.) The Alpine is the highest, most extensive, and most complex of the mountain systems of Europe. It connects itself with the Pyrenees, through the mountain districts of France west of the Rhone,—the Cevennes, the Puy, and the Vosges Mountains, a district generally elevated above 2000 feet, but rising to peaks of 6220 feet (Puy de Sancy), 6093 (Plomb du Cantal), and 4806 in the Puy de Dome, the mountain on which the decrease of barometric pressure was first observed by Pascal in the middle of the seventeenth century. This district, which consists in large measure of granite and crystalline rocks, is full of vestiges of most intense volcanic action, and presents, in the chain of the Puys near Clermont, in the Mont D'or and in Auvergne and the Vivarais, multitudes of cones of scoriæ and ashes apparently quite fresh, together with trachytic domes (Puy de Dome, Sarcouy, &c.), basaltic colonnades and plateaus of immense extent which occur in a country of most picturesque beauty, affording the most accessible and agreeable field for the study of volcanic phenomena which Europe affords. East of the Rhone the mountains become more elevated, and through the Dauphiné and Grenoble mountains, or, as they have been called, the Cottian Alps, connect themselves with the great system of the Pennine Alps, of which there are two principal distinct chains separated by the upper Rhone. The southern and loftier, or the Sardinian Alps, in which are Mont Blanc (15,744 feet), Monte Rosa (15,174), and Mont Cervin (14,836), and the northern or Bernese chain, the highest points of which are the Finsteraarhorn (14,026), and the Jungfrau (13,716). These unite in a central knot at St Gothard, from which, spreading eastward, extends a wilderness of lofty peaks and ridges through the Grisons and Tyrol to the Glockner on the eastern extremity of that province, from which point, as from another centre or ganglion, branches ramify in various directions, the chain of the Buch Alps extending north-eastward towards Vienna, and other chains proceeding east and south-east, and accompanying the coast line of the Adriatic, under the names of the Julian, Carnic, and Dinaric Alps, a range whose mean altitude may be reckoned at above 5000 feet, and which rises in Mount Kom to 9000, from which part off innumerable ramifications, covering the whole region south of the Danube to the utmost confines of Europe.

(169.) The system of the Eastern Alps (the Slavo-Hellenic system), however, mainly diverges from the Sharah Tagh (10,000 feet) in two directions. The Pindus chain running southward, traverses Macedonia, Albania, Thessaly, and Greece, down to the extremity of the Morea, and comprises in its course the most celebrated summits in classic lore, Olympus in Thessaly (9749 feet), and Parnassus (8068). The other, or Balkan chain, runs eastward along the forty-third parallel of latitude to the Black Sea, which it encounters near the Gulf of Bourgas and the promontory of Emineh Burun, consisting, in its highest range, of the rugged and almost impassable chain of the ancient Hæmus (8874), parallel to which, lying directly east and west in the latitude of Constantinople, is the ancient Rhodope (8313). The whole is rugged in the extremest degree, and the broken outline of Greece, full of deep bays and harbours, and admirably adapted for a maritime centre, as well as the multitude of islands in the Archipelago, with the sheltered coasts of Thessaly on one side, and of Asia Minor on the other, testify to the continuation of the mountain system in the same general direction beneath the sea level.

(170.) The great southern chain of the Pennine Alps descends with precipitous rapidity on the plains of Piedmont and Lombardy, around which the Cottian range, prolonged into the chain of Maritime Alps, skirting the Gulf of Lyons, makes a vast circular sweep, and, crossing over Italy nearly to its eastern coast, embraces in its circuit the basin of the Po, and runs down the whole length of the peninsula, as the chain of the Apennines, attaining at one point, Monte Corno, near Aquila, an altitude of 10,114 feet. Nor does it terminate with the Italian peninsula, but may be considered as prolonged into Sicily, running across the north of the island from east to west, and having for outliers the active volcanoes of Vesuvius, the Lipari Isles, and Etna. The ridge of the Apennines is of secondary limestone, and flanked on both sides, and largely interspersed, with tertiary strata, and along the west coast of Italy with volcanic rocks, both recent and ancient.

(171.) Of the Alps Proper, one of the most striking characters in contrast with other great chains, is the absence of elevated plateaus. Where the principal chains meet, instead of enclosing, as in similar circumstances in America and Central Asia, lofty districts, like Bolivia, Utah, and Thibet, we find quite the reverse—deep open valleys, giving to the whole system a decided out-branching character. In their eastern ramifications this feature is modified, and among the Balkan group we find elevated districts of considerable extent, from which the higher summits rise as from a vantage ground.

(172.) The base of the higher Alps is calculated by Humboldt to cover an area of 24,300 square geographical miles. The principal chain, that of the Sardinian Alps, consists almost entirely of gneiss, mica slate, serpentine, with here and there granite, and other rocks more or less allied to true granite; that of the Bernese Alps is for the most part of secondary limestones, oolites, &c., much disturbed and altered by heat. North of the higher ranges occur a broad zone of tertiary formation, and towards France the Jura limestone is so developed as to have received its name from the mountains in which it occurs. The Alps are considered by geologists to have gained an accession of nearly 4000 feet in height since the tertiary period.

(173.) The great plains of the north-east of Europe are separated in a very decided manner from the northern slope of the Alpine region, by the chains of the Hercynian and Carpathian Mountains, which form an oval basin (that of the upper Danube and the Theiss), including Bavaria, Austria Proper, Hungary, and Transylvania, and which connect themselves with the Balkan range by the North Balkan, a narrow passage only being left open at Orsova for the Danube. Some of the Carpathian Mountains are of considerable elevation, as the Lomnitz Point of Mount Tatra (8524) in the northern, and Pojano Ruska (9912) in the southern part of their chain. The Transylvanian system is remarkable for its mineral riches.

(174.) The great northern plain of the eastern continent is unbroken almost to the extremity of Siberia by any elevation worth mentioning, except the Ural chain, which marks the division of Europe and Asia, and which runs down in an exact meridional direction from the 70th to the 48th degree of north latitude, forming a rectilinear and nearly unbroken chain of 1300 geographical miles in length. Indeed, it may be considered as extending nearly 400 miles farther, to the extremity of Nova Zembla, making a considerable bend in its course at the arctic circle. It consists, along its western declivity, of the older palæozoic rocks, upraised by a line of metamorphic formation, along the whole length of which occur at intervals a series of newer igneous rocks, which would appear to have broken through at the time of upheaval, while yet forming a coast line, or chain of islands; at the southern end, for a considerable distance, granitic or other analogous rocks appear. Scarcely any mountain region is more rich in mineral productions, gold and platinum being richly produced in its central portions, and even diamonds in its southern. No part of this chain is very elevated. The Konstantinow Kamen (lat. 68° 30′) being 5000 feet, the Koniakofski Kamen (lat. 60°), 5397, and the Iremel (lat. 54° 20′) 5075 feet; nor does it exhibit any of those rugged and precipitous features which attend mountain chains in general. It would seem as if the upheaving force, whose general feebleness is manifested over the whole of this vast region, had barely been able along this line to overcome the superposed weight, and break out to day, but not to shatter rocks or throw up cones.

(175.) The transition from the great mountain masses to those of Asia, is through the elevated plateaus of Asia Minor and Armenia, and the mountain chains of the Caucasus and Elbrouz, beyond which, to the north, the level sinks at once to that of the lowlands of the great northern area. Asia Minor presents several considerable mountain chains, the principal of which are that of the Taurus, which runs along the southern coast, and rises, in Mount Argeus in Karamania, to 13,197 feet, and the Anti-Taurus, bordering the Euxine, which at one point (Argischtagh) attains 13,000. Asia Minor, moreover, offers the first striking instance in our progress eastward, of the general tendency to rise in elevated plateaus and table-lands, which distinguishes the medial zone of the great eastern continent. The mean elevation of the surface of the whole peninsula is not less than 3280 feet, with a central depression which, though not sufficient to form a basin (the country being intersected with many valleys affording an outlet), allows the collection of numerous lakes, many of which are salt, one of them at Tutzla of considerable size.

(176.) The plateau of Armenia is still more elevated (7000 feet). It occupies a belt extending across the neck of Asia Minor between the Caspian, the Caucasian range, the Euxine, and the Mediterranean. It has several very lofty eminences, among others, Ararat, an extinct volcano, 17,212 feet in height, the summit of which is always covered with snow. The Caucasian chain itself runs along the north-eastern coast of the Euxine and the southern shores of the Caspian. Its highest points are Mount Elbrouz, a volcano still showing some faint signs of activity, 18,493 feet, and Mount Kasbeck, 16,523, and the still, though torpidly, active volcano of Demawend, 14,695, not far from Teheran, the capital of the Persian empire.

(177.) We are now fairly entered upon that great succession of table-lands and elevated plateaus, which give a peculiar character to the eastern continent, and which, according to the opinions of the best geologists, existed as such anteriorly to the protrusion of the great mountain chains which run across them. The general direction of this series of elevated districts (which comprehends the whole of Arabia, Armenia, Persia, Afghanistan, Thibet, and Upper Tartary, as far as, and beyond the desert of Gobi into Mongolia), is from W.S.W. to E.N.E., while the general direction of the loftier mountain ranges, commencing with the Pyrenees and ending with the Himalayas, is from W.N.W. to E S.E., forming an angle of from 45° to 50° with the former—a very significant fact as regards the geological history of the continent, and one to which, it appears to us, sufficient attention has not been paid.

(178.) Arabia consists generally of very elevated land. Along the eastern and central parts, an elevation of 7000 or 8000 feet has been assigned to it; but this is perhaps exaggerated, no country being so difficult of access, and offering such obstacles to exact determination. Its general character is that of excessive aridity, and an all but complete absence of rivers, and, in the interior, of any running water whatever. Towards the southern coast it becomes somewhat lower, and a little less inhospitable. The Louskebir and Seger mountains, which skirt the south coast, range from 3000 to 5000 feet in height, and are rather to be regarded as the termination of the interior plateau than as chains *per se*. At the south-east corner in Yemen, they retreat a little, and leave some room for cultivation; and for the course of one of the only two streams which can be called a river, in the whole of this vast country, whose general area is not less than 720,000 square geographical miles. The east coast, from Aden to Medina, along the Red Sea, is skirted, at a distance of 100 or 150 miles, by an almost continuous range of mountains, which extend as far as Medina, from whence to the Gulf Akabah the coast-line is low, and admits of the passage of the caravans to Medinah and Mecca; but the mountainous character recommences at this point with Mount Sinai (7498), Horeb (8593), and Um Shomah (9300), granitic and slaty masses, intersected with basaltic dykes, and plunging down like huge towers and buttressed fortresses on the narrow plains or "wadies," which form the only habitable portion of the country. Arabia is crossed from the Red Sea to the Persian Gulf (from Mecca to Lahsa, celebrated for the pearl fisheries of Bahrein) by a mountain axis, along which lies one of the few lines of route by which the desert can be crossed, and from which a small river (the only other Arabia can boast) descends to the Gulf of Lahsa. The plateau of Arabia may be regarded as continued across the Red Sea (which runs up it as a deep but narrow rectilinear cleft about 150 miles in breadth, and 1300 in length, from Aden to Suez), into Africa, to form the lofty table-land of Abyssinia and Upper Ethiopia, where M. d'Abbadie has ascertained the existence of mountains 14,000 to 16,000 feet in height.

(179.) The plateau of Iran, which comprises about 350,000 square geographical miles, is also very elevated, though less so than Arabia. Its mean height may be stated at about 3000 feet, and, like Arabia, its interior is almost entirely destitute of rivers, and parched and desolate to an extreme degree. The line of the Zagros mountains, which forms the watershed of the Euphrates on its east bank, continues along the Persian Gulf into Beluchistan, and nearly to the Indus. It consists of a series of bordering ridges running parallel to, and separating the narrow sea-bord of that gulf from an immense inland or closed basin, to be more particularly described hereafter, and of whose entire extent the whole of this region forms but a very small fraction. On its northern limit, the Persian plateau runs up to the range of mountains bordering the South Caspian, which may be considered as prolonging the Caucasian range through Mazanderan and Khorasan to the lofty chain of the Hindu

Kho, or Koosh; being, however, rather a mural limit to the extension of the table-land in that direction, than an independent mountain chain. Its junction with the much more lofty and continuous chain of the Hindu Kho is at Herat, which stands as it were in the Gate of India, from whence to Kuttore, at the eastern corner of Little Thibet, the incipient chain of the Kuen Lun to the north (of which the mountains in question may be considered a prolongation), and the terminal outlying eminences of the Hindu Kho on the south, run parallel for nearly 500 miles. The entrance to India from Herat, however, lies to the south of both these ranges, through Upper Afghanistan by the pass of Cabul, immediately adjacent to the lofty peak (20,232 feet) of the Hindu Kho, the mountain which gives its name to the whole chain, and between this and the Sufieh Koh, the road lies along the Khyber Pass (of disastrous memory) to Peshawur, on the Upper Indus.

(180.) At Kuttore, about lat. 36° 40′ N., long. 72° 40′ E., the chain of the Kuen Lun, considered as prolonged westward in that of the Hindu Kho, and the Himalaya range, considered as prolonged in the arc of a vast circle north-westward into the Bolor Mountains, cross each other; and from hence up to the Lakes Rewan, or R'akas, and Manasarowar, at the eastern extremity of Thibet Proper, in which the Sutlej and the Ganges have their highest recognized sources, these two great chains interlace and ramify in a vast ganglion of mountain masses of the first magnitude. In the eastern corner of this knot we find the elevated valley of Cashmir, an almost closed basin of an oval form, surrounded on all sides by the loftiest mountains, and 5800 feet above the sea, and in the interval the chain of the Himalaya rises to the altitude of 25,669 feet in the peak of Jumnotri, and 25,749 in that of Nanda-devi, the mean altitude being from 18,000 to 20,000 feet. These peaks, as is the case with most of the loftiest summits of the Himalaya, stand out at some distance southward from the main ridge, with which they are connected by long spurs. Pursuing thence the line of this chain along the province of Nepaul, where it skirts the districts of Kemaon, Sikkim, and Bhotan up to Assam (a total length from Kuttore of not less than 1300 geographical miles), it comprises within its range a most astonishing series of lofty and snow-clad pinnacles. At least 40 peaks exceeding Chimborazo in altitude are enumerated in its course; among which we may name Dwalagiri (27,600 feet), long supposed the highest mountain in the world, which stands out from the general chain where the valley of the Gunduc River intersects it about the 83d meridian, but whose supremacy has been supplanted by two other summits at least, viz., Kinchinjunga (88° 30′ E.), which overhangs the Lacheh pass into Thibet (28,178 feet), and Gahurishanka, Chingopamari, or Deodunga (at present considered as the culminating summit of the world), in long. 86° E. (29,002 feet.)

(181.) The Himalaya and Kuen Lun ranges afford a parallel on a much vaster scale to the phenomenon exhibited by the great mountain ranges both of North and South America. From their point of intersection at Kuttore to the 93d meridian, they open out into an oval expanse, about 500 or 550 geographical miles across, which is occupied by the plateau of Thibet, the loftiest inhabited region in the world, having, in its western or lowest portion—that occupied by the district of Ladak—an average elevation of 12,000 feet, and in its eastern, or highest portion, 17,000. Fifteen thousand feet may be taken as the average height of this wonderful plateau, which serves as a base for a mountain system of its own, and which extends over 166,000 square geographical miles. On either side of it the mountains sink rapidly—to the north into the inferior but still elevated plateau of Upper Tartary; and to the south, by three gradations of inferior mountain ranges, running parallel to, and serving as terraced bases to the great central masses. The first descent is exceedingly abrupt, so much so, that in Bhotan, the change of level is upwards of 10,000 feet in ten miles, being, in fact, in many places almost a mural precipice. The substratum of the Thibetian plateau consists of secondary formations, but much of the surface is composed of quite modern detritus, in which are found the fossil remains of elephants, rhinoceroses, and other animals of the latest tertiary epoch. In the pass of Niti, too, by which the sacred lakes of Mansowarowar and Rewan are approached, the occurrence of tertiary beds, already noticed in art. 120, proves the astonishing fact that this enormous plateau has actually been raised from the sea-level to its present elevation subsequently to the deposition of the newest of the great geological groups of strata. That it has been thrust up bodily through the general mass of the continent is equally clear — the detritus lying in horizontal beds, and the remnant of the formation thus marvellously preserved existing here alone, where the lofty ridges surrounding it on all sides, and the extreme dryness of its new climate (a consequence of its great elevation), have preserved it intact from the causes of denudation that have acted on all the surrounding masses, and swept away from the south side of the Himalaya all but the older strata. With this exception, and with that of a considerable mass of volcanic formation in the neighbourhood of the sacred lakes, the highest portions of the Himalayas consist of granite, gneiss, and metamorphic rocks, and their southern flanks of fossiliferous limestones, and other members of the older and newer Palæozoic series—among which the Siwalik Hills are remarkable as having furnished specimens of that extraordinary fossil, the Sivatherium, or four-horned camel, discovered by Captain Cautley.

(182.) The chain of the Himalayas terminates rather abruptly about the 94th meridian east, where it is cut through by the Brahmaputra River and its tributaries, unless we prefer to consider it as continued somewhat further eastward by the parallel chains of the Assam and Khasyah mountains, on the opposite side of the valley of the last-named river, at about 120 miles to the south; after which a system of mountain-lines, following nearly a meridional direction, stretches into Arracan and the Malayan and Cambodian peninsulas, directing their rivers in nearly parallel courses southwards. The chain itself, for the last 330 geographical miles of its extent (from Darjeeling eastward), follows very nearly indeed the 28th parallel of latitude. It is by no means correct, however, to consider, as is usually done, the whole chain as, "generally speaking, parallel to the equator:" its whole previous course of 960 miles from the knot of Bolor, making an angle of 30° with that direction, from N.W. to S.E.

(183.) The line of the Assam and Khasya mountains, if prolonged across the valley of the Ganges, would find its continuation in the Rhamghur, Khymore, and Vindhya mountains, a range which separates Hindostan proper from the plateau of Malwa and Upper India; and it deserves remark that, so prolonged, the line runs a precise parallel to the Thian-shan, and nearly so to the eastern line of the Himalaya and the Tengri-nor range in Thibet. These mountains form the northern watershed of the valley of the Nerbudda, as the Satpore range does the southern, up to the Gulf of Cambay. The peninsula of Hindostan itself is a great triangular table-land, or congeries of such, with intermediate low levels, bounded or sustained by these mountain-ranges on the northern side, and by the Eastern and Western Ghauts on the others. Of these, the western forms an almost continuous wall,

upwards of 600 miles long, rising, towards its southern extremity, to an elevation of 4700 feet. They support, as by a series of steep and mural buttresses, the plateaus of the Deccan, 1500 or 2000 feet high, and the still loftier table-land of Mysore (4000-5000 feet), the granite nucleus of which has been deluged with an enormous flood of basaltic lava. In this district are situate the diamond mines of Golconda, where this precious mineral is found in iron-stone, and disintegrated clayey and marly strata. Towards the southern termination of the peninsula, the mountains become loftier. The Nilgheri hills (enjoying the most uniform and perfect climate on earth) rise to 8760 feet above the sea, and form a group in which, in a space of 40 miles long by 15 broad, 17 peaks, between 5800 and 8800 feet high, are enumerated. The Eastern Ghauts are lower and less continuous, and the general level of the peninsula slopes downwards towards the eastern coast.

(184.) The Kuen-lun system of mountains is but imperfectly known, being very difficult of access from either side. It would appear to be prolonged far into China by the Pe-ling and Tapa-ling ranges; and, so prolonged, would present the imposing fact of a mountain-range extending over 64° of longitude from the Caspian nearly to the Pacific (3350 geographical miles), and nowhere deviating more than 2° in latitude from the parallel of 35½°. But in addition to this, it sends out a great branch to the N.E., which, under the names of Yn Shan and Kingan Oulah, prolongs the system into and over Mantchouria, up to the Sea of Japan and the mouth of the Amur.

(185.) The Asiatic chain next in extent and importance, is that of the Tengri or Thian Shan (Celestial Mountains), between which and the Kuen-Lun chain intervene the immense, high, and desolate plateau of Upper Tartary, and the sandy and rainless deserts of Gobi and Shamo, divided from each other by a deep depression, occupying together 380,000 geographical square miles in area, at a mean elevation, the former of 3000, the latter of 4300 feet of altitude. This chain is in many respects extremely remarkable; and although less elevated, is quite as leading a feature in a geological and geographical point of view as the Himalayas. In direction it is almost exactly rectilinear, and 1150 geographical miles in length, from the 72d east meridian, where it intersects the Bolor range, running north and south, to the 97th, and between the parallels of 41° and 43° N. lat. It may be considered, indeed, as continued west of the Bolor by the lower chains of Asferagh and Ak-tagh to the 66th meridian. And this can hardly be considered as a mere ideal extension, when taken in connection with geological relations, for it points directly towards the southern extremity of the Caspian, and but for the intervening flat and desert region of Kharesm, might be looked upon as a branch of the volcanic chain of Elbrouz. And, in fact, the most marking feature it offers is the frequency in it of volcanic vents, mostly extinct, but two of which, Pe-shan and Ho-tscheou (art. 127), may perhaps be still occasionally active. These mark it out to have been one of the ancient coast-lines of elevation (an indication, on the great scale, quite as convincing as the traces of ancient sea-beaches on a small one) of a former tropical continent, to which the great plains of North Asia and North Europe form the same kind of appendage as the flat eastern portions of America do to the western coast-chain—a formation, that is to say, out of the detritus of the elevated region washed outwards into what was then a great and shallow northern ocean, and which, up to the present era, is in continual process of extension —along the coasts of Arctic Asia by the action of river deposit, and along those of north-western Europe by the more active agency of upheaving forces, the effects of which are traceable, from century to century, by the bodily uprise of the coast-line of Scandinavia, and which, in the lapse of some twenty or thirty thousand years (a period, geologically speaking, trifling), will, if continued, obliterate the Baltic.

(186.) The Altai mountain system covers an area of about 35° of longitude and 8° of latitude, between the 46th and 54th parallels. They separate the Dzungharian and Mongolian plateaus (of no great elevation) from the low country of North-East Siberia. They consist of a series of ranges (the Ala-Tagh, Tangnou, Kianghan, and Tschokindo mountains, which last, with the mountain knot of Kentei Khan, attain an elevation of 7000 or 8000 feet, and inclose the Lake Baikal, and the sources of the Great Russian rivers, the Lena, the Yenesi, and the Obi. In the Tangnou are many eminences which rise above the limit of perpetual snow, and some near the head of the Oubsa river, above 11,000 feet. These mountains are extremely rich in mineral productions; and, to judge from the beautifully-executed drawings of Mr Atkinson (*Western and Oriental Siberia*), it would seem scarcely possible for any region to surpass the whole of this mountain district in picturesque beauty. Around the Baikal Lake granitic masses abound, interspersed with newer igneous formations, and Mr Atkinson reports an extinct crater near the Lake Karanur in the Tangnou, with a cone of ashes 800 feet in height (lat. 53° N., long. 97° E.) From the Baikal the mountain system is continued northward and eastward, through the Daurian mountains, in a series of branches under various names, as the Yablonoi, Udskoi, Aldan, and Stanovoi mountain ranges (or Krebets), up to the furthest extremity of the Sea of Ochotsk, and terminating in the volcanic system of Kamschatka, where there are several active vents, an eruption of one of which (that of Klieutschewsk, lat. 56° 33′, long. 160° 20′), 15,955 feet in height, in September 1829, Erman was fortunate enough to witness. (*Reise um die Erde*, iii. chap. 19.)

(187.) *African Mountains.*—Of the mountain systems of Africa our knowledge is very imperfect. The Atlas system and that of Abyssinia have already been noticed. The southern termination of the continent is formed of tabular sandstone masses, from 3806 feet (height of the Table Mountain) to 6000 or 7000, reposing on slate and granite, dykes of which latter run up into the superposed rock. The granitic formation, which, in many places, is thus capped with sandstone, is very extensively developed in South Africa. In the Kamies Berg it rises to 5100 feet in height, and the whole plateau of the Bushman flat, with a general elevation of from 2000 to 3600 feet, is granitic. The sandstone (which incloses rolled pebbles of pure quartz) is disposed in perfectly horizontal strata, proving the elevation of the land to have been performed with little of paroxysmal disturbance. From the rounded forms of the lower eminences, and the wide, sloping taluses, contrasted with the mural cliffs above in the loftier ones, from a definite level uniform over large tracts of country, we may consider this elevation to have been performed in two steps, with a long interval of tidal washing in a shallow sea between them. The Quotlambi or Snowy Mountains, a range rising to the altitude of 10,000 feet, run along the east coast northwards toward the Zambesi river, explored by Dr Livingstone, being prolonged in that direction under the names of the Fura Mountains, while the chains of the Beth and Lupata, 8000 or 10,000 feet in altitude, follow the coast of Zanzibar, and a loftier and more central chain (the Sierra Maxengo) runs north from the 16th parallel of south latitude, supposed to rise to 17,000 feet in its highest part. This divides into two branches, which enclose between them (as it is

supposed, from the reports of natives to M. Ehrardt, rather than any actual exploration) a great interior lake, Nyassi or Uniamesi, equal to the Caspian in size, of fresh water, beyond which they reunite and form a system of equatorial mountains covered with perpetual snow, two of which, Kilimanjaro (lat. 3° 20′ S., long. 37° 15′ E.) and Kenia or Kignea, very nearly on the equator, in long. 38° E., have been visited by M. Rebmann and Dr Krapff. A large part of South Africa, however, appears, from the account of Dr Livingstone, to be occupied by a considerably elevated table-land, and towards this region the mountains of the coasts would seem to dip inwards both ways. From the equator, in the direction of Abyssinia, would seem to extend lofty table-lands of 7000 or 8000 feet in elevation. Along the west coast, from the Cape of Good Hope northwards to Cape Negro, occur no lofty mountain ranges. Inland, behind Benguela, Congo, and Loango, the land rises in a terrace, backed by the Sierra Cumpleda, a range 12,000 or 15,000 feet in height, and at the Bight of Biafra the Cameroon mountain attains 13,000, to the north of which the Kong mountains, and the coast range of Sierra Leone, are probably to be considered an extension of the equatorial mountain system, dying out northward towards the Great Sahara Desert.

(188.) *Australian Mountains.*—Of this great continental mass, so little of the interior has been explored that we hardly know anything of its general mountain system. So far as we do know, the highest land lies along the east coast, forming a range from Torres Strait, continued out southward to Van Diemen's Land, nowhere receding more than 150 miles from the sea. Though not lofty (Mount Koschiusko, the highest point, does not exceed 6500 feet), the material of which it consists (which is chiefly granite and porphyritic mixed with volcanic rock) gives them a singularly rugged and inaccessible character, especially coastwise, while towards the interior the slope is gradual. The heights of several points in this range, determined by Count Strzelecki, will be found in the Appendix to this article.

(189.) Of Rivers.—All rivers owe their origin, of course, to atmospheric precipitation, and their magnitudes are in a compound proportion of the area of their basins of drainage, and the average annual amount of precipitation. But the greater or less deviation from uniformity in the volume of water delivered in different seasons, which is a feature of the greatest importance in the physical character of a river, depends much on the mode in which the water reaches its channels, which may be in either of three ways. 1. From immediate surface-drainage, *i. e.*, from rain actually falling, and drained off without penetrating the soil. 2. From springs, *i. e.*, rain-water which has penetrated the ground by infiltration, and collected in subterranean channels, which at length open out at the surface, or in some cases in the beds of lakes and rivers; and 3. From the melting of snow on the summits of mountains during the summer. Intermediate between the supply from springs and from surface drainage, must be classed that portion of the rain which oozes out at low levels from a saturated soil, in innumerable rills, not distinctly traceable to any perennial spring delivering a visible volume of water. The soil, when porous, acts as a reservoir, and its gradual drainage tends to equalize the monthly delivery of rivers, and feed them in the dry season. In climates, then, where there is no broad division of the year into a rainy and a dry season, where the soil is porous and habitually moist, and where the highest levels of the watershed are below the line of perpetual snow, or where such snow-fields are not largely developed, the rivers are subject to no periodical irregularities, but only to those which result from unusual, long continued rains and droughts. Such are most rivers in the temperate zones. Where floods occur in such rivers, they depend quite as much on the nature of the soil drained as on the weather. The floods of the Rhone, occasionally so very destructive, arise mainly from the sudden delivery of heavy rains on the rocky soil and steep valleys of the Côte d'Or and Jura mountains, which form the basin of the Saone. Those which, in 1829, desolated Morayshire, in Scotland, originated in no sudden and violent rains, but in a long-continued drizzling and misty state of the atmosphere, bringing great tracts of heathery and mossy ground to the state of a saturated sponge—a state of things which sometimes results in the breaking loose of peat mosses, as that of the Solway Moss in 1772.

(190.) On the other hand, when the rains are periodical, and the year divided into a dry and a wet season, which is the case with intertropical regions generally (Meteorology, art. 112), the rivers rise and fall periodically also; the commencement of the rise in the lower part of the river-course being posterior to that of the upland rains, owing to the time required for the water to descend, and the more so the longer the course of the stream. Thus, the inundation of the Nile, which may be taken as a normal case of river periodicity, and whose continuance for successive ages as the source of all the prosperity of the most anciently civilized region in the world, has been an unvarying theme of wonder and eulogy, begins to be felt in Abyssinia and Sennaar in April, while the rise is not perceptible at Cairo till near the summer solstice. In the last 1200 miles of its course, the Nile receives no affluents, and the increasing evaporation consequent on the progressive rise of annual temperature no doubt has some share in producing the retardation.

(191.) When the watershed line of a river basin is sufficiently lofty to receive and retain abundant snow, this acts as a reservoir, and detains the precipitated moisture during all the cold season. As the summer advances, the snow melts; and if the limit of *perpetual* snow be attained, the supply so husbanded continues during all the warm season. This may or may not be strictly coincident with that from the periodical rains, though since, generally speaking, in intertropical regions these are at their maximum when the sun is most nearly vertical, the two causes for the most part conspire. Thus, the floods of the Indus depend chiefly on the melting of the snows of the Himalaya from April to September (but little rain falling on its lower basin), and are at their maximum in July. Those of the Ganges and Brahmaputra afford an example of a want of exact coincidence in this respect, all the lower country adjacent to them being flooded by very heavy rains before the water from the melting of the snows (which in the Brahmaputra has a wide circuit to make before reaching the plains) has time to arrive.

(192.) When the level of perpetual snow in the watershed is not attained, its complete fusion sets a limit to that supply; and where little rain falls in summer, we have mountain torrents which cease, or afford but a scanty supply during the hottest months, as is the case with many streams in Greece, Italy, and especially Spain, with the Orange River in South Africa, &c.

(193.) Extensive lakes in the upper part of a river's course greatly tend to equalize its flow by acting as reservoirs. Thus the St Lawrence, which, with a drainage basin of 297,600 square geographical miles, has 94,000 of them occupied by lakes, maintains an almost perfectly equable flow in all seasons. On the contrary, where no lakes exist, owing to a want of surface inequality, and especially where the declivity of the ground over large regions is very slight, inundations take place on every considerable increase of the volume of water to be disposed of, owing

Physical Geography. to the want of proper channels to carry it off. Thus the Silvas, or flat wooded plains of the basin of the Amazons River (an area of more than half a million of square miles), are for the most part so level and so little inclined, that the tract of country, 1740 geographical miles in breadth, from the eastern declivity of the Andes to Grand Para, has only a slope of 25″, and under the parallel of 5°, from Cape St Roque westward to Jaen de Bracamoros, 2640 geographical miles, across the greatest breadth of South America, a fall of 16″ only, or 1 foot in 13,000 (Humboldt, *Asie Cent.* i. 90). In consequence, in March, when the river is fullest, a very large proportion of this vast area is one great standing pool, all the small drainage channels having become obliterated in the dry season.

(194) But besides the detention of snow on the watershed lines of a river basin, the general elevation of those lines, and of the district they inclose, is very influential in determining the annual average of precipitation itself, that is to say, the degree in which the rain-bearing winds, in passing over the river basin, become drained of their moisture. Such precipitation (METEOROLOGY, art. 110) is mainly determined by the vapour-laden air rising to a higher level in its progress, dilating, and losing temperature by so doing, a process which takes place of necessity whenever the atmosphere of any district is swept bodily *up the country* during the moist winds. The height of the watershed then, and its situation as regards the prevailing moist winds, are points of primary importance in determining the volume of water discharged by a river. This consideration, we may observe, is alone sufficient to render an account of the great meteorological fact (if such it really be), that the northern hemisphere receives more rain than the southern, without having recourse to the hypothesis of the trade-winds crossing at the equator, which it has been adduced as a proof.—(Maury, *Phys. Geog. of the Sea*, § 174.)

(195.) *Courses and Slopes of Rivers.*—The courses of rivers are of necessity regulated entirely by the direction of the lines of lowest level (art. 137), and are determined therefore by the same causes which have regulated the upheaval of mountain chains, and the dislocation of their strata. Hence it follows that the courses of rivers very frequently follow the escarpments of cliffs abutting on flat or gently-sloping country; such cliffs, when not ancient sea cliffs, being usually indications of lines of fracture in the act of upheaval, or the outcropping edges of inclined strata dipping from the escarpment inward; and thus it often happens that sudden turns in a river course correspond to changes in the geological features of the country. When a river, too, which has run for some distance between parallel mountain chains, escapes by a cross valley laterally, such valley is very commonly identifiable, by the inclination of the strata on either side of it, as a valley of cross fracture, accompanied with its own peculiar dislocations. And in some cases earthquakes have been known to open channels by which the courses of rivers have been diverted. The falls of the Zambesi, as described by Dr Livingstone (see art. 232), can hardly have originated in any other way.

(196.) The velocity of the water in a river is greatest in mid-stream, at some little distance below the surface; the bottom and sides being retarded by the friction of its bed and banks, and the intermediate water by friction on that which moves with less velocity than itself. The retardation is greater the more the river bed winds, the more it is obstructed by shoals or by irregularities in its bottom, especially where shallow; and thus it happens that in the case of an inundation, such as that of the Amazon, the slope there indicated, which, if uniform, and along a regularly-worn channel, would be quite sufficient to carry off the water across the country, fails to do so. The slopes of rivers are for the most part very gentle. Thus, Mr Rennie found the fall of the Thames from Chertsey to Teddington Lock to be $17\frac{1}{2}$ inches per mile, corresponding to a slope of 57″ (one inch per mile corresponds to 3·26″). The Nile, between Assouan and Cairo, has an average slope of $6\frac{1}{2}$ inches per mile (21″). La Condamine assigns to the Amazons an average slope of $6\frac{1}{3}$ inches per mile (20″·65). The Ganges, according to Rennie, slopes 4 inches, or 13″·04. The Rhone is the most rapid river in Europe (perhaps, for so long a course, in the world). From the Lake of Geneva to Lyons its slope is 4′ 24″, from Lyons to its mouth, 1′ 46″. The average velocity of the Nile is about $2\frac{3}{4}$ miles per hour, of the Ganges from 3 to 5. The velocity of rivers, however, depends much more on their depth, and on the body of water conveyed, than on their slope (except when much exceeding these limits), as the velocity generated by the mere fall of water is almost wholly destroyed at every instant by friction.

(197.) *Springs—Caves—Thermal and Gaseous Springs—Petroleum and Naphtha Wells—Gaseous Orifices.*—The welling forth of streams from perennial springs is of the most ordinary occurrence, but it is seldom more than a rivulet which rises in this manner. There are, however, some instances of considerable streams so originating. When this is the case, they issue from caverns, and these occur usually either in ice or in limestone. In the former case they are evidently only the drainage of melted snow, which pours out at the foot of a glacier by the contribution of subglacial streams converging to the lowest point. Such is the source of the Arve from the Glacier des Bois, at Chamouni, and such that of the Ganges, which emerges as a stream, already 40 yards in breadth, from a huge cavern in a perpendicular wall of ice near the temple of Gangutri (lat. 30° 59′ N., long. 78° 59′ E.) Limestone formations are very apt to be hollowed into caverns by the solvent power of carbonic, and perhaps also of other acids derived from vegetable decomposition, held in solution in the percolating water. Such caverns often run to great distances under ground, and frequently contain running streams, even considerable rivers, as is the case in the caverns of the Peak and Castleton in Derbyshire, and in that of the Nicojack Cave in Georgia, U. S., on the Tennessee river, where a waterfall occurs at a distance of three miles under ground (*Ed. Ph. Jour.*, i. 426). When such streams emerge to day, we have the phenomenon in question, as in the cavern of the Guacheros, in the valley of Caripe, in Cumana, described by Humboldt; in the celebrated fountain of Vaucluse, which issues as a considerable stream from a cave at the foot of a perpendicular limestone cliff; and in a great number of caves in Carniola and Illyria, where "almost every lake or river has a subterraneous source, and often a subterraneous exit. The Laibach river rises twice from the limestone rock, and is twice again swallowed up by the earth before it makes its final appearance"—(Davy). The rivers Sarapa and Blanco, which flow from the lake of Yojoa in Honduras, both enter subterranean channels, through which having passed, in the one case a mile, in the other a mile and a half under ground, they reappear.

(198.) When water, carried down to a great depth into the earth, is forced up again by hydrostatic pressure through other channels, and rises as a spring, it brings up the temperature of the greatest depth to which it has penetrated, and that sometimes a very high one, even out of the neighbourhood of any volcanic formation. The warm springs at Bath have a temperature from 93° to 117° Fahr., those of Bareges and Bagneres 120° and 123°. In the county of Bath, in Virginia, a "warm spring" (96°

Fahr.) issues in sufficient volume to turn a mill, and a "hot spring" (108°) rises at a few miles distance. Three springs at Yom Mack, near Macao, have temperatures of 132°, 150°, and 186° Fahr. respectively. On the Arkansas river are springs of 180° and 190°; at Broussa, in Asia Minor, the water rises scalding hot; at La Trinchera, near Valencia, 194°·5, in a stream 2 feet deep and 18 feet broad; at Jumnotri, in the Himalaya, nearly boiling; at Urijino, in Japan, fully boiling; and in the Geyser fountains at Reikiavik, in Iceland, it is spouted, intermittently, in a torrent to the height of 150...200 feet, actually boiling. In this case there can be no doubt of its having traversed a bed of lava not yet cold. A simple and perfect imitation of the phenomenon is produced by heating the stem of a tobacco-pipe red hot, and holding it horizontal, the bowl being filled with cold water. If we consider that the temperature of the earth increases at an average rate of about 1° Fahr. for every 90 feet of depth, these facts will not appear at all surprising. The permanence of their temperature is a proof of their obtaining it at great depths. At Mont Dor the very bath exists which was constructed in the time of Cæsar. At Yakutsk, where the soil is frozen to a depth of 630 feet, Mr Atkinson informs us that hot springs exist, and afford in their neighbourhood opportunities of culture.

(199.) Many springs rise impregnated with carbonic acid,—those of Carlsbad to the amount of 12 cubic inches to the pint, and that of Bilin 34 inches. The warm spring of Wildbad, in Wirtemberg, contains in a pint of water 12 cubic inches of carbonic acid, 7·9 of azote, and 8 of oxygen (Daubeny, *Report*, &c., B. A. 1836). Sulphuretted hydrogen also is no uncommon ingredient, as in the sources of Baden, Harrowgate, and St Amand. Saline ingredients often enter to a large extent, and springs of brine occur in many localities, as at Droitwich in Worcestershire, at Halle in Saxony, and at Luneburg. Other salts of soda also occur in abundance; thus the springs of Carlsbad alone have been computed (from analysis) to give out annually more than 13,000,000 lbs. of carbonate, and 20,000,000 lbs. of sulphate of that alkali (Gilbert). Borax is found in the lakes of Thibet, and free boracic acid in the Lagune of Tuscany. Lime and magnesia enter as muriate and sulphate. Silica occurs in the boiling springs of the Geysers.

(200.) Springs of petroleum and naphtha occur in Zante, in Modena and Parma, in Sicily, and many other localities. In the Burmese territory, on the Irawadi, there are upwards of 500 wells yielding annually 400,000 hogsheads of petroleum. In Trinidad there is a lake of mineral pitch three miles in circumference, partly liquid, partly solid, and fluid bitumen rises through the sea near that island.

(201.) Carburetted hydrogen gas is discharged from the earth is many regions where coal abounds. At Fredonia, in New York, U.S., it is conveyed in pipes for lighting and domestic use. In the province of Tsechuan, in China, it is also so used. At Thsee-lieou-tsing, a single source of gas heats 300 kettles. At Pietra Mala, near Florence, carburetted hydrogen rises through limestone, and may be set on fire. At Bacou, on the Caspian, flames (doubtless owing to gas on fire) are often observed to run over the hills. Something of the same kind is said to occur in the country between Namur and Liege.

(202.) Springs occasionally intermit and flow again in regularly recurring periods. That of Paderborn, in Westphalia, discharges water twice in the 24 hours—the discharge being accompanied with a loud rumbling noise. The Cave of Kilcorney, county Clare, in Ireland, generally dry, discharges a great flood of water quite suddenly two or three times in the year (*Phil. Trans.*, 1741). The lake of Zirknitz, near Trieste, is half the year a hay field, and the other half full of water discharged from a limestone cavern.

(203.) *Perpetual Snow.*—The summits of many mountains are covered with perpetual snow. The cause is found in the decrease of temperature in ascending from the sea-level (METEOROLOGY, art. 22). The rate of decrease being pretty nearly alike everywhere, the snow-line is sooner attained in high than in low latitudes. In EUROPE, in Iceland, and at the North Cape (lat. 71° 10′), the snow-level is about 2000 feet above the sea. In Norway, between 59° and 65° N., from 4000 to 5000. On the Alps (47°) and Pyrenees (43°), from 8000 to 9000. In the NEW WORLD, along the Andes, commencing with the Straits of Magellan, we find it in 54° S. so low as 3700 feet, with glaciers descending to the sea-level; but it rises rapidly on proceeding northward, attaining 8300 in 40° S., 12,780 in 33° S., and 13,800 in 27° S. Along the Chilian Cordillera, from 14½° to 18° S., the snow-level is 15,900 feet on the eastern, and 18,500 on the western side—the cause of the difference being the greater hygrometric dryness of the leeward side of the ridge; and in the great equatorial range of volcanoes (Cotopaxi, &c.), its mean altitude may be stated at 15,800, while in the northern prolongation of the chain in Mexico (19° N.), it is 14,760. In ASIA, the snow-levels present a contrast to these quite as striking as that between the mountain systems of the two continents, with whose general direction and manner of grouping they stand connected. Thus proceeding from high to low latitudes, we find (Humboldt, *Asie Cent.* iii. 360),

	Lat. N	Snow-level. Feet.
Aldan Mountains	60°55′	4476
Kamschatka	56 40	5233
Altai Mountains	50 —	7034
Caucasus	43 —	10,840
Ararat	39 42	14,170
Mount Argæus	38 33	10,705
Bolor Mountains	37 30	17,010
Hindu Kho	34 30	18,735
Himalaya, North side	31 —	20,930
——— South side		13,070

In AFRICA, we have nothing dependable except that in Morocco, Abyssinia, and on the equator, snowy mountains occur. But in the southern ocean, it deserves notice, that not only in such high latitudes as 75° S., that of Mounts Erebus and Terror, but in the much lower latitudes of South Shetland (62° 30′), the South Sandwich group (59°), and even South Georgia (54° 40′), the snow-line reaches the sea-level.

(204). The snows and glaciers of the Alps are reckoned to occupy 1400 square miles (Forbes, citing Ebel), upon which the melting effect of a hot summer day, taken at 3 millions of cubic feet per square mile per diem,[1] would afford 4200 millions of cubic feet of water, or about 1-40th of a cubic mile per diem for the supply of the streams running from them.

(205). The snow-fields on the tops of mountains are prolonged downwards beyond their natural and proper level, by *glaciers*, which are accumulations of snow thrust down by pressure, *a tergo*, into precipitous valleys, and pressed and hardened by alternate partial thawing and "regelation" into ice. Their phenomena are very curious; but having been made the subject of a lucid and elaborate special article in this work (See GLACIER), by one who, from personal research, and long meditation, is probably better qualified than any one else to describe and

[1] This supposes one-third of the sun's vertical power (at the sea level) to be effective for fusion during nine hours per diem.

explain them, we prefer referring the reader to that article for all that concerns their descent and progress. There is, however, one feature in their history which especially concerns our subject, viz., the abrading and transporting power of glaciers. Every glacier carries down with it blocks of stone, and smaller fragments, which it deposits, on melting in the valleys, in heaps and mounds of "moraine," distinguishable as such by the angular and little-worn character of the masses. Where such glaciers run out to the sea-coast in high latitudes, and break off, they carry with them, as icebergs, these masses (often of very great size), which they deposit on melting at the bottom of the sea. Thus is explained satisfactorily a phenomenon which at one time gave rise to an infinity of wild speculation—the occurrence of "erratic blocks" and granite boulders, in localities very far from any mountain-masses of like material: on the limestone slopes of the Jura, for instance, with the whole valley of Geneva and its lake interposed between them and their obvious original site in the peaks of Mont Blanc, or on the sandy, alluvial plains of North Germany, with the Baltic intercepting their transport, otherwise than by this sort of water-carriage from the Scandinavian mountains. Geologists seem agreed, that in such cases resort must be had either to a formerly existing glacier slope at an earlier geological epoch, or to their floating off on icebergs on the bosom of an ancient ocean, a process which we see going on under our eyes. Often, too, unequivocal signs of glacier action are exhibited in deeply-grooved and friction-worn surfaces of rocks *in situ*, the evident work of angular fragments forced along them with violent pressure; and in northern latitudes, similar indications (as in the hills north of the St Lawrence) testify to the heavy grinding of icebergs drifted along at an epoch when the whole of that region formed the bed of a shallow sea, extending probably to the pole. We come now to describe more particularly the phenomena of rivers, commencing with those of the New World, as in the case of the mountains.

(206.) *Rivers of South America.*—All the more considerable South American streams flow eastward into the Atlantic, the narrow strip of western slope from the Andes to the Pacific being too confined, and the climate for the most part too dry, to nurture anything beyond small mountain-streams. In fact, from Valdivia northward, their whole supply is from the snow, which lies in much less abundance on that side. Of the rivers that flow eastward, those of Patagonia, from the extremity of the continent to the mouth of the La Plata (lat. 35° S.), are of small magnitude, with few or no affluents, and making straight across the dry and shingly desert terraces of Patagonia for the sea, a region sterile and desolate in the extremest sense of the word. Beyond these, a total change of character in the river system, consequent on the changed character of the climate, commences, and we find vast rivers, with an immense development of affluents—the principal of which, in their order of occurrence, are, 1. The La Plata or Parana—for the former name appertains only to the wide estuary of Buenos Ayres. 2. The San Francisco, whose mouth is in 10° 40′ S. lat. 3. The Paranahyba (2° 45′ S.). 4. The Rio Para, or Tocantins (0°40′ S.). 5. The Maragnon, or Amazon, which may be considered as falling into the sea exactly on the equator; and, 6. The Orinoco (8° 40′ N.)

(207.) The Rio de la Plata collects its waters from three very different descriptions of country. From the eastern slope of the Andes, between the 19th and 25th parallel of south latitude, it receives the Pilcomayo, the Vermejo, and the Salado, streams not much explored, which traverse salt deserts, and the wild and inhospitable region of the Gran Chaco. The Salado is brackish, and, as laid down by Commander Page in his track survey, exhibits perhaps the most tortuous sinuosities which can be found in river navigation. From the north it receives the Paraguay, with its numerous affluents, which drain the central plains between the 13th and 25th degrees of S. lat., and the western slopes of the Brazilian mountain system, the Sierras of Arapares, Calhano, and Amambahi. This is a magnificent river, navigable from Corrientes (lat. 27° 28′ S., where it joins the main river) nearly to its sources in lat. 13° S. It flows through a country of most luxuriant vegetation, but in all the lower part of its course, is subject to great and destructive inundations. The eastern branch, which carries the name of the Parana till it forks into the Rio Grande and Paranahyba (not the great river of that name), drains the interior of a large basin included by the coast sierras on the east, the sierras just mentioned on the west, and the Montes Pyreneos on the north, a district including much of the richest part of the Brazilian territory. The Uruguay, which drains the basin included between the Sierra de Bitoanos and the Albardao de S. Ana, runs parallel to the Parana, and joins it at the estuary of La Plata, a shallow sea of fresh water, 180 geographical miles in depth inland from the coast, and 120 broad at its mouth. The total area drained by this magnificent river system is no less than 886,000 square miles. A fine survey of the course of the Paraguay has been recently executed (1855) by the government of the United States, under the direction of Commander Page above mentioned, in the steamer Waterwitch.

(208.) The basin of the San Francisco is contained between the coast sierras from Rio de Janeiro to Cape St Roque, and the mountains parallel to them forming the next interior range of the Brazilian system, the Sierras Tiririca, Tabatinga, Gorgueha, and S. dos Irmaos. Its course between these ranges is generally from south to north, and their direction and continuance northward would lead, by a natural course, to an embouchure on the north-west coast, beyond the Cape. But about the 10th degree of S. lat. it turns suddenly to the eastward, and, cutting through three successive parallel sierras, empties itself on the east coast, thus affording a striking illustration of the general fact noticed in art. 195, since the course actually pursued is precisely along the line of demarcation which separates the granitic formations of this coast from the tertiary and alluvial ones of Pernambuco and Maranham. The basin of the San Francisco includes the district of Minas Geraes, the great source of the mineral wealth of Brazil. It includes an area of 187,200 square geographical miles, and the river itself is 1400 miles in length to its source in the Sierra da Matta da Corda. The Paranahyba River, which drains the province of Maranham (a basin of 115,200 square miles), offers little of interest beyond the facilities it affords for internal communication, which, as is the case with all the rivers of South America, are the most complete and perfect which the world possesses, the whole of that vast continent east of the Andes being accessible from the sea into almost every corner, granting only the aid of steam navigation.

(209.) The Rio da Para is the joint estuary of two great streams, the Araguay and the Tocantins, which drain the interior of the Brazilian mountain system, following a parallel course on either side of the meridional chain of the Cordillera Grande. It enters the sea so near the mouth of the Amazon (being separated from it, however, by the so-called island of Marajos, of about 9000 square miles, behind which the narrow channel of Tagipuru runs from river to river), that it is sometimes called an affluent of that river. The Amazon itself, by far the largest river in the world, since the area of its basin ex-

ceeds 1,500,000 square geographical miles, is fed from the eastern slopes of the Andes, from the 2d degree of N. to the 19th degree of S. latitude. Its most remote feeder is the Apurimac, which descends from the extreme edge of the plateau of Bolivia, near Caillomas, 3000 miles from its mouth (following the stream), and among its affluents has many which would rank as first-rate rivers. It enters the ocean by an estuary 135 geographical miles broad and 200 long, but which wholly consists (at least superficially) of fresh water. It is navigable 2200 miles from its mouth, and by reason of the flatness of the greater part of the region it traverses, there is but little interval between its head waters and those of the Paraguay, on the one side, and none between it and the Orinoco on the other, inasmuch as one and the same tributary, the Cassequiare, belongs indifferently to both river systems, the level being so complete at one point between them as to obliterate the line of watershed, and establish a natural and permanent canal uniting the two basins (see art. 140). The principal affluent of the Amazon (considered as prolonged in its main stream under the names of the Solimaes, the Maragnon, and the Yucatale, to the Apurimac) is the Madeira, which rises among the farthest inland mountains of the Brazilian system, and whose course, from the extremity of the Cordillera Geral, where it leaves them, is by a great series of cataracts and rapids down to the plains. The length of this river, from its junction in 57° 40′ W. to its extreme source in the Rio Grande, which rises among the mountains north of Potosi, is not less than 1600 geographical miles; the vast and almost unexplored region between the two rivers, and, indeed, nearly the whole course of the Maragnon itself, from the junction upward (an area of more than half a million square miles), being occupied by dense and all but impenetrable forests (the Silvas of the Amazon), deluged by the equatorial rains, whose effects in flooding the country during the northward progress of the sun have been already described (art. 193). Besides the Madeira, the Amazon receives as tributaries the important rivers of the Negro, the Tapajos, and the Xingu, the former extending towards the sources of the Orinoco, and forming a junction with it by the Cassequiare, as already mentioned, the two latter draining the interior basin between the watersheds of the Araguay, the Paraguay, and the Madeira.

(210.) The basin of the Orinoco includes the western slopes of the mountain system of Parimé, and the eastern of the Cordilleras of New Granada. North of the equator its supply of water, area for area, is even greater than that of the Amazon. For, in the interior of Guiana, 560 miles from the coast, when full, it exceeds three miles in breadth, and the rise of the waters at this part of its course, in the periodical floods, is from 30 to 36 feet. These floods take place in that half of the year when the sun is north of the equator (the course of the river lying on that side of the line), and the quantity of rain which falls on the area must be enormous, probably not less 200 or 300 inches annually. (Mrs Somerville, indeed, states it at 1000 inches, we know not on what authority, but if this be correct, it can only be that the rain which falls during one period of the day, in the wet season, is in great part evaporated in the other, and, in fact, that the same water falls over and over again.) Where the Orinoco leaves the Parimé mountains at Atures, its course is broken by falls and rapids there and at Maypures, which, though not deep enough to merit the name of cataracts (being only 30 or 40 feet), have attained celebrity in the picturesque description of Humboldt (*Aspects*, i. 219), from the vast volume of water poured down, and the singularly rugged nature of the ground. At these falls, too, there are manifest indications of the course of the river having at some former period been elevated from 160 to 190 feet above its present level.

(211.) *Rivers of North America.*—In North, as in South America, all the great development of the hydraulic system is on the east side of the Pacific mountain chain, the *North American Andes*, as it may fittingly be designated. Towards the Pacific, however, owing to the broader extent of the mountain belt, the streams are not so stinted as in the South, and we find, too, the Colorado and the Columbia, which merit the epithet of great rivers, the former (which falls into the Gulf of California) having a basin of 170,000, the latter of 194,000, square miles,—streams which, however, derive greater importance than belongs to their mere magnitude, from their representing, with the Sacramento, the drainage of the great gold-fields of the West. The loftiest waterfall in the world (unless exaggerated, is to be found in the Yohamite Valley, in Mariposa (?) County, California, where a river as large as the Thames at Richmond makes a single leap of 2100 feet perpendicular, the total height of the fall being 3100 (Gibson). On the east side of the coast ranges we have six great river systems, two of them of the first magnitude, viz. the Rio Grande del Norte and the *Mississippi*, which fall into the Gulf of Mexico; the *St Lawrence*, into the Atlantic; the Saskatchewan and Churchill, into Hudson's Bay, and the Mackenzie, into the Arctic Ocean.

(212.) The Rio del Norte derives its waters almost entirely from the mountain ranges which buttress the table-land of Mexico (the Cordillera of Cohahuela, and the Sierras Madre and de lo Mimbre), and receives little or no accession in traversing the intervening slopes to seaward. Its extreme feeders abut on the eastern borders of two considerable closed areas, or "continental basins," which collect, and suffice to evaporate, the waters of the northern portion of the Mexican plateau, leaving, as usual, lakes more or less salt.

(213.) The magnitude and importance of the Mississippi will be at once appretiated from the fact of its draining nearly a million square miles of territory, admirably adapted for human habitation, and inhabited, in fact, by the most active and rapidly-increasing population in the world. Its line of watershed is very remarkable for the difference of altitude in different parts of its extent. On the west, from the 38th to the 48th degree of N. lat., it consists of the ridges of the Rocky Mountain range, averaging eight or ten thousand feet in altitude, while on the north, the division of the American waters which flow north from those which run to the south, cuts across the central plain of the continent, between the 46th and 50th parallels, and (except where it branches from the mountains) is nowhere more than 1500 or 1600 feet in elevation, to its intersection with the western watershed of the St Lawrence basin. This entire river system consists of three great branches, the Missouri and the Mississippi (uniting at St Louis, lat. 34° 84′, long. 90° 12′), and the Ohio, which falls in somewhat lower at New Madrid (36° 32′, 89° 32′), the Missouri receiving the waters from the western mountains, the Mississippi from the central slope, and the Ohio the inland drainage from the Appalachian mountain chain. Each of these is a magnificent river, with a great system of affluents. The Missouri is navigable from the *Great Falls*, in the Rocky Mountains, to the sea, a distance of 4000 miles; the Mississippi, from those of St Anthony, 2240; while the Ohio, being connected by a system of canals with Lake Erie, and thence with Lake Ontario (so as to evade the falls of Niagara), carries out a water communication between the Gulfs of Mexico and St Lawrence. The average slope of the Mississippi, from its source, is 19·87 in. per mile, or 1 in

3189 (corresponding to a slope of 1′ 4″), or about three-fourths that of the Rhone. It is therefore no sluggish river, but in many parts of its course, a torrent, against which steamers with difficulty make head, and which rushes down laden with drift timber from the (yearly disappearing) forests of the vast alluvial region it traverses, cutting down timber-laden banks (whose section discloses the forest growth and destruction of hundreds of thousands of years—*Lyell*), and carrying all out to sea through a delta of unexampled extent (see art. 106). The Arkansas and Red River join the Mississippi below New Madrid. Their course is through the desert country on the east slope of the Chippawyan range, and they and their affluents cut through the terraces parallel to that range almost at right angles.

(214.) The St Lawrence drains a vast table-land, whose highest point is not more than 1680 feet above the sea, and of which a very large portion is occupied by lakes, whose united waters constitute more than half the fresh water on the globe, and of whose extent, depth, and height of their surfaces above the sea, Mr Johnston (*Phys. Atlas*, p. 157) has given the following synopsis:—

	Extent in Square Miles	Elevation above Sea	Mean Depth
		Feet.	Feet.
Lake Superior	32,000	630	900
Lake Michigan	22,400	600	1000
Lake Huron	20,400	600	1000
Lake Erie	9,600	565	120
Lake Ontario	6,300	234	530

The estuary of this river enters the sea very obliquely. (The water being purified by subsidence in the lakes, it forms no delta.) It is 80 geographical miles broad at its opening into the Gulf of St Lawrence, and contracts very gradually for 350 miles inland to Quebec. The communication along the chain of lakes is broken between lakes Erie and Ontario by the stupendous fall of Niagara, the largest and most magnificent, though far from the highest, in the world, the total breadth of the river (which is divided into two great cataracts by Goat Island) being 3225 feet, with a depth of descent of 162 feet in the one fall, and 149 on the other. The action of the water cuts back the cliff over which it falls at a supposed average rate of about a foot per annum, so that in 30,000 years it will probably have worked its way up to Lake Erie. The sublimity of this fall is declared by all who have seen it, to be such as no language is adequate to describe.

(215.) The basin of the Saskatchewan, 300,000 square miles in extent, includes several large lakes, the chief of which is Lake Winnepeg; as does also that of the Mackenzie (441,000), within whose dreary confines lie the Athabasca, the Slave, and the Great Bear Lakes, visited only by fur hunters, or by those heroic explorers who, in the cause of science, have furnished examples of all but superhuman exertion and endurance.

(216.) The *European Rivers* are for the most part of very small magnitude in comparison with those of America. The largest are the Danube, the Dnieper, and the Don, the two former of which fall into the Euxine, and the latter into the Sea of Azof, and thus ultimately belong to the Mediterranean system.

(217.) The arid nature of the Spanish climate, and the small amount of snow in the Pyrenees, prevent the formation of any large peninsular river, for the Douro and Ebro, though considerable streams, cannot be said to merit that title. As little can any of the French rivers which flow westward. The waters of the Alps are carried northward by the Rhine, southward by the Rhone and Po, and eastward by the Danube, which receives all those of the Carpathian basin, the Tyrolese and Illyrian Alps—a total area of 234,000 square geographical miles. It is navigable nearly 1000 miles from the Euxine Sea, the last 400 of its course lying through the flat countries of Wallachia and Bulgaria, into which it enters by a rapid called "the Iron Gate," between Orsova and Gladova, through the Balkan mountains, immediately below the Pass of Kasan, cut by Trajan along the towering cliffs which descend to the water, in his first Dacian campaign, A.D. 103, and still bearing his inscription on the face of the rock. The total course of the Danube, windings included, is reckoned at 1494 geographical miles.

(218.) The north of Germany and Poland are drained by the Elbe, the Oder, and the Vistula, of which the former flows into the Atlantic, and the two last into the Baltic. The Elbe and Oder receive most of their waters from the most northern outliers of the Alpine system of mountains, and traverse a country considerably undulated and diversified; but the Vistula, with which commences the northern hydraulic system of the great Sarmatian plain, traverses, through almost the whole extent of its basin, a nearly dead level, full of lakes and morasses. The same may be said of much of the upper course of the Dnieper, a river only remarkable as furnishing, by means of canals, a complete system of navigable communication between the Euxine and the Baltic Seas.

(219.) The most notable European waterfalls are those of the Rhine at Schaffhausen, not lofty, being only 70 feet in height, but very picturesque; those of the Velino at Terni, and the Anio at Tivoli, both artificial, but of exquisite beauty; that of Riukan Fossan, where the Maanelvan, a large river flowing out of the Mióvatn lake in Tellemarken, in Norway, springs 946 feet at a single leap; the Glommen Falls, and those of the Moxa, near Stav, in the same country. The Falls of the Clyde, in Scotland, are not wanting in grandeur or beauty. Those of Gavarnie (1400 feet) in the Pyrenees, and of the Staubbach (1004, as measured barometrically by the writer of this article) in Switzerland, are mere rills, remarkable only for their height, in which, however, both are surpassed by that of the Orco, a stream which springs 2400 feet from Monte Rosa, on the Italian side of the Alps, (*Woodbridge and Willard*), and of which some further account would be desirable.

(220.) With exception of the Ural chain, as observed in art. 174, the northern portion of the Europo-Asiatic continent, from the Valdai to Kamtschatka, is one vast unbroken plain from the Arctic Ocean to the Altai—an area of 3,600,000 geographical square miles, through which, besides the Dwina, Indigirka, and Kolyma—no inconsiderable streams—three rivers of the first magnitude (the Obi, the Yenesei, and the Lena) deliver their waters into the Arctic Ocean. To form some idea of the excessive flatness of this immense region, and of that through which the Volga flows into the Caspian, it will suffice to mention the heights above the sea-level of some of its more notable positions—viz. St Petersburg, 0; Moscow, 363 feet; Tobolsk, 115; Perm, 370; Pinsk, 434; Casan, 57; Barnaoul, 383; Jakutsk, 268. Now, Tobolsk is situated on the Irtisch, a tributary of the Obi, and Barnaoul on the Obi itself, the one at 525 geographical miles, the other at 920 geographical miles direct distances from their respective mouths, which gives an average slope of the country in the one case of 8″·11, in the other of 4″·87. The Yenesei, after leaving the mountains, has, in like manner, nearly 800 miles to traverse, in a direct line, of a similar flat region, to the head of its estuary. Both rivers, therefore, in the lower part of their courses, are sluggish and monotonous, and, owing to the high latitude, desolate to the last degree in their fea-

tures. The latter, however, in the superior part of its course from Yeneseisk upwards, has more the character of a mountain river. It derives a large portion of its waters from the lake Baikal, 1535 feet above the sea, a most romantic and beautiful mountain-basin, which is itself fed by the Selenga River, which carries into it the waters of the Tangnou, Kentei Khan and Tschokindo. The basins of these great rivers respectively occupy 924,800, and 784,500 square miles, and their total lengths 2320, and 2800 geographical miles respectively.

(221.) The Lena takes its rise among the mountains of north-east Siberia, on the northern and western slopes of the Daourian, the Yablonoi, Udskoi, and Aldan mountains, from which it issues at Yakutzk, "the coldest of inhabited places;" thence to the sea its course is between banks of ice or frozen soil, which, where undermined in the summer, expose to view the carcases (not mere skeletons, but with the skins, and even the flesh remaining) of extinct elephants, evidently adapted for inhabiting a cold climate, being covered with a thick coating of long shaggy hair—the flesh being in some instances so fresh as to have been devoured by dogs. The total length of the Lena is 2400 miles, and the area of its basin 594,000 square geographical miles.

(222.) The mountains which form the southern watershed of these rivers by no means alone separate the waters which run into the Arctic from those received by the Indian Ocean. Between these slopes is interposed that great continental basin spoken of in art. 137, which, however, owing to the peculiar aridity of its climate, has few rivers, and those for the most part terminating in salt lakes. The greatest of these are the Caspian Sea, and that of Aral—expanses of salt water, though less so than the ocean—the former of 140,000, the latter of 23,000 square geographical miles. Of these, the Caspian is fed by the Volga, one of the largest Russian rivers, which, with the Ural, drains the south-western slopes of the mountains so called, and the flat steppe country from Moscow to Casan, entering the Caspian at Astrakan, after a course of 2400 miles. The Volga is admirably adapted for navigation, and by means of canals connecting its upper waters with the lakes Ladoga and Onega, near St Petersburg, forms a complete water communication between the Caspian and the Baltic by the Neva. The Aral Sea is fed by the Amu or Gihon River, which descends from the plateau of Pamir, and the Syr, or Sihon, which, breaking through the Bolor range, drains a somewhat similar plateau, of a triangular form, between that range, the western extremity of the Thian-Shan, and an offset of that chain running in a north-west direction. Of this region scarcely anything is known, nor is our information much more complete respecting that portion of the great basin in question which extends from the Altai to the Kuen Lun, and along the axis of which, centrally placed, runs the whole length of the Thian-Shan, dividing the waters of the discontinuous salt-lake system, on its north side, from the more connected one of the lake Lop or Loph on its south.

(223.) To the south of this basin (which includes in its westward prolongation the whole of Persia, and which probably exists as such only in virtue of its aridity, since, had it a more humid climate, a great lake and river system would assuredly have been established of west-flowing waters, communicating with the Euxine by self-cut channels), commences the river system of India, which consists of three gigantic rivers, the Indus, the Ganges, and the Brahmaputra (which carry off the waters of Upper and Central India, including the plateau of Malwa), and a number of smaller streams which drain the peninsula, the chief of which are the Nerbudda, the Godavery, and the Kistna, the former flowing westward, the two latter east.

(224.) The Indus is fed by the streams of the celebrated Punjab, or Five Rivers, from the lofty region of Ladak, the western and inferior portion of the Thibetan plateau (penetrated by the Sutlej to the lake Rewan), and the southern slopes of the Himalaya, as far east as the Peak of Jumnotri. These rivers, once free of the mountain intricacies, converge to and unite at a point near the southern extremity of the Suleiman mountains, after which the Indus receives no tributaries of any importance in the rest of its course (280 geographical miles), to Hyderabad, where it forks out into a delta 115 geographical miles in length, and 105 in breadth from Kurraci to Kori,[1] whence it affords a free navigation up the country to Multan and Lahore, the current (except in the flood-season) running about a mile an hour. Its eastern branches were early connected with the Ganges by canals for purposes of commerce and irrigation. Its total length is 1960 geographical miles, and its basin extends over 312,000 square geographical miles.

(225.) The Ganges receives by far the greater portion of its waters from the Himalaya range, from Jumnotri to the Lacheh Pass near Darjiling, east of which all the waters from those mountains flow to join the Brahmaputra. Very little of the plateau beyond the first range of the snowy peaks is drained by it, the whole of their northern slopes down to the level of the plateau being divided between the Sutlej (the eastern branch of the Indus) on the west, and the Yaru or Sanpi (a feeder of the Brahmaputra) on the east. In the western part of its upper course, its branches spread out like a fan, and collect not only the waters of the south Himalaya, but those of a great basin between the Aravulli, the Vindhya, and the Kymor ranges of mountains forming the plateau of Malwa. In fact, it may be considered as resulting from the union of "nineteen or twenty large rivers, of which twelve are larger than the Rhine," (Somerville). Its delta has already been noticed, art. 106. The floods of the Ganges commence, as already stated, in April, attain their maximum about the middle of August, and continue till October. The effect of the causes which produce them may best be estimated from the ratio of the water delivered per second at the maximum and at the minimum, viz. 494,208 and 36,330 cubic feet respectively. The Ganges is remarkable for the great and rapid changes in its course in certain districts, by which it cuts away its banks in one part to add to them in others. Forty square miles (25,600 acres) are said to have been so carried away in one district, in the course of a few years.

(226.) The Ganges and Brahmaputra unite in a common delta, or rather in two deltas, distinct at their commencement, but which, in their prolongation seaward, have met and overlapped, presenting the form of an inverted M, the points turned inland. They drain a joint area of 432,000 square geographical miles; but the latter is by far the larger stream, its minimum delivery of water being 150,000 cubic feet per second (Wilcox), against 36,000 delivered by the Ganges. Its course is remarkable for the sudden turn it takes round the eastern extremity of the Himalaya range, after draining the northern slopes of those mountains, and the mountain valleys of the Thibetan plateau; a turn evidently corresponding to the sudden change in the direction of the upheaving forces acting at this point. Its floods are of immense volume; the plains of Upper Assam are an entire sheet of water, eight or ten

[1] We follow, in these Indian names, the Italian system of pronunciation as to the vowels, and as nearly as to the consonants as each case admits.

feet deep, from the middle of June to that of September; and no wonder, when we consider that at one point (Cherra-pongi, in the Khasya hills) nearly 600 inches of rain fall annually (*i. e.* in the six wet months). The upper course of the Brahmaputra is but little known, and the wanderings of its branches among the mountains east and north of Assam belong rather to speculation than to knowledge.

(227.) Before passing to the river systems of Eastern Asia, we must revert to that of its south-western area. The peninsula of Arabia is riverless as it is rainless, and it is not till we pass out of the reach of the tropical indraft of the north-east winds, that we find in the twin rivers, the Euphrates and Tigris, indications of a different set of conditions. These celebrated streams are supplied entirely from the Armenian and Kurdistan watershed, receiving positively no accession from the Syrian desert on their western side. They both run in a south-eastern, generally parallel course, to the head of the Persian Gulf, the Euphrates being the larger, and its upper waters curving round along the slope of the Armenian plateau, so as to inclose the upper basin of the Tigris. From Bir, in 37° N. lat., where it leaves the mountain country, it pursues a course skirting the eastern border of the desert, and for the last 700 or 800 miles from Kirkesia downwards, receives not the smallest tributary. Near Bagdad, it approaches the Tigris within twelve miles, including between them the plains of Mesopotamia; and here, in those old historic times when Babylon and Nineveh were cities, and empire held its seat in these now desolate regions, the rivers were connected by canals, which served the joint purposes of commerce and irrigation. Like the Ganges and Brahmaputra, they have a common delta, which is supposed by many geologists (not without historical evidence in support of the opinion) to have been in great measure produced within the last 3000 years. The local circumstances are peculiarly favourable to the growth of a delta, the long narrow Persian Gulf allowing of no lateral sweep of the tides to carry off and disperse the deposited matter; and it is extremely probable that at some remoter epoch, but still quite within the *most recent* geological period, the Gulf occupied the whole of Mesopotamia to Bir and Diarbekir, leaving only a narrow but hilly isthmus at Scanderoon to connect Arabia with Asia Minor, as that of Suez connects it with Africa. At present, the Tigris sends out branches to the Euphrates from Amara, 150 miles from the mouth, but the complete junction of the rivers takes place 100 miles lower at Korna, from which to Bassora they form a single stream, subdividing again to form the modern delta. We now return to the river systems of Eastern Asia.

(228.) Each of the long and strait valleys which run southward from the breaking up of the Himalaya mountain system, between the ranges of the Cambodian peninsula, has its river, of which the chief are the Irawadi, the Martaban or Saluen, the Menam, and the Meking or Cambodia, which water the Burmese empire, the kingdom of Siam, and the territory of Cochin-China. They are but little known to Europeans, with exception of the Irawadi, which has been ascended 450 miles from its mouth to Ava, the Burmese capital. It is a magnificent stream, delivering into the ocean no less than 350,000 cubic feet of water per second on an average of the whole year (of which 1-3000th part by weight is silt). Like all tropical rivers, it has its season of flood, during which its volume increases tenfold (from the minimum), running then with a velocity of $3\frac{1}{2}$ to 5 miles per hour. It enters the sea at Cape Negrais, through an extensive delta, which is prevented from spreading westward by the subaqueous prolongation of the chain of the mountains of Aracan, which goes to form the Andaman and Nicobar Islands, Sumatra and Java. There is reason to believe this coast to have been in a state of upheaval at least since the year 1750, and perhaps longer, though it is only from that date that positive evidence of changes of level are procurable. In the volcanic island of Reguain, not far from the coast, three distinct steps of this process have been clearly pointed out.

(229.) The Chinese empire is watered by four great river systems, emptying themselves into the Pacific: the Hong-kiang, Tche-kiang or Canton River, the least of the four, and the Yang-tse-kiang, the Hoang-ho (or Yellow River), and the Amur, all three of gigantic magnitude, the two former of which form what may be considered as a twin system, having a near approach to a common embouchure. The Yellow River derives its upper waters from the south-eastern border of the continental basin above mentioned, including the watershed of the Thibetan plateau on its northern and eastern side, as also from the Yung-ling, Pe-ling, and Tapa-ling mountains, which traverse China from west to east, and direct its waters to the sea at Nankin through a course of 2900 geographical miles, and over a basin area of 548,000 square miles. Branches of the last-named mountains separate it from the Hoang-ho until near the sea, when they communicate in the low levels by innumerable canals; their mouths, however, being separated by an interval of about 90 miles, and by a delta, the common produce of both. The Hoang-ho has a basin of 537,000 square, and a course of 2300 linear, geographical miles.

(230.) The Amur takes its rise among the Daourian, Tschokindo, and Kiang-khan mountains, and the southern slope of the Yablonoi Krebet. It is a river of very peculiar interest as regards the progress of Russian domination in the direction of China, though little known to other than Russian explorers. It has a basin of 583,000 square geographical miles in extent, and a course of 2380 geographical miles, so that it is a river system of the first order, and entering the sea at the very junction of the two great land-locked seas of Ochotsk and Japan, will assume, at some period in the world's history, a commensurate degree of political and commercial importance.

(231.) Among *African Rivers* the Nile is the only conspicuous one, and is in many respects the most remarkable river in the world,—as the seat of the earliest civilization, as a perpetual witness to the stability of those great natural arrangements by which the wants of one region are supplied by the superfluities of another, and as a geological chronometer by which some insight may be obtained into the duration of the existing order of things antecedent to history. Its ultimate sources are in all probability to be looked for in the mountains on, or adjacent to, the equator, and perhaps in the lake Ungiamesi. The main stream, the Bahr-el-Abiad or White River, has been traced as far as 3° 39′ N. lat., and may therefore very well derive its waters from snowy ranges, such as we know to exist in equatorial Africa, or from the lake above mentioned (which, be it remembered, is fresh), or from a generally boggy or lacustrine district, watered by equatorial rains; for there is reason to believe that during the sojourn of the sun north of the equator, the vapours of the Indian Ocean must of necessity be swept by the south-east trade over that precise district, and there precipitated in torrents of rain. It is joined by the Blue Nile (Bahr-el-Azrek), which rises in the Galla country, south of Abyssinia, at Khartum, and by the Atbara, which traverses Sennaar at Goos, about the 18th degree of north latitude, from which point, in its farther passage through Dongola, Nubia, and Egypt, a distance of nearly 1300 miles, following the windings of the stream, it ceases to receive any accession

of waters. Its course through Nubia is a succession of low rapids, called cataracts, at the last of which, at Assouan or Syene, it enters Upper Egypt. Hence it runs in a valley varying from 2 to 18 miles in breadth, through a succession of monuments of ancient splendour, to which the world affords no parallel, to its delta,—the mountains on either side being low ranges (decreasing in height from Assouan downwards) of granite, sandstone, and nummulite, but of which all the lower portions are buried beneath vast alluvial deposits brought down by the inundations. The Nile delivers at Assouan 24,000 cubic feet of water per second when at its lowest at the summer solstice, and 362,000 when at the highest in October (Horner, *P. T.*, 1855). Its *mean annual* delivery is calculated by M. Talabot at 101,000. At the time of the flood it is loaded with black mud of most fertilizing quality, to the amount of 1-633d of its weight, so that the total quantity of fertilizing matter spread over Egypt, or carried out to sea, is about 140 millions of tons. This immense deposit is computed, from the evidence afforded by ancient monuments, the bases of which have been silted (not sanded) up, to cause a rise of the soil of the valley of $3\frac{1}{2}$ inches per century. From borings made, at the instance of Mr Horner, under the colossal statue of Rameses at Memphis, the true Nile sediment was found to terminate at 30 feet beneath the foundation of the platform on which the colossus stands, itself 10 feet below the present surface, which gives an interval of 10,285 years from the commencement of deposition at that spot to the age of Rameses, or a date of B.C. 11,646. At the depth of 39 feet a piece of pottery was found, which (unless subsequently buried there) must have dated its construction from B.C. 11,517 (Horner, *P. T.*, 1858). The supposed drainage basin of the Nile is 520,000 square, and its supposed total course 2240 linear, geographical miles.

(232.) The next African river in importance, as regards internal communication, is the Zambesi, Cuama, or Quilimano, recently explored by Dr Livingstone, which enters the sea at Quilimane, in lat. 18° S., and, if really connected, as he appears to consider demonstrated, through the Victoria Falls, with the Liba, the Liambi, the Luambesi, and an innumerable host of other rivers which cover the interior of south Central Africa like a vast network of anastomosing streams, drains an area of not less than 120 square degrees, or 432,000 square geographical miles. The falls referred to are perhaps the most striking, after Niagara, which exist. The river, 1000 yards in breadth, is suddenly swallowed up in a narrow perpendicular cleft, 100 feet deep, in a black basaltic rock directly across its course, which is prolonged from the bank 40 or 50 miles, in which the river takes its new course compressed in a deep channel of 15 or 20 yards. The hydraulic system of the interior of South Africa, disclosed by Dr Livingstone's researches, is anomalous in the extreme, and is only compatible with the idea of a generally level plateau, deluged with periodical rains, but not, like the plain of the Amazons, dominated by a great range of high lands on one side, with a slope to the other, but as if the periodical rains fell on a very gently rising convexity, so as to leave the waters undecided by what channels to seek the main arterial drainage. It would seem very probable that the cleft of the Victoria Falls has been of comparatively recent origin, and has determined a new system of drainage by which the water of those regions has been carried off more rapidly than heretofore, since the general tenor of Dr Livingstone's narrative points to what may be termed a secular desiccation of the districts traversed by him.

(233.) The Niger, Joliba, or Quorra, rises in the Kong Mountains, and after running a considerable distance along their bases to the east-and-by-north, makes a sudden turn at Timbuctoo to the south, and penetrating the chain of mountains, reverts to the west coast, and falls into the sea in the Gulf of Guinea at the New and Old Calabar, the extreme rivers of its delta,—streams foul and fetid, redolent of marsh poison and the moral pestilence of the slave trade. The expedition under Baikie, in 1854, has shewn the possibility of penetrating through this disgusting basin into regions full of tropical life, and exhibiting humanity under an aspect a few shades less repulsive than its savage forms for the most part assume.

(234.) Of *Australian Rivers* the catalogue is small, and, so far as can be at present ascertained, confined to very moderate distances from the coast. It would seem most probable that the central regions of that singular continent will furnish another instance of a "continental basin," with a system of internal drainage and salt lakes. Most of its streams flow in deep rocky clefts, affording no irrigation, and assuming alternately the impetuosity of torrents and the stagnancy of a chain of pools with a communicating thread of water sunk in deep gulleys channelled in a table-land. These streams rush with wonderful rapidity in the rainy season. The Hawkesbury has been known to swell to 100 feet above its usual level, sweeping away everything in its course. From Count Strzelecki we learn that the average fall of the rivers running eastward in the colony of New South Wales, is 48 feet per mile, of those which run westward 9 feet, the land sloping inwards more gradually.

(235.) *Pampas, Silvas, Llanos, Prairies, Savannahs, Steppes, Tundras, &c.*—The mountains which constitute the central ridge of the old continent and the lateral of the new, tower to a vast height, while on their flanks, and after a more or less extensive interval of broken country and lower chains, they fall away into sloping sheets, terracing down by steps into the low lands, which ultimately flatten into what becomes at last an unvaried plain, extending to the borders of a far remote ocean. The easier accessibility of these regions, and in many cases their high fertility (formed as they have been by alluvial deposition from the washings of the higher ground), constitute some of them the principal theatres of human habitation; though it would seem that the higher developments of civilized life require something of the excitement and hardihood generated by the neighbourhood of at least a hilly country, and languish in the monotonous ease of an uninterrupted level, however adapted by its luxuriance for that material civilization which commerce fosters.

(236.) Each of the more extensive regions of this kind has some peculiar character due to its soil, climate, and the nature of its vegetable and animal tenants. Our limits forbid lengthened or minute description; but we will endeavour, in as few words as possible, to convey some notion of the leading features of the principal among these flat regions.

(237.) *The Pampas of Patagonia* seem destined to perpetual desolation, not only by their climate (art. 274), but also by the nature of their soil, which terraces down in almost unbroken sheets of shingle and basalt, diversified with huge boulders, the whole brought down, no doubt, by ancient glaciers, and deposited by their melting when floated off to sea, and which occupy the whole eastern slope of the continent, from its extremity to the Rio Colorado. In these regions the vegetation is stunted, the winds fierce and tempestuous, and the population almost *nil.*

(238.) This desolate region is succeeded by one hardly less so, though different in its style of desolation. In the pampas of Brazil and Buenos Ayres, vast tracts are destitute of trees, and almost of water, but lying in a warmer latitude, and having, therefore, been exempt from the

action of those causes alluded to in the last article, which have covered the alluvium with stony fragments, hardly a stone or a pebble is to be found in them for hundreds of miles. In this region, which extends southward from the estuary of the La Plata to Patagonia, and westward to the feet of the Andes, the alternation of the wet and dry season, acting on a soil composed entirely of a red argillaceous alluvium, with here and there calcareous concretions, effect no other variety than the growth and decay of gigantic thistles for some distance from the coast, replaced further inland by the long-tufted pampas grass, ranged over by innumerable herds of wild or semi-wild horses and cattle, whose skins are exported, and whose fat and dried flesh serves for fuel; and where, in the dry season, the pampero's transient wind-storms from the interior raise clouds of dust, involving the whole horizon in darkness so impenetrable, that even the lightning which accompanies them is only *heard*, not seen. Roads there are none, nor any need of them. Lassoing a wild horse, mounting and riding him till he falls from fatigue, and is exchanged for another, the traveller, with his Gaucho guide, speeds on, day after day, and week after week, as for the bare life, towards the far-distant and long-invisible hills. The exciting gallop of Captain Head across this country, will probably be familiar to many of our readers. A tract of swamp and bog, succeeded by a region of ravines and stones, with a zone of thorny bushes and dwarf trees reaching to the Andes, complete the picture of this uninviting region, which communicates northwards, along the western slopes of the Parana Valley, with the hideous wilderness of the Gran Chaco traversed by the Salado, Vermejo, and Pilcomayo rivers, where the wild Indian still ranges in inaccessible freedom. The pampas of La Plata and Patagonia together, are computed by Humboldt to occupy 135,200 square leagues, or 1,217,000 square geographical miles. If they offer little of interest on their surface, the buried, and in many cases hardly buried, gigantic remains of the Glyptodon, Mylodon, and Megatherium, with other singularly-formed monsters of an earlier Fauna, which they cover, amply compensate to the geologist for this deficiency by presenting him with the enigma of a once animated creation, which seems to have simply died out, without any of those geological cataclysms and catastrophes, or changes of climate, to which we are in the habit of attributing such events in general. It is somewhat singular, too, that among all these remains, few attributable to carnivora have been discovered, the most remarkable among them being the Machairodon Neogeum, Sabre-tusked Tiger, a truly dreadful form of fossil voracity.

(239.) The *Silvas of the Amazon River* include a tract of perhaps not less than half a million square miles of the central area of South America, where, owing to the rich quality of the alluvium brought down by that river and its tributaries, and spread over the country by its inundations, aided, in the wet season, by an immense rain-fall, and by the general heat of the climate, vegetation seems carried to the extreme of exuberance. A region more than six times the area of France, crossed by the equator, and reaching from the cordilleras of the Andes to the mountains of Parimé, is clothed with a mass of forest, so dense and impenetrable as to defy access, except by navigation, and tenanted by innumerable wild animals, among which the monkey tribe holds a very conspicuous place. The descriptions given by Humboldt of this region, present pictures of forest life and scenery in which every feature of grandeur, gloom, and savage wildness is concentered.

(240.) *The Llanos of the Orinoco* occupy a perfectly level area of nearly 160,000 square miles, so level, indeed, that elevations of a few feet, quite imperceptible to the eye as slopes, suffice to form the watershed lines between adjacent streams. After the rains (during whose continuance the whole country is inundated) a rich pasture covers it, which has procured it, from the natives, the designation of the "Sea of Grass." This speedily dries and furnishes the material of extensive conflagrations, which, repeated year after year, effectually serve to maintain the treeless character of the region. The dust-storms here also are terrific, and are admirably described by Humboldt (*Aspects*, p. 17).

(241.) About half the total area of North America, from the Alleghanies to the Rocky Mountains, including great part of Canada, Labrador, and the Indian country to the north, to the amount of nearly 3,000,000 of square miles, has been characterised by Humboldt as "an almost continuous region of savannahs and prairies." The terms, however, apply more correctly to those regions of the Great North American plain and flat river basins which are deficient in timber. These, however, differ much in climate, soil, and aspect. To the west of the Mississippi, where the ground rises in terraces towards the Rocky Mountains, the climate is arid, the soil sterile, often full of salt, and destitute, at all events, of fresh springs. The prairies of Texas, however, have a rich soil, a profusion of grass, and flowers of fine hues and delicate scent, and are adorned, not indeed with forests, but with frequent clumps of large trees, or here and there a single one of vast breadth of growth, covered with long pendent moss. To the east of the Mississippi, along the coast of the Gulf of Florida, extends a region of so-called Pine Barrens, where only trees of that family can extract nutriment from the sour sand. These are not confined to Alabama and Florida, but extend far inland, and occupy large tracts in North Carolina and Virginia. East of the Mississippi, the country, till cleared by the increasing population, was for the most part richly wooded, interspersed, however, with savannah and prairie grounds, the treeless character of which, as in the case of the Llanos, was perpetuated by frequent conflagrations, which swept across whole districts, and destroyed every living thing within their area. In the southern districts, the air, especially in the "bottoms," or low swampy regions bordering on the rivers, from the heat and quantity of decaying vegetation, is impregnated with malarious miasma, producing ultimately, at New Orleans, the most virulent type of yellow fever.

(242.) The great northern plain of the old continent occupies an area of between 4,000,000 and 5,000,000 of square miles. From Belgium, through Holland (much of which lies actually below high-water mark), and North Germany and Prussia to the Vistula, we find a cultivated though sandy soil, with large tracts of heath interspersed, and presenting over all the area bordering on the North Sea and the Baltic, the phenomenon of granitic and syenitic blocks scattered in abundance, not uniformly, but in patches here and there, and referable as their origin to the older igneous rocks of the Scandinavian mountains—a phenomenon first brought into prominent notice by Deluc (*Geol. Travels*), and since received as one of the chief supports of the "Glacier Theory."

(243.) At the Vistula may be said to commence the great Sarmatian, or East European plain, which, with exception of the Valdai Hills, extends from the Baltic to the Black and Caspian Seas, and to the Ural Mountains. It may be divided into three regions—a northern, extending along the coasts of the Gulf of Bothnia and Finland, and the White Sea, and including all the region north of the Valdai to the middle of the Ural. Its climate, soil, and swampy character admit but little cultivation, and only a scanty growth of trees—chiefly birch and fir;

while much of the ground is covered with a species of moss or peat called tundra, which reappears over all the northern area of the Asiatic continent where similar conditions prevail. The middle region of Russia is fertile and well watered, with a climate of only moderate severity, a soil of rich alluvial mould, admitting of high culture, a surface gently undulated, and extensive forests of pine, birch, and deciduous trees. This region is surrounded, to the south, by sandy, barren, and often saline *steppes*, which commence at the Dnieper river and extend along the Sea of Azof, including all the country north and east of the Caspian, and connect themselves by the desert of Kharesm, and the steppes of Kirghiz, Ishim and Baraba, with the great Siberian plain north of the Altai. Nothing can exceed the dreary monotony of these steppes, wandered over by nomadic tribes—grassy indeed, and covered with flowering shrubs, tulips, and rosaceous plants for a few months, but parched by the sun and drying winds in summer, while in winter they become howling and shelterless wastes of snow. Some of these Asiatic steppes are covered with succulent ever-green articulated soda plants; in some, on the borders of the great salt districts, the salsola assumes a rich crimson or orange colour, giving a peculiar glow to the distant plains on the borders of salt lakes, while the plains themselves glisten with flakes of exuded salt, like fresh-fallen snow.

(244.) In North Siberia winter reigns supreme. Beyond the 62d parallel corn does not ripen, and beyond this the fir forests intermix with and gradually give place to the tundra, among the swamps of which, buried or half buried, mammoth tusks, or rather those of the Elephas Primigenius (art. 221), occur so frequently as to constitute a very valuable article of search and commerce. These tusks, together with the skeletons of these and several other animals, form immense local accumulations, which become richer and more extensive the further one advances north. They are found in greatest abundance in New Siberia, and in the islands which fringe the borders of the continent between the Lena and the Indijirka, especially Lachow or Liakhoff, which is represented as almost wholly consisting of such remains. Hundreds of poods (40 lbs. Eng.) are thence extracted annually for exportation. They are frequent also in Kamschatka.

(245.) The great alluvial plain of China occupies upwards of 200,000 square miles, and is the seat of the oldest civilization of which we have any authentic account (sacred history, of course, excepted), and of actually the most numerous and condensed population anywhere to be found on the globe. It is for the most part a vast plain, crossed in all directions and irrigated by canals, devoted wholly to culture, of which rice forms the principal article of produce, while the low hills afford tea to so vast an extent, that between 60 and 70 millions of pounds are imported annually into Britain alone.

(246.) The principal southern slope of the Asiatic continent is that of Central and Lower India, or the great plain of the Ganges and Indus, of which all the lower part is alluvial and of wonderful productiveness, at least under the influence of artificial irrigation. What may be called the Plain extends almost to the foot of the Himalayas, the slope of the Ganges (art 196) being only one foot in 15,840. Benares, distant from Calcutta between 500 and 600 miles along the river, is only 270 feet above the sea. The valley of the Indus is sandy and barren, unless where artificially irrigated. On the east of the river, in its lower part, the plains expand into a sandy and desert district of many square degrees in extent, called the Thur, which is so low near the mouth of the river as to be overflowed by the tide, and incapable of cultivation. The Runn of Cutch, an extensive region, the coast line of which is laid down very differently in different maps, adjacent to the delta of the Indus, is supposed to be subject to frequent alterations of level from geological causes, one of which is on record so late as 1819, by which a considerable extent of what before was land was submerged, and a portion of the internal navigation of the country, which had been closed for centuries, was again rendered practicable, while another part adjoining was permanently elevated.

(247.) Of *Climates*.—What we term the climate of a country is the result of all the meteorological influences to which it is habitually subject, and includes not merely the mean amount or intensity of the meteorological elements, but their distribution over the several months of the year and the several hours of the day. The mode of ascertaining exactly the mean annual amount and the laws of periodical fluctuation of these elements separately considered, of calculating them numerically, and representing the final conclusions to the eye by curves laid down in charts, is abundantly explained in our article on METEOROLOGY.

(248.) The elements which go to constitute our notions of climate, are chiefly temperature and moisture. These, indeed, are by no means the sole causes which affect vegetable and animal life. There are other elements, such as the greater or less habitual violence of the wind; solar light, as a vital stimulus, apart from the heat which accompanies it, and which stands in relation to the greater or less habitual obscuration of the sky by cloud; electrical manifestations; and lastly, barometric pressure, as a measure of the *quantity* of air taken up at each inspiration of an animal, or present to a given surface of leaf in a plant, an element whose importance has been rather overlooked. All these constitute items in our estimate of a climate, and each of them, when present in a high degree, gives it a marked character. But temperature and moisture exercise so preponderating an influence, that, in a general view of climates, we may limit ourselves to their consideration, regarding the others as subordinate, and their excess or deficiency as incidental and special causes of variety. Even thus limited, the number of cases which arise by simple combination of high, low, and medium annual averages, and of great and small annual and diurnal fluctuation (each of which exists as a reality over some more or less extensive region of the earth's surface), would become embarrassing. The diurnal fluctuations, however, assume importance only in two cases,—1st, When, as in the circumpolar regions, the year is divided into two very unequally illuminated seasons, and where the diurnal fluctuation in effect merges in the annual; and 2dly, at very great elevations in or near the tropics, as in the Bolivian and Thibetan plateaus, where, owing to radiation in clear sky and rarefied air, the difference of night and day temperature becomes excessive, and where the nightly dews perform the office of rain, and supply its place.

(249.) Elevation above the sea-level exercises a peculiar influence on all the elements of climate. As we rise above that level, the temperature sinks at the rate of a degree for every 350 feet of elevation, and of course the mean temperature of the year is affected at an elevated station to that full extent. Thus it happens that in ascending a mountain from the sea-level to the limit of perpetual snow, we pass through the same series of climates, so far as temperature is concerned, which we should do by travelling from the same station to the polar regions of the globe; and in a country where very great differences of level exist, we find every variety of climate arranged in zones according to the altitude, and characterized by the vegetable productions appropriate to their

habitual temperatures. The amount of rain, too, is very greatly dependent on the level of *the soil*. It increases on mountain slopes exposed to moist winds, up to a certain level, different in different geographical districts, and then diminishes, in virtue of the general law of hygrometric siccity in the upper regions of the atmosphere. At great elevations, too, the force and direction of winds, and the amount of cloud, are often very different from what prevails below. Thus, on the Peak of Teneriffe, the summer wind is habitually S.W., and the sky almost always cloudless, while at the foot of the mountain the N.E. trade prevails, and a dense stratum of cloud covers all the surrounding ocean. Not only the amount, too, but the *quality* of solar radiation is affected. The chemical rays of the spectrum are powerfully absorbed in passing through the atmosphere, and the effect of their greater abundance aloft is shewn in the superior brilliancy of colour in the flowers of Alpine regions. Nor can the difference of density in the air itself be devoid of influence either on plants or animals. Dr Muhry, in a work of great merit recently published (*Klimatologische-Untersuchungen*, Leipzig, 1858), informs us, for instance, that among the inhabitants of very elevated regions, pulmonary phthisis is a disease unknown.

(250.) *Distribution of Temperature.*—The law of distribution of heat over the earth's surface is represented to the eye by the systems of Isothermal, Isothĕral, and Isocheimōnal lines described in METEOROLOGY, art. 149, which severally connect those points of the globe which have equal *mean annual*, *mean summer*, and *mean winter* temperatures; the important points as regards climates being, that these several sets of lines are not coincident (except locally and accidentally), so that, even as regards temperature alone, it is rare to find two places that have the same annual average, and also the same distribution of heat in the several months. How this may affect climate will be obvious, if we consider the cases of two places of the same mean or average temperature, which in the one is maintained nearly uniform throughout the year, while in the other a burning summer is compensated by a rigorous winter.

(251.) If the sea covered the whole earth, or if it were uniformly occupied by land, there would prevail in all regions a climate dependent wholly on the latitude of the place, and on the sun's declination at different seasons. What would be the exact mean temperatures, and the exact annual fluctuations corresponding to each latitude in either case, it is needless to inquire; but it is certain they would be very different in the two cases, by reason of the different relations of land and water to heat. But if we take an average of the actual mean temperatures corresponding to each degree of latitude all round the globe, we shall obtain a mean law under the actual state of things which may be called the *normal law* of mean temperature, and which is not very inaptly represented by the formula $41^\circ{\cdot}8 + 39^\circ{\cdot}7 \times \cos.$ (twice latitude); and by attaching to each parallel of latitude a number expressing the temperature computed from this, there would arise a system of normal isothermic lines. The actual system, as may be seen in our plate CLXXIII., vol. vi., deviates much from this regularity; and the manner of this deviation, which constitutes the first and greatest basis of distinction between the heat-climates of the globe, is not a little remarkable.

(252.) Mr Dove has constructed a chart, in which places which have the same excess above, or defect below, the normal mean temperature, are connected by lines which he terms Isabnormal lines—the order of the lines corresponding to the amount of deviation; and on an inspection of this chart, three very prominent features are apparent. 1*st*, That the lines which limit the regions into which the globe becomes thus divided, or the lines of normal temperature, do not, as would at first sight appear probable (and as would be the case had the earth no rotation on its axis), follow meridional directions, but are *systematically* oblique to the equator, being directed from N.W. to S.E. 2*d*, That they divide the globe into two hot and two cold regions, in the form of broad belts, whose medial lines have a generally similar direction, and which, so far from being emphatically regions of much land and of much water, run systematically *across the great masses of both*. Thus, the principal hot region includes nearly all Australia, the Indian Ocean, India, and all south-west Asia and east Africa, Europe, and the North Atlantic; and the principal cold one, the western half of South America, the south-west, equatorial, and north-east Pacific, and all east Asia, from Cochin-China northwards. The other hot region includes the S.W. Atlantic, all the eastern side of South America, and the Caribbean Sea, and (after a small interruption or suspension) springs over to the other side of the American continent, to reappear in north-west America and the North Pacific, while the other cold one takes in west Africa, the south-east and equatorial Atlantic, and all the east side of North America. 3*dly*, That these regions, so distributed, bear evident reference both to the situation of the coast-lines of the great land-masses and to the trade-winds. To make our meaning clear, we will suppose the globe divided, not by the true geographical equator, but by the tropic of Cancer (which may be considered as the medial parallel of the land, and to which, rather than to the true equator, the sources of heat-disturbance have reference). Land lying to the north of this being considered as *northern*, and to the south, *southern*, it appears that, in the *northern* masses, the regions in which the temperature is in excess occupy their western, and in the *southern* their eastern coasts, while the reverse rule holds good for those in which it is deficient. A comparison of this rule with what is above stated, in reference to the regions themselves, will verify its enunciation in these terms.

(253.) So stated, the cause is not far to seek, and it is one of a generality commensurate to that of the observed facts. Referring to our account of the oceanic currents as traced in arts. 51-65, we see—That the hot water of the equatorial currents in *all* the seas is dashed against the *eastern coasts* of *southern masses*, while the cold supplying currents from the southern ocean, sweep along the west sides of those masses; that, in its northern circulation, the hot water is carried across the great oceans north-eastward, to strike on the west sides of the *northern masses*, while cold return-currents flow down their east sides; and that, in its southern circulation, the hot water is thrown off southwards by the eastern coasts of the southern masses. The only point which remains unexplained in the view here presented, is a small breach of continuity in the hot region between the Caribbean Sea and the north-west coast of North America, where the two cold regions run together across it over Mexico. It should also be observed, 1*st*, That though the immediate influence of these causes is greatest on the coasts, their prevalence extends deep into the continents, being propagated onwards by the winds; and, 2*dly*, That the inequality now in question is independent of another law more general still in its enunciation, though of smaller influence, viz., that the whole northern hemisphere is, on a general average, $3\frac{1}{2}^\circ$ warmer than the whole southern, as containing more land to be heated by the sun when north of the equator.

(254.) Within each of these four great geographical regions the mean temperature increases or decreases (ac-

cording to the character of the region) from the borders towards the middle, and each of them has within it certain poles or foci (which may be called poles of relative warmth and cold), at which the peculiar character of the region is most conspicuous. The principal, or Europo-African Hot Region, for instance, is separated from the cold region to the west by a normal line running in an undulating curve from Baffin's Bay to the Cape of Good Hope, and from that, on the east, by one commencing opposite Nova Zembla, dividing Europe from Asia almost conterminously as far as the Caspian Sea, and then passing off south-eastward to the Philippine Islands, and across the South Pacific. Within this area the north pole of relative warmth occurs almost precisely on the Arctic circle in long. 4° east, between Iceland and the Norwegian coast (full in the sweep of the Gulf-stream drift). At this point the mean annual temperature is *fully* 20° *above* that which would be due to its latitude on the supposition of a normal climate, and in receding from this point as a focus on all sides, the excess of mean temperature decreases so as to mark out a series of ovals, the interior of each of which is *relatively* warmer than those outside. Thus, the oval of 18° excess just grazes the North Cape; that of 12° takes in the whole coast of Norway and the north of Scotland; that of 9° the whole of Britain, the French coast (including Paris), Holland, Denmark, the greater part of the Baltic, and the Gulfs of Bothnia and Finland (just excluding Petersburg), up to Archangel; and, lastly, the oval of 4° excess cuts the coast of Greenland at Cape Farewell, passes nearly through Madrid and Algiers, crosses Sicily, Calabria, Hungary, and Russia, and includes all the capitals of Europe. In the southern hemisphere there is no very prominent focus of this kind, but a point in 30° S. in the meridian of Madagascar, just where the warm currents of the Indian Ocean unite after rounding that island on their way to the Cape, offers a feeble and rudimentary one.

(255.) The east Asiatic cold region has a strongly marked focus of relative cold at Yakutsk, where the deficiency of annual temperature amounts to −15°, and round which, in all directions, this deficiency decreases, over a series of ovals, of which that of −7° includes the whole of north-east Siberia, from the mouth of the Jenesei to that of the Kolyma, and descends south through the Baikal Lake and Ochotzk into Chinese Tartary. Continued south across the Pacific, this region, as above stated, enters upon the west coast of South America. Off that coast, at 300 or 400 miles south-west of Lima, in lat. 15° S., long. 82° W., occurs another very well marked focus of the same character, but less intense, the deficit of temperature being only 9°. The oval of −7° about this focus enters on the South American coast, and includes Lima, which thus (owing to the refrigerating power of Humboldt's current, to which this focus is clearly referable) enjoys a far cooler climate than its proximity to the equator would otherwise entail on it. In the Pacific, in lat. 20° N., long. 225° E., is also the central point of a small subordinate oval of relative cold (of about −2°), a feature which we shall have occasion to notice in another part of our subject.

(256.) The next, which may be called the American Warm Region, has its northern focus in the Pacific, in lat. 56° N., long. 141° W., not far from Sitka, in Russian America. It is far less strongly developed than the Atlantic focus of a similar character, its excess of temperature being +9°, and its influence on the continent of America is very limited, but nevertheless sufficient to afford the whole coast, from Vancouver's Island northwards to the Aliaskan peninsula, a climate 7° warmer than the normal one, an advantage equivalent to that of a transfer from North Iceland to New Halifax, and which forms a most important consideration as regards the future fortunes of the new colonies of Vancouver's Island and New Caledonia. In the southern hemisphere we find no marked indication of a corresponding focus, which is perhaps owing to a deficiency of the requisite observations. Owing, however, to the large portion of this hemisphere occupied by sea, the warmer areas by no means stand in so strong a contrast to the colder, as in the other.

(257.) The last of these regions we have to notice is the American cold region. It is very strongly marked, and distinctly so even in its prolongation into the southern hemisphere. In the northern continent it has a focus of relative cold in lat. 65° N., long. 96° W., near Wager Inlet, at the north-east corner of Hudson's Bay, whose intensity (−13°) nearly equals that of the Siberian focus, and whose influence is very great over the whole north-east portion of the continent, affecting Quebec with a mean deficit of 6½° (equivalent to a transfer from the south of England to the Orkneys), and even New York by one of 4°. In the southern hemisphere there is a sufficiently well-marked focus of the same character, and which bears nearly the same relation to the south-east coast of Africa that the focus off Lima does to South America, being only rather less intense (−6°), and not extending its influence very materially on the continent. It is, however, precisely on the spot where, from the indraft of cold water from the southern ocean, we should expect to find it.

(258.) The extreme cold of north-east America is evidently referable to the delivery of the whole circulating water of the Arctic Ocean, together with all which is introduced through Behring's Straits along its coast, and through the intricacies of Baffin's and Hudson's Bays, and the channels leading into them, deep into the continent, and among its outlying appendages. That of Siberia, and east Asia in general, is not so obvious a result of oceanic causes. It arises rather from the extension across Asia of the lofty mountain-chains between the 30th and 40th parallel, which increase the rigour of winter to the countries north of them, by intercepting the south-west anti-trade, and obliging it to deposit its moisture on their summits, thus draining it of its latent heat, which would otherwise be given out to the plains beyond in rain or snow.

(259.) The deviations of the isothĕral and isocheimŏnal lines from each other, and from the annual isothermals, or the exaggerations of the annual fluctuation of temperature at any place, refer themselves quite as obviously to a prevalence in its neighbourhood of great tracts of land or of water, and are, in fact, where not accounted for by special and local causes, no other than thermic expressions of its more or less approximation to a "continental" or "insular" situation. (See METEOROLOGY, art. 40.) As instances of purely insular climates, we may take those of the Azores, where the difference of mean summer and winter temperatures is only 8°; at Bermuda, 13°; in the Friendly Isles only 2°; at St Helena, 9°. As examples of continental ones, we find at Prague a difference of 29°; at Tiflis, 44°; at Astrachan, 61°; at Orenburg, 63°; and at Yakutsk no less than 102°, the *mean* winter temperature there being −40°, and the summer +62°. In the interior of North America we find this difference carried not quite to so great an extent, but still far beyond what prevails over the whole of Europe, amounting to 44° at Philadelphia and Washington, and to 54° at Fort Snelling, in latitude 44° north, and longitude 94° west; the winter temperature being −14°, and the summer +68°; while at Florence, in the

same latitude, the corresponding temperatures are 41° and 74°.

(260.) The difference between land and sea climates in this respect falls upon the general average of the whole earth, the northern hemisphere having so great a preponderance of land. By comparing the results of registers, in positions adapted for the purpose, Mr Dove has arrived at the remarkable conclusions that the mean summer temperature (July) in the whole northern hemisphere is 70°·9, and in the southern (January) 59°·5—while the winter means for the two hemispheres (respectively January and July) are 48°·9 and 53°·6—giving to the whole earth an average surface temperature of 58°·25, with an average excess of 8° in July, a kind of general summer, due to the cause above mentioned, and which would be even more influential were it not partly counteracted by the greater proximity of the sun to the earth in January.

(261.) Mr Dove calculates the *mean* temperature of the whole terrestrial equator at 79°·8, and that of the north pole at +2°·2, and the mean summer and winter temperatures at the poles at +30°·6 and −58°·6. It hardly need be observed that the extremes of absolute temperature over the globe vary within much wider limits. Sir C. Napier records a temperature of +132° in the shade in Scinde in June. A *midnight* temperature of 108° has been observed in the Northern Circars of India (Thomson). On the other hand Dr Kane records −67° in January and February at Rensellaer Bay (78° 38′ N. lat., 71° 41′ E. long). Captain Back, at Fort Reliance, observed −70°, and Gmelin, at Kiringa, in Siberia, has recorded an observation of −120° (Thomson). *The difference of the extremes exceeds by* 72° *the whole range of Fahrenheit's scale from zero to the boiling point of water.*

(262.) The isotherm 32° F. limits the region round the pole at which (below a few feet from the surface) the soil may be expected to be found habitually frozen. The course of this isotherm, as drawn in K. Johnston's Physical Atlas, is as follows:—

[illegible]	[illegible]	[illegible]	Latitude N	Longitude	Latitude N
Degrees	Degrees	Degrees	Degrees	Degrees	Degrees.
0	71½	120	49½	240	56½
30	70	150	53	270	50½
60	60	180	58	300	53
90	51¾	210	62¾	330	64

(263.) The line descends then, in the two continents, to nearly equal latitudes (50°). The places where this takes place are at Irkutsk, on the Baikal Lake, and at the southern extremity of Hudson's Bay. The latitude is about that of Cornwall, whose mean temperature is 52°. At Yakutsk the soil is frozen to a depth of upwards of 630 feet, and would be so no doubt to a much greater depth, but that the prevalence of hot springs about that region (Atkinson) indicates a subterranean source of warmth. Throughout Russia and Siberia, if we put confidence in the conclusions of M. Kupffer, there would seem to exist some internal cause of disturbance in the temperature of *the soil*, as distinct from the mean temperature of the air above it.

(264.) The line of maximum mean temperature, or the thermic equator, by no means coincides with the true equator. Over a great part of the Pacific, indeed, and in Mid-Atlantic, it does so pretty nearly; but in those longitudes which include the great masses of land, it deviates northward, crossing South America in about 5° north latitude; and in the 180 degrees of longitude, which include all the eastern world, from the west of Africa to the east of Australia, it approximates much more nearly to a great circle, inclined at an angle of 15° to the equator, and crossing east Africa, Arabia, and the peninsula of India nearly in that latitude north.

(265.) *Distribution of Moisture.*—In considering this branch of our subject, we must distinguish between hygrometrical moisture, which exists as vapour in the atmosphere, and is ready to be deposited in dew at night, and that which falls in rain or snow. The former is always present to a considerable extent, at least within a few hundred feet of the sea-level, and in its average amount (under that condition) is regulated in great measure by the mean temperature of the place. To such an extent is this the case, that, with the exception of four places (Hobartown, Madrid, Tiflis, and Washington, the three last of which are obviously exceptional, and influenced by very special and local causes),[1] the mean pressure of aqueous vapour at all the stations (21 in number) in all latitudes, set down in the list of carefully determined ones, at the end of our article METEOROLOGY, will be found to be represented by the formula—

$$0{\cdot}067436 \text{ in.} \times (1{\cdot}032075)^{t}$$

(Where t is the mean annual temperature in degrees of Fahrenheit), within limits hardly exceeding the difference between the mean results of successive years for each. It increases rapidly therefore in approaching the equator from the poles. The *relative humidity* of the air, however, or the proportion of its vapour to that of saturation, on which depends what is commonly called the *moisture or dryness* of the air, or its evaporating power, is much less dependent on local situation; and, with certain remarkable exceptions, may be taken, on a general average, as about 0·75, or three-quarters of complete saturation at the mean temperature.

(266.) The laws which regulate the distribution of rain (including snow, hail, etc.) over the globe are more complex, and its amount, both average and occasional, subject to much greater local deviations from a normal quantity depending on latitude than either heat or hygrometric moisture. Generally speaking, the average rain-fall of the year is greatest at the equator, and diminishes rapidly, but very far from regularly, in approaching either pole. The average annual rain-fall over the whole globe has been roughly estimated at 60 inches, or 5 feet in depth—between the tropics, 96, and in the temperate zones, 35; that is to say, 37 for the northern hemisphere, and 33 for the southern. In high latitudes, where unaffected by abnormal causes, it is much less,—thus we find an average of only 13 at Uleaborg, and 17 for Petersburg.[2] When we consider, however, that regions of several millions of square miles in extent exist not far from the tropics, in which the average of rain is *nil*, while in others it amounts to 200, 300, and even 600 inches, we see that it is an element to baffle all exact calculation, and that all that can be done is to indicate the sort of local conditions favourable or unfavourable to a high average.

(267.) The favourable circumstances, besides proximity to the equator, are,—1*st*, and within certain limits, elevation above the sea-level. Thus we find for the non-mountainous districts of Europe an average of 23 inches, and for the mountainous ones 42. The influence of this condition, however, diminishes beyond a certain height,

[1] Philadelphia is normal.

[2] These particulars, as well as many of the data, and much of the general statements which follow, are taken (or concluded) from Mr Keith Johnston's excellent synopsis of this subject.—*Physical Atlas.*

which is not the same in all countries, varying from 2000 to 7000 or 8000 feet. Nor is it absolute, but depends much on exposure and on the general configuration of the soil. Thus an elevated and extensive table-land, like the interior of Spain, receives less rain than the plains around it, the current of vapour-bearing wind being tossed up into a higher region after travelling up its slopes, and in so rising, precipitating its moisture. To give the rise of level its full power, a slope increasing in steepness, and facing the moist-wind (whichever that may be), is requisite. A table-land surrounded by mountain ridges overtopping it (such as Thibet, Bolivia, and Utah), is necessarily arid.

(268.) *2dly*, Exposure on the sea-coast to warm winds blowing from the sea. These, in the temperate zones, are the anti-trades. West coasts, then, are rainy in these zones, in comparison with east. The mean annual rain on the west coast of England and Scotland is 45 inches, according to Mr Keith Johnston, while the average for the east coast is only 27·4 inches. This is among the most prominent and general influences. If the west coast be a high one, and especially if the sea adjacent to it be habitually warm, it is carried to a maximum. Thus we find along the north-west coast of America, from Sitka to Vancouver's Island, and along our own west coasts and that of Scandinavia, an annual amount of rain far beyond that which might be expected from the latitude. The average for Sitka (lat. 58°) and for Bergen (lat. 60°) are each of them 88 inches, which, for so high a latitude, is enormous. Now, both these stations are in close proximity to the northern "foci of maximum relative warmth," which is situated at sea to the westward in either case (arts. 254, 256). The west coast of Patagonia is also remarkable for deluges of rain, but being in the immediate proximity of the principal focus of maximum relative *cold* in that hemisphere, the rainfall is chiefly confined to the winter months, whereas in the northern stations it occurs indifferently at all seasons.

(269.) Between the tropics the rains are periodical, and closely accompany the progress of the vertical sun. In India, however, it is the monsoon which blows *on* the coast, and not the position of the sun, which determines the rainy season. This sets in on east coasts with the north-east monsoon (April to October), and on west with the south-west (October to February). The region of the monsoons extends over China, and there it is the north-east monsoon (that which blows over the north-west Pacific) which brings the rains.

(270.) Influences unfavourable to rain are—*1st*, Situation under the lee of high land intercepting the vaporiferous winds. Exposure on east coasts in the temperate zones, and on coasts remote from the monsoon in India, is one form of this condition. It is carried to its extreme when immense and lofty mountain-chains, rising through half the atmosphere of air, and much more than half that of vapour, intercepts the latter in its progress towards them, and effectually drains the winds of their moisture. In such cases, when the lee-country is at a comparatively much lower level, the descending wind, having parted with its vapour, and acquiring warmth by condensation, becomes arid and parching. *2dly*, Exposure to the indraft of trade-winds coming in from a *colder* region. This influence is carried to a maximum when such winds, to arrive at the place, have to traverse much land and little sea, the supply of moisture being less. Even in the open ocean, as we have seen (art. 20), little or no rain falls within the sweep of the trades. *3dly*, Absence of vegetation in warm climates, and especially of trees. This is no doubt one of the reasons of the extreme aridity of the interior of Spain. The hatred of a Spaniard towards a tree is proverbial. Many districts in France have been materially injured in respect of climate by denudation (Earl of Lovelace *on Climate, &c.*), and, on the other hand, rain has become more frequent in Egypt since the more vigorous cultivation of the palm-tree. A sandy or rocky soil is no less influential in producing aridity.

(271.) *Rainless Districts.*—Commencing within a small distance of the coast of Morocco, and including all the north of Africa (except Tunis and Algeria), Syria, the northern half of Arabia as far as the 20th degree of latitude, and almost the whole of Persia, extends a zone of an average breadth of 900 geographical miles, in which rain is altogether absent, or of very unusual occurrence. With a narrow interruption, where the chain of the Himalaya passes into that of the Hindu Kho, and which includes Afghanistan and the Upper Punjab, this zone is prolonged north-east through Thibet, Upper Tartary, and into Mongolia, expanding somewhat in breadth, under the name of the Deserts of Gobi and Shamo. (In Africa it is known as the Sahara, and extends southward, when widest, nearly to the 15th parallel.) It is thus broken into two great rainless districts, the one comprising about three millions, and the other nearly two millions [1] of square miles, which exist as such under widely different conditions, both geographical and meteorological, the separation between them being strongly indicative of this diversity.

(272.) *Deserts of Gobi and Shamo.*—The aridity of this region is of very easy explanation. It unites in perfection all the conditions of dryness. It is fully within the sweep of the north-east winds drawing in from Siberia towards the sun, when vertical over the burning plains of Hindostan, with an immense region of land to windward. It is sandy or rocky, and treeless; and it is completely cut off from receiving any rain from the anti-trades in the winter half of the year by the barrier of the Himalaya.

(273.) *Deserts of Africa, Arabia, Syria, and Persia.*—I. During the months when the sun is north of the equator, the whole of the region occupied by these deserts is within the sweep of the N. E. trades, which, it will be borne in mind, extend over continents to a far wider range from the equator than at sea; both because the medial line of heat follows the sun more closely, and therefore oscillates within wider limits of latitude; and because the heat itself on and adjoining to that medial line is greater. These winds, in arriving at Arabia, Syria, and Persia, have travelled almost entirely over land. Those which arrive in Africa, it is true, have traversed the Mediterranean; but this is a narrow sea; and we have already seen that even the ocean cannot supply vapour enough to saturate the continually-increasing thirst of these winds. II. When the sun is south of the equator these regions lie within the district of the anti-trades, and being under no intercepting influence, might be expected to receive rain. But the winds can only deliver what they have taken up and not re-deposited. Now, if we trace (as in the annexed figure) the course of any parcel of air arriving from any part of the dry region at the medial line of heat (indicated at its greatest southern limit by the dotted line) as a surface or trade-wind (following, that is, a parabolic or hyperbolic curve having its vertex on the equator), indicated by ‡ and returning as an upper current along *the same track reversed* ‡, until it shall return to the surface as an anti-trade, we shall find it to lie wholly, or almost wholly, over intertropical land, and that land hot and dry, for its moisture has been *continually*

[1] By a rough measurement, as laid down in K. Johnston's *Physical Atlas* (allowing for the projections). As usually stated, the areas are much less. Humboldt made the Desert of Gobi, with Thibet, only 549,000 square miles.

swept upwards towards the hottest line in the southward progress of that line, and continually discharged upon it in

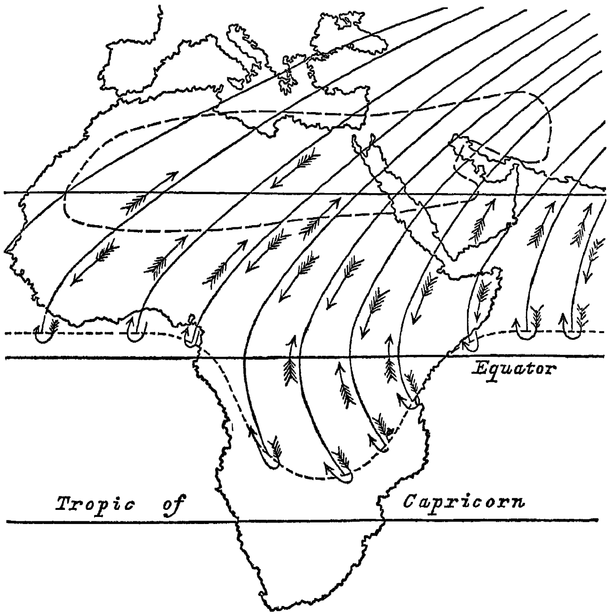

Fig. 1

torrential rains, much more copious, and therefore more exhausting, than the equatorial rains at sea, by reason of the greater elevation attained under the influence of more intense heat. The consideration of the figure will sufficiently explain any point left unsaid. The reader will observe that we decline adopting the doctrine recently propounded of a systematic crossing of the south-east and north-east trades at the medial line. In so doing we are no way disturbed by the phenomenon of infusorial dust of South American origin which occasionally falls on the north-east of Africa. Such dust might be taken up by winds tracing in inter-tropical South America precisely the same parabolic courses as these in Africa, and carried in their return northward as an upper current across the Atlantic. A good portion of "South America" too—all the sultry Llanos of the Orinoco, in which much infusorial dust, the dried residuum of the inundations, might be produced and whirled aloft, lies north of the equator.

(274.) The west coast of Peru and Bolivia, as far as the 30th parallel, is rainless, as is also very nearly so the plateau of Mexico and the west coast of Guatemala. These lie within the region of the trades, and though these sweep over sea as regards Mexico, any rains they may bring are discharged on the eastern slopes of the mountains which receive them. A similar cause, reversed in the direction of its influence, deprives the eastern side of extra-tropical South America of rain, which the Patagonian Andes almost completely intercept, as brought from the Pacific by the north-west anti-trades. California, Utah, and the countries under the lee of the Chippewyan mountains, are, in like manner, hindered of their due supply from the south-west anti-trades, which is discharged on the western slopes of the coast ranges.

(275.) South Africa, though arid, yet as it receives both the trades and the anti-trades from over wide oceans, is not condemned to that extreme of siccity which characterizes its northern region. The west coast receives a great deal of rain from winds sweeping over the warm water of the Mozambique current, drawn inland by the proximity of the heated interior of the continent, and discharging their moisture on the coast ranges of Zanzibar and Mozambique.

(276.) Snow never falls at the sea-level between the tropics. Canton, just on the northern tropic, has been occasionally astonished by a snow fall. In the southern hemisphere the limit is more remote from the equator—Sydney (lat. 36° S.) and the southern parts of the Cape Colony, as far as the 32d parallel, lie within its occasional range.[1] In the north Atlantic it hardly attains so low as 45° of latitude.

(277.) The transition from an inter- to an extra-tropical climate, as regards the fall of rain, is characterized by a very marked change in the season of the rains. In the former, as we have seen, torrential rains accompany the sun in its approach to the zenith. In the latter, on the contrary, the regions adjacent to the tropics are visited exclusively, or chiefly, by rain in the winter months. The reason is obvious. In the former case the rains are those which fall on the first elevation of the vapours into the higher region of the atmosphere, and therefore occur vertically, or nearly so, over the place where that happens. In the latter, they are the *first rains given out by the residual vapour on the descent of the upper current to the surface* as an anti-trade wind, and are, so, periodical in another sense, owing to the fluctuation of the limit between the trades and anti-trades. In open ocean, under the equator, or rather from 4° to 9° north, there is a zone in which it rains heavily, and almost daily, in the afternoon hours, the rains being accompanied with frequent and violent electric discharges, while the nights are serene and cloudless. In the higher atmosphere, between the levels of the upper and under current, occurs a calm stratum, which, over the sea, is almost always uniformly and densely clouded.

(278.) *Distribution of Thunder-Storms, Hurricanes, and Earthquakes.*—The explanation of these phenomena, as physical facts, belongs to the departments of METEOROLOGY and GEOLOGY as bodies of science. Their distribution and greater or less intensity and frequency in different regions of the earth, with reference to the local conditions and peculiarities on which these depend, however, form part of our present subject. As electricity is accumulated during the evaporation, and discharged in lightning during the rapid and copious condensation of moisture, we should expect to find thunder-storms most frequent in those regions where, owing to any general or special cause, the condensation of vapour is frequent and sudden, and least so where moisture is most copiously and continually abstracted from the surface by evaporation, with but little return in rain. And such is the case, for it is observed that in those parts of the ocean over which the trade-winds sweep, thunder-storms are very unfrequent, while in the zone of the equatorial rains, from 4° to 9° north latitude, where the first and most copious discharge of the up-cast vapour takes place, and where the clouds form rapidly, and hurry to their resolution at regular hours of the day in rain, electric discharges are exceedingly frequent and violent. So also the setting in of the rainy monsoon, in the monsoon countries, is ushered in with violent thunder-storms, and so in certain localities, where, during certain seasons, and at regular hours of the day, clouds collect and rain falls copiously (as in the mountainous parts of Jamaica, and in certain valleys leading off from the Lake of Como in Italy), thunder-storms occur daily, during the hottest season.

(279.) In the Polar regions, both arctic and antarctic, thunder-storms are of very rare occurrence, a sufficiently

[1] On the continent of America it has been known to fall at Buenos Ayres (33° S.)—Ed. *Phil. Trans.* vi. 387.

copious supply and sudden condensation of vapour being wanting. M. Geisecke, who resided six years in Greenland, only heard thunder once (Mrs Somerville). Thunderstorms, too, are unknown in the rainless districts of Peru and in California (Gibson), under the lee of the coast-ranges of mountains, which, at the same time that they condense the clouds, attract and carry off the atmospheric electricity. Generally speaking, they are more frequent on mountains than on plains. About forty per annum are reckoned to occur in Greece and Italy, and about twenty-four on the coasts of the Atlantic and in Germany (Mrs Somerville). In the United States they are more frequent and fatal than in Europe.

(280.) Violent gales of wind, amounting to what may be called hurricanes, occur pretty generally everywhere except on the equatorial seas; but in the Steppes, in the interior of Asia, and in the Siberian plains, at the foot of the Altai, as well as among those and the Tangnou mountains, as described by Mr Atkinson, they appear to be singularly frequent and furious. The true hurricane, cyclone, or typhoon, however, is restricted to very special regions, and its production (as explained in METEOROLOGY) is the result of conditions requiring the ascent of locally-heated columns of air or vapour, with a free in-draft from all sides. Accordingly, they are limited at sea to those situations where (under the necessary conditions as to latitude) currents of heated water exist. Where (as in the Gulf Stream) the current is limited in breadth by a well-defined boundary, within which the water is very much warmer than the sea on either side, they follow, with what may well be called considerable precision, the general course of the current. In the Indian and China seas they appear in the neighbourhood of the warm currents, but these currents being much more diffuse and ill-defined than in the case of the Gulf Stream, the region over which they prevail is correspondingly ill-defined; and in the China Sea this is still more markedly the case, though bearing a very obvious relation to the warm-water currents skirting the east coasts of Asia.

(281.) Earthquakes, of course, habitually infest countries adjacent to active volcanoes—such as Sicily and Calabria in Europe, and the neighbourhood of the Andes in South America, where they are stated by Humboldt to be so frequent, that their occurrence, unless severe, is no more regarded than that of a shower in Europe. Java, Sumatra, Japan, and the islands of the Eastern Archipelago, are also exceedingly subject to such visitations. But, besides these, there are districts which, for geological regions less apparent, being out of the vicinity of any active volcanic vent, are infested with frequent earthquakes. They may, however, be for the most part traced for an origin to mountain chains in which either unequivocal evidence of long extinct, and therefore possibly still dormant, volcanic power, can be adduced, or which stand out as grand original axes of upheaval. Thus the whole of Upper India, and a large portion of Western India, from the Himalaya to the mouths of the Indus, is very liable to earthquakes, evidently referable to the Himalayan range as an axis of emanation, and proving clearly that the forces which originally upheaved those mountain masses, are still active, though their energy may perhaps be expended in maintaining them at their present elevation. Between 1800 and 1842, no less than 162 earthquakes have been recorded in these districts (K. Johnston). In 1843, 23 were observed, and since that time 4 or 5 annually. In the peninsula of India they seldom occur below 15° N. latitude.

(282.) Traceable to the neighbourhood of volcanoes not quite extinct, or which, within historic times, have shewn signs of activity, we find Greece, Turkey, Asia Minor, Syria, and Palestine, with the district adjacent to Elbruz and the Caspian Sea and the Caucasus. Antioch was the centre of one of the most terrible and destructive earthquakes on record in A.D. 526, and Syria was visited no longer ago than 1837 with an earthquake extending over 4000 or 5000 square miles of country.

(283.) The south-eastern districts of North America, along the ranges of the Appalachian and Alleghany Mountains, are liable to frequent earthquakes. More than a hundred have been noticed in the last two centuries (Keith Johnston), which, to judge from the direction habitually taken by their oscillatory motion (from S.E. to N.W.), would seem to owe their origin to some deep-seated centre of action beneath the line of the great Mexican volcanoes. By one of the more recent of these, the whole valley of the Lower Mississippi was violently agitated, and its levels permanently altered. Lastly, quite beyond all reference to any reasonably distant source of volcanic power, we find a district of very limited extent in the county of Perth, near Comrie, in Scotland, where a year seldom passes without a shock, though never severe enough to do any material damage. In the Cape districts of South Africa, too, still more remote from any such centre of action, slight shocks are far from unfrequent. Generally speaking, what may be called the earthquake belt of Europe is conterminous, or nearly so, with the zone of newer igneous formation and extinct volcanoes, described in art. 127.

(284.) On the other hand, vast regions, chiefly extensive alluvial plains, or the low districts which extend out to great distances from the principal mountain chains, enjoy an immunity from earthquake shocks, as, for instance, America east of the Andes, and the great plains on the north-east of Europe and the north of Asia. Where historical evidence is deficient, we have often proof, from the continued upright position of ancient monuments, both natural and artificial, of the absence of at least any great earthquake since their creation, or since their attaining their present form, and that, too, in situations where such complete exemption could hardly have been expected. Thus in Mexico, on the Mimbre River, near El Paso on the Rio Grande, we find described and figured by Bartlett (*Personal Narrative*, &c), rocks, as in the annexed cut,

Fig 2.

which could not possibly have resisted even a very inconsiderable shock. On the west coast of Greenland (much of which is of volcanic origin) the same conclusion may be drawn from the existence of a remarkable slender pillar of rock 200 feet in height, figured by Dr Kane under the name of Tennyson's Monument. An ancient column in the country bordering on the Indus, said to have been erected by Alexander the Great as the landmark of his Indian conquests, has been in like manner appealed to in favour of an exceptional degree of stability in its site in a region generally much subject to agitation.

Pompey's Pillar affords similar evidence for Egypt during the last eighteen centuries, though its prostrate obelisks testify no less distinctly to earlier concussions. The Pierre Botte, in the isle of Mauritius, offers a similar testimony. From the immense weight and singularly slender support of the block on its summit (perched on a pillar of rock 1500 feet above the sea), it must have been precipitated by a very moderate shock given to its base.

(285.) *Terrestrial Magnetism.*—This branch of terrestrial physics is treated in considerable detail in the article on MAGNETISM, in a former volume of this work, in connexion with the general subject of that science. We shall here therefore, confine ourselves to a very general coup d'œil of the subject, and to the exposition of the chief outlines of, those facts which regard the distribution of magnetism over the globe, and which are rather of a geographical than a physical nature. In so doing we will suppose the reader to have before him a chart of the world on the Mercator projection, with two polar charts of the arctic and antarctic regions.

(286.) The magnetic elements which observation furnishes are—1*st*, The horizontal direction of the needle, or its "declination" east or west from that of the astronomical meridian of the place of observation, which may be regarded as + or —; the zero corresponding to the absence of any such deviation. 2*dly*, Its dip, or the "inclination" to the horizon, when suspended by its centre of gravity, and allowed freely to take its own position. When the north end of the needle points downwards, the inclination may be regarded as +, when it rests horizontal as 0, and when pointing upwards, as —. 3*dly*, The intensity of the horizontal component of the total directive power of the earth on it; and 4*thly*, That of the vertical component of the same total power. By the relation subsisting between these forces and the geometrical elements above mentioned, any three of them being given, the other may be found, and, moreover, the "total intensity," or the absolute directive power of the earth on the needle, from whose vertical and horizontal resolution the two forces originate. The *declination*, the *inclination*, and the *total intensity*, or simply *the intensity*, are the three primary features which the magnetist regards, whose amount and character in all regions of the globe magnetic charts are constructed to exhibit to the eye, on the same principle as the exhibition of the distribution of heat by a series of isothermic lines. If all the places in which each of these primary elements holds one and the same value be connected on a chart of the world by its appropriate curve, and if a series of such curves be laid down, in which that value is varied by successive steps of 5°, or 10° + and — from 0° for the angular elements, and by successive 10ths or 20ths of the maximum intensity, or of any arbitrary and convenient unit of directive force, we obtain charts respectively of the "Isogonal," "Isoclinal," and "Isodynamic" magnetic lines as they stand related to the configuration of the land and water of the globe, and to its meridians and parallels. The several elements themselves, it should be observed, are attainable by observation, even at sea, with a precision truly marvellous, and little short of that attained by astronomical observation. General Sabine, who has bestowed infinite pains on the collation and discussion of all the recorded observations of voyagers, travellers, and those specially instituted in "Magnetic Surveys," has constructed such charts for the epoch of 1840, which form part of the Physical Atlas of Mr Keith Johnston, from which, and from the introduction to vol. iii. of the Toronto Observations, the following particulars are mainly collected:—

(287.) The globe is divided into two magnetic hemispheres, a northern and southern, in the one of which the needle dips northwards, or the inclination is +, and in the other the reverse. The line dividing these is not precisely a great circle of the globe, but does not deviate very widely from one. It is not coincident, however, with the earth's true terrestrial equator, but inclined to it at an angle of 12°, having its nodes or points of intersection with it, the *ascending* in longitude 3° ±, and the *descending* in 187° ± east of Greenwich. Its principal deviation from a great circle consists in a rather abrupt abnormal excursion from its general course southwards, where it crosses the east coast of South America and runs into the Atlantic.

(288.) Along the whole of this "line of no dip," which is sometimes called the "magnetic equator," the needle, of course, rests horizontally. Receding from it on either side, the dip increases gradually (and, on the whole, not very irregularly in low magnetic latitudes) from 0° up to 90°, which it attains at two points, and *two points only*, which are very commonly designated as the North and South Magnetic Poles. These points have been attained, the northern pretty accurately, the southern nearly, by Sir J. C. Ross in his memorable arctic and antarctic voyages of exploration. The former lies in lat. 70° N., long. 263° E.; the latter in lat. 75° S., long. 154° E. They are, therefore, not diametrically opposite to each other, nor either of them coincident with the geometrical pole of the magnetic equator; and hence arises a want of symmetry in the isoclinal curves, which, however, follow, with some approach to fidelity, a parallel course on both sides to the magnetic equator.

(289.) The globe is also divided into two ideal magnetic hemispheres, by a medial line, or equator of *minimum intensity*; and these hemispheres are, upon the whole, pretty nearly conterminous with those of north and south dip, the medial line being here also not very widely different from a great circle, 12° or 14° inclined to the true equator, and intersecting it in two points, 180° distant in longitude, viz., 32° ± and 212° ± east, for the ascending and descending nodes respectively. And it deserves remark, that in this also the chief abnormal deviation from the general course of the great circle is of the same character, and occurs nearly at the same place, as in the other equator, about the middle of the Atlantic. The intensity is, however, not exactly equal in every part of this line, though always less in it than in any part of the adjacent region north or south of it. The point of absolutely least magnetic intensity on the globe is situate in the mid-Atlantic, somewhere about the parallel of the tropic of Capricorn, its exact position being, from the nature of the case, very difficult to define. The system of isodynamic lines is more complex than that of the isoclinal, and the simplest conception which can be formed of them is, to regard them as the level lines of an ideal model surface, of which the elevations above the sea-level are proportional in every place to the intensity at that place. So defined, this surface will have a channel or valley running round the whole course of the magnetic equator, from which it will ascend on either side, so as to form two great mountain-like protuberances, each occupying one hemisphere. The least magnetic intensity anywhere observed being 0·9 parts of an arbitrary scale, on which the greatest is 2·05, if we suppose the lowest point of the equatorial depression to be 900 feet above the sea-level, the highest culminating point of the whole surface will be 2050. This point is ascertained by the observations of Ross to be situated nearly on the antarctic circle, at about 130° long. E., in Adelie Island. Besides this, the course of the level lines indicates the existence of a second culminating point or pole of maximum intensity, at a still higher southern latitude, and somewhere about the 240th degree of longitude, but which has not yet been approached near

enough to define its exact situation. In the northern hemisphere are also two similar culminating points or maxima, the one in Siberia, rising to 1750, nearly at the point where the river Lena crosses the arctic circle, about the 120th degree of longitude, and the other to 1850 in North America, about 54° N. lat. and 270° E. long. south-west of Hudson's Bay. Between these culminations runs a line of depression, following nearly the course of the meridian, passing through Behring's Straits, and bisecting the Pacific on one side of the globe, and passing out of the Arctic Sea by Spitzbergen, and down the Atlantic on the other.

(290.) Lastly, the globe is again divided (though less definitely) into two magnetic hemispheres, or rather two very unequal compartments, an eastern and a western, by the *line of no declination.* This line (which necessarily passes through both the poles) appears on a Mercator's chart (in which the poles cannot be represented), as two distinct lines, which, were it a meridian, would be at right angles to the equator, and entering it at 180° difference of longitude. Such, however, is not the case; neglecting sinuosities, it assumes the aspect of two oblique lines running from N.W. to S.E., at angles of about 70° with the equator, and dividing it into two unequal arcs of longitude at the 100th and 310th degrees east in the Indian Ocean, south-west of Sumatra, and at the mouth of the Amazon river. Of the compartments so defined, the smaller, which may be termed the western, inasmuch as in every part of it the needle deviates westward from the meridian, includes the north-eastern corners of both North and South America, the whole of the Atlantic, all Europe and Africa, nearly the whole Indian Ocean, and the west of Australia. The other includes, with one exception, all the rest of the world, but that exception is a very remarkable one. Insulated in the midst of its north-western portion, occurs an oval space of an elliptic form, its longer axis following the meridian of 133° E. and its shorter the parallel of 50° N., extending over a large portion of Eastern Siberia (including Yakutsk), half the Sea of Ochotsk, the Sea and Isles of Japan, the Yellow Sea, and the North of China, within which the declination is westerly, and in its central portions exceeds 6° W. This oval is part and parcel of a medial belt of relatively smaller easterly declination which may be traced along the whole course of the easterly compartment, and which leads directly across that small equatorial oval of relative cold spoken of in art. 255, the line of junction holding a similar inclination to the equator, and pointing, with the other features of this system, strongly to an analogy between it and the system of lines marking out the regions of relative warmth and cold there described.

(291.) In middle latitudes of the northern hemisphere, when the sun is *east of the meridian* during the *forenoon*, the needle points more eastward than on the average of the twenty-four hours; when west *also* during the afternoon, more to the westward. These movements are reversed at stations in the southern hemisphere. The fluctuation so arising is called the solar diurnal variation, and its average over the year the *mean solar* diurnal variation. There exists, then, a line which may be regarded as a magnetic equator of a third kind, in which the *mean solar diurnal variation* is *nil.* This line is supposed to be not very different from the line of *minimum intensity.* But in addition to these diurnal periodicities, there is an annual one depending on the sun's declination. When the sun is north of the equator, the diurnal variation, as above described, at stations north of the magnetic equator is exaggerated, at southern ones palliated, and *vice versâ;* and in consequence of this it happens, that at stations *on* this third magnetic equator, although the *mean* diurnal variation on an average of the whole year is *nil*, yet, during one-half of the year a diurnal variation, having a northerly character, exists, and during the other half a southerly.

(292.) Besides these regular fluctuations of magnetic action, others of a very singular character exist, to which the name of "Magnetic Storms," or "irregular disturbances" of the three elements, has been given. They are in the nature of sudden and extensive deviations of the needle from its normal position and force. They occur quite unexpectedly (subject to a condition presently to be mentioned) and simultaneously over very extensive regions, and even, in some instances, over the whole earth; so simultaneously, indeed, that differences of longitude may, in particular instances, be ascertained by their means. Their cause is unknown, but is presumed to be connected with electric discharges, restoring the equilibrium of electric tension, somehow disturbed. Utterly irregular as these magnetic shocks are as to their particular moments of occurrence, and as to their degree of intensity, they yet, taken in their totality, and on a great average, obey the law of solar diurnal periodicity, but with the singular peculiarity of having, at each station, epochal hours peculiar to that station, and not identical with the regular epochal hours.

(293.) By far the most remarkable feature in the magnetic system of the globe, as expressed by their several systems of allineation, is its state of secular change, by which all the isogonal lines are sweeping *westward* in the northern hemisphere, and *eastward* in the southern. From this it happens, as a necessary consequence, that *their forms* are in a constant state of change, and from this, too, we may learn to receive with much suspicion any general theories as to the dependence of directions of mountain chains and mineral veins, on the direction of the magnetic forces in action, seeing that if the present rate of variation should continue, or have continued uniform for a few centuries (to say nothing of great geological periods), the magnetic state of the globe must have been in former ages, and will be in future ones, quite different from the present.

(294.) It appears to be placed beyond a doubt that the moon acts *directly* as a magnet on the earth's magnetism, the latter producing periodical fluctuations of extremely small amount, and which belong rather to the department of Cosmical Physics than to that with which we are here concerned.

(295.) *Distribution of Mineral Products.*—The number of chemical elements which go to constitute the total mass of our planet, so far as at present known, amounts to about 60, and every year is adding to their number, and to that of the already innumerable compounds which they form with each other. They are distributed, however, in such extremely unequal proportions throughout nature, and there are so many of them which, so far as we at present see, play quite a subordinate part in the general economy of the world and in useful applications, that when we come to confine our regards to those of primary importance, we find the list much narrowed.

(296.) The elementary substances which occur among the materials of the accessible crust of the globe in such abundance as to constitute appretiable aliquot parts of its total amount, are—I. *Gaseous.* (1.) Oxygen.—This constitutes one-fifth of the atmosphere, eight-ninths of the sea, half the siliceous and calcareous, and more than half the aluminous rocks and soils, besides entering as a large element into almost every other mineral substance, so that it cannot be reckoned as constituting less than half the ponderable matter of the globe. (2.) Hydrogen; which forms one-ninth of the ocean, and of all that water which

enters into the essential composition of a great many minerals, and the whole hygrometric contents of the atmosphere and of the soil. It enters also largely into the composition of coal, combined with carbon. (3.) Chlorine, as an element of sea salt, and, with this exception, occurring only very sparingly. (4.) Nitrogen, constituting four-fifths of the atmosphere, and otherwise very sparingly disseminated, existing chiefly as a constituent of the nitrates of potash, soda, and lime, which occur in some abundance, disseminated through the soil in India, Persia, and the deserts of Arabia and Africa, efflorescing in caves in America. The nitrate of soda forms strata of considerable thickness in Peru and Chili, on the western slope of the Andes.

(297.) II. *Solid.* The oxides of silicon, aluminium, and calcium, with that of carbon in the state of carbonic acid in the limestones, and of iron as an ingredient of almost universal intrusion into every other substance, constitute an overwhelming majority of the solid materials of the earth. After these probably may be placed those of potassium and sodium in the state of alkalis, forming a very notable portion of the granitic masses (as felspar and albite), and entering into the composition of a great many other bodies, especially (soda at least) into rock salt and sea water. Magnesia, too, as a characteristic element of the rocks of the serpentine character, and entering very influentially into dolomite and into many limestones, is entitled to rank among the more prominent ingredients of the land, though the sea is the source from which, exclusively, it is procured for human use. Carbon occurs as a primary and principal ingredient only in the anthracite and coal formations. The other chemical elements occur only occasionally and locally in any abundance, in veins, mines, and quarries, or disseminated in crystals and nodules in rocks, or as subordinate elements of composition in some or other of the more abundant rocks, or scattered through nature by their disintegration and dispersion.

(298.) The crystalline rocks have no doubt been the origin from which (ultimately) the stratified ones have been derived. From their destruction, partly mechanical, partly chemical, have been produced, by water-washing and graduated subsidence, siliceous and argillaceous strata—the former essentially consisting of the quartz and other hard and unattackable crystalline ingredients, which the action of the waves has been able only coarsely to pulverize, and which have, therefore, been deposited near the shore; the latter, of the aluminous portion chiefly set free, in a chemically divided or flocculent state, by the decomposition of the other ingredients, such as felspar, and of the infinitesimally thin and filmy micaceous scales set loose and floated away to remoter places of quiet deposit. Thus have originated the two great families of the secondary and tertiary rocks; the siliceous and argillaceous, however, hardened and recompacted by subterranean heat and pressure. The third, or calcareous and cretaceous family, it can hardly be doubted, have arisen—1st, From the labours of the animalcule and mollusc; 2dly, From the submarine effusion of calcareous springs (Lyell); and 3dly, From the degradation of calcareous mountain masses, themselves the successors and representatives of former ones, but which have yet, in all probability, undergone the solvent action of sea-water, preparatory to their re-aggregation by the agency of organic chemistry.

(299.) We may consider the mineral products of the earth, in relation to human use, under the general heads of materials for our structures, for our tools and utensils, for objects of ornament and luxury, and for medical use, and domestic and manufacturing consumption. The first of these divisions need not detain us long. Wherever rocky masses occur capable of being quarried and shaped into blocks of sufficient coherence to resist the weather (and there are few strata which, in some part or other of their extent, do not furnish such), building materials are not wanting. For vast and massive structures intended for indefinite duration, and in which delicacy of finish is of less importance than resistance to weather or to violence, granite is admirably adapted; not, however, all equally so. Such granites as contain potash-felspar in great abundance are attacked and corroded by the carbonic acid of the air, assisted by rain and frost. The syenitic granites, or porphyries (of which, as examples, the Egyptian obelisks consist), and those granites in which felspar is replaced by albite (soda-felspar) are far less liable to such disintegration. That of the Aberdeen quarries, of which most of the great granite structures of London consist, is of this description. As a material for the greatest structures, granite presents the advantage that masses of any magnitude can be procured of perfect continuity. These are detached from their beds by primitive but very ingenious contrivances, which must have been known and practised from the earliest times. In some cases grooves are chiselled in the rocky mass, and holes cut at brief intervals along them, into which wedges of baked wood are driven. These, when moistened, swell, and by their simultaneous expansion determine a fissure along the direction of the groove. In erecting an obelisk at Seringapatam, a block 70 feet long was separated from its bed by native workmen, by cutting a deep groove, along which was maintained a line of fires. When the rock had become sufficiently heated, water was poured along, the fires extinguished, and a crack determined along the groove.

(300.) Few but the vastest and most important structures are of granite. Its hardness, and the expense of working it to a smooth surface, prevent its general use as a building material. It is chiefly among the calcareous rocks, the marbles, the oolites, the nummulite limestones, and the harder portions of the chalk formation, as also among the close-grained sandstones, which admit of being easily quarried and sawed into shape, that the architect finds his best resource. Many of the grandest monuments in ancient Rome are constructed of the Traventine, a calcareous deposit from the numerous carbonated sources which occur in abundance along the base of the Apennines, at Volterra in Tuscany, at Terni, and over great districts in the immediate neighbourhood of Rome, and which is seen in process of formation to the present day, by the concretion of mosses, and other small aquatic vegetation percolated by water saturated with super-carbonate of lime. Marbles, adapted for architectural purposes, are of pretty common occurrence, but those fitted for the sculptor's use are exceedingly rare. The finest are those which have furnished, from the quarries of Pentelicus, near Athens, the material of the Parthenon, and those of Mount Marpesus in the Isle of Paros, whence have been derived those masses on which the genius of the Greek sculptors has stamped the impress of immortality, and which, in the Arundel marbles, yet preserve the recorded chronology of that wonderful nation. The finer grain and snowy purity of the marble from the quarries of Carrara, on the Gulf of Genoa, makes it even still more prized. An excellent marble for the more costly architectural purposes, though less so for sculpture (being deficient in whiteness), is obtained in abundance from the Pic de Gerx, in the French Pyrenees.

(301.) The wide dissemination of the calcareous formations is of the last importance in an architectural point of view, from their furnishing the chief and most indispensable material of cement. Where lime is wanting, oyster and

other sea-shells near the sea-coast may offer an excellent substitute; but its absence in the interior of a continent is an evil of no small magnitude. Much of the Cape Colony is seriously inconvenienced by it. As a chemical agent, too, and as an agricultural application, it is of immense importance, though when magnesia occurs as an ingredient in limestone, it acts as a poison on vegetation; and large tracts of country in which this is the case, in the interior of France, in the north of England, in the neighbourhood of Naples, and elsewhere, are doomed to hopeless sterility from this cause.

(302.) Among the argillaceous rocks, the slaty ones claim attention, by reason of their fissile structure and great resistance to weathering, which renders them peculiarly adapted to roofing, and to a variety of other purposes. It is very remarkable that the "slaty cleavage" is never coincident with, but always highly inclined to, the planes of stratification. This Messrs Tyndall and Sorby have explained, we think, to a certain extent satisfactorily, by referring it to the effect of lateral pressure determining the parallel direction among innumerable disseminated infinitesimal films of mica; but they have not shown how such pressure originated, or why it is always lateral. Perhaps we may be pardoned for interrupting the matter immediately in hand by a few words on this point. It is well known to geologists that the slaty rocks are subject to very singular and extravagant contortions, the layers being often folded and refolded on each other like the folds of linen. This is generally ascribed to the effect of violent intrusion of other rocks by the action of upheaving forces, acting on matter softened by heat, or only partially consolidated. A less violent origin of the phenomenon seems to us not improbable. The aluminous strata have probably been deposited in a much more minute state of subdivision, and of a more slimy consistency than the siliceous. Suppose such a deposit to take place in an ocean-basin, with sides inclining generally inwards, and having irregularities in them uniformly over the whole, till the irregularities are filled in, and the bottom reduced to a, generally speaking, basin-like concavity. Up to a certain point, the friction of the bed will retain the deposited matter on the slope, and in this way strata nearly uniform and parallel will be formed. But as the thickness of the whole increases, the weight will overcome the friction, and the still soft strata will yield inwards on all sides towards the central portion of the basin, increasing the thickness there, and at the same time crumpling the strata into contortions where they slide over the irregularities, and congregate towards local centres of depression, while yet the middle thickness increases, and that of each stratum individually (if the process go on slowly and tranquilly), by a general lateral compression and vertical dilatation of the whole central mass (however crumpled): which is all that the compression theory requires to account for the existence and direction of the cleavage in question. It seems by no means impossible, indeed, that instead of requiring the motive power of the volcano and the earthquake to wrinkle and contort the strata in the manner observed, such wrinklings and contortions (or rather the slippages to which they are here attributed, when sudden), may, by displacing the incidence of pressure on the ocean bed, be themselves causes to which some, at least, of those phenomena may be owing.

(303.) The finest slate quarries in Britain, and probably in the world, are those of Penrhyn in North Wales. Between two and three thousand workmen are there constantly employed in quarrying and cleaving the slates, which are conveyed to every part of Britain and of the world, for roofing and writing slates and slabs.

(304.) Among the crystalline schists of the metamorphic series, it is no uncommon thing to find portions, especially of the mica slate, which allow large and tolerably even slabs to be detached, which in Alpine countries are used largely in buildings of the common kind. Many basalts and lavas afford excellent material, but their dark colour gives the piles constructed from them a sombre and heavy aspect. The cathedrals of Clermont and Le Puy afford examples of this.

(305.) Gypsum (sulphate of lime) enters as an ingredient in cements, casts, and stuccos, and is largely used wherever moulded forms are required and great hardness is not essential. In its natural *habitat* it is an almost universal concomitant of rock salt and salt springs, though in some (as at Cardona, in Spain) it is absent, and in others (as at Bex, near Vevay) it occurs anhydrous, and therefore useless for such purposes. Large beds of it, however, occur in the secondary and tertiary formations (seldom or never in the lower series) without the accompaniment of salt, as in the older tertiary basin of Paris (whence its ordinary name of plaster of Paris), in many parts of Switzerland, in North Italy (as at the head of the Lake of Garda), and in the sub-Apennine marls of the older Pleiocene, in Sicily, near Girgente, where it outcrops in crystals of very singular structure.

(306.) The mineral products which contribute to the construction of our tools and utensils are almost entirely either the metals, or those which go to the formation of earthenware and glass. Among the useful metals, *iron* holds the first rank. Owing to its high attraction for oxygen it is seldom found native (though instances do occur, as at Steinbach, Eibestock, at Kamsdorf in Saxony, and in Mont d'Oulle, near Grenoble, in France), unless in masses to which a meteoric origin is usually assigned, and which occur detached and insulated in various places. The principal masses are—the great Siberian one described by Pallas, containing crysolites; that of Otumpa, 70 leagues east of Santiago, "in the vast plains of the Gran Chaco, where, as in the Pampas of Buenos Ayres, *not a stone is to be seen*," which was brought to England by Sir Woodbine Parish, and now in the British Museum, and which weighs 14 cwt.; that of Elbogen, in Bohemia; and that of Hraschina, near Agram, in Croatia (which was seen to fall). Many masses are scattered over Louisiana, and others have been discovered in the Esquimaux country and on the Senegal river. The great mass of Otumpa is far from solitary, however, in that region, and the masses which there occur are described "as huge trunks with deep roots, supposed to communicate with each other." Though alloyed with nickel (a character common to all these so-called meteoric masses) this circumstance, and their abundance near Santiago, "induced" Sir W. Parish, "as well as others in S. America, to hesitate in adopting the meteoric theory," a hesitation greatly increased by the existence in some sandy plains near Toconao, ten leagues from San Pedro, in the province of Atacama, in Peru, of an extraordinary quantity; where, besides detached masses, a vein of solid iron of the same kind is asserted by the natives to exist. This suspicion of other than a meteoric origin of these masses is considerably increased by the occurrence of a similar fact in South Africa. "Eight days' journey east of Bethany missionary station, 'meteoric iron' is found in apparently inexhaustible quantities." Anderssen, to whom we owe the account of this fact, had "seen lumps of several cwts. brought thence, so pure and malleable that the natives convert it into balls for their guns, without any previous application of fire.—*Lake 'Ngami*, 2d ed. p. 325.

(307.) Iron, however, happily for man, mineralized either by sulphur or by oxygen (in which latter state of

combination only it is available for smelting), is diffused over all the world in immense abundance. In the island of Elba are whole mountains consisting of the specular oxide. The mountains of Taberg in Lapland, and Pumachanche in Chili, consist almost entirely of magnetic iron ore, and mountains of it occur in the Minas Geraes in Brazil, where in one place it forms a mountain (Itabira) of the pure oxide, 5250 feet high. It is also plentiful in Corsica, Savoy, Bohemia, Saxony, Russia, and the East Indies. In Britain the principal iron mines fortunately accompany the coal-fields, as around Birmingham, in Staffordshire, and in the great coal-basins near Pontypool, Merthyr Tydvil, and Glasgow. The same coincidence happens in Belgium, and in the coal district near the St. Etienne, in France. It is chiefly the red and argillaceous iron ores which are so associated. These, though mostly occurring in secondary and alluvial countries, are also, though more rarely, found in the so-called primary formations. On the other hand, the oxydulated and brown iron ores belong mainly, though not exclusively, to these formations.

(308.) Among the other metals, it may be observed generally that manganese, like iron, is found among the oldest rocks. Tin, molybdœna, tungsten, titanium, cerium, uranium, chrome, and bismuth, are found almost exclusively in such veins as traverse the lower crystalline rocks. Arsenic, cobalt, silver, nickel, and copper, in these and in the higher members of these series. Gold, tellurium, and antimony, in the upper crystalline metamorphic, and in the older secondary or silurian rocks. Lead, zinc, and mercury are found in greatest quantity in secondary formations. Platina, with its associated metals (the platinoid group), has, with one exception, not hitherto been found in the matrix *in situ*, but (as is also largely the case with gold) dispersed in alluvial gravels, sands, and clays.

(309.) Many of the metals are found almost exclusively in veins. These are fissures or cracks in the rocks, usually of no great breadth, which are filled—whether by injection from below, by sublimation, by infiltration from above, or by crystalline segregation determined by voltaic currents resulting from chemical reactions—with materials of quite a different nature from the rocks in which the fissures occur. The contents of a vein are usually highly crystallized, and arranged with a certain symmetrical reference to the boundary surfaces, so as to form corresponding layers on either face of several different spars (especially fluor), with the metallic deposit, whether sulphuret, oxide, or in union with acids, occupying the middle; such at least is the normal arrangement of the contents of a mineral vein, though it is often widely departed from. Wherever a mineral vein traverses stratified rock, or differently characterized beds of an unstratified one, the strata on its two faces are very frequently, indeed almost generally, found not to correspond—one or other side of the mass having shifted in level (whether by upheaval or subsidence), forming what are called *faults* in the strata. When the fissure has been accompanied with and perhaps formed by the violent injection of non-metallic liquid matter, the vein is called a dyke, whether of granite, basalt, or other igneous rock. In such a case the dislocation is a natural concomitant of the violence used in the formation of the dyke; but it would seem probable that metalliferous veins have, at least in many instances, subsequently and quietly filled up empty intervals, themselves the results of previous violent displacement, not accompanied with the injection of melted matter.

(310.) Veins, as well as dykes, are evidently of different ages, and belong to different and successive actions of the dislocating forces. In Cornwall, where the principal tin mines in Britain, and perhaps in the world, are situated, the stanniferous veins run almost universally east and west, while those which intersect and upheave them, producing or accompanying dislocations and faults in them (which this fact proves to be posterior in date), cut them at various angles, and those which run north and south are rarely metalliferous. The same tendency to an east and west direction in metalliferous veins generally has been remarked in other mining districts, and has been (perhaps rather hastily) drawn into a general law, and referred to a generally westerly course of voltaic currents, connected, as is assumed, with the generally meridional direction of the magnetic needle.

(311.) *Copper, Tin, Lead.*—Of the metals found in veins, these are the most abundant and most generally useful, either pure or in mixture. Copper occurs in granite in the slate formations, in the sandstones of the "Trias" (a connected system of three members—Keuper, Muschelkalk, and Bunter Sandstein—common in Germany), in certain porphyries, and in serpentine. The copper mines of Tunaberg in Sweden are in secondary limestone. In Cornwall, where, in the granite, a copper vein intersects a tin one, the former always disturbs the latter—a proof of later origin. Mines of copper are largely wrought in England, Germany, Sweden, and Siberia; less so in Spain, France, Ireland, Norway, and Hungary. Native copper is of common occurrence, and in North America, in the neighbourhood of Lake Superior, about its upper end, is found in blocks of several hundred tons in weight, so pure as to require to be cut with the cold chisel. Malachite, or the carbonate of copper, which is valued almost as a gem when in fine specimens, is largely procured in the Siberian mines of the Ural and Altai mountains, and in the copper mines of Burra-Burra in Australia.

(312.) Tin has been generally considered to occur native in Cornwall; but, according to Phillips (*Mineralogy*, lxx.), the specimens which have given rise to this opinion have been found on the sites of old smelting works. Mohs (*Mineralogy*) does not admit it into his Order ix. of *native* metals. Its ores (always either oxide or sulphuret) belong exclusively to primitive countries, and the localities of its occurrence are comparatively few, viz., Cornwall, Saxony, and Bohemia in Europe, Tenasserim, in the Malayan Peninsula, and Banca Island in the Straits of Malacca. Some stream works, in which the oxide is found, exist in Mexico and Chili. At Chesterfield, in North America, it has also been found.

(313.) Lead occurs very rarely in a native state. Its chief ore is the sulphuret, which is very abundant in most European countries—comparatively rare in Asia. In England, perhaps the greatest known depository of this ore, it occurs in the secondary limestones of Derby, Durham, and Northumberland, in clay slate in Cornwall and Devon. In Scotland, in the Lead Hills in Lanark and in Dumfries. In North America, in Massachusetts, it occurs in granite and other crystalline or metamorphic rocks, which is also the case in France and Spain.

(314.) *Gold, Silver, Platina.*—Gold and silver, though they derive their high estimation mainly from their application to utensils and ornaments of luxury and splendour, yet perform most eminently the offices of *useful* metals, as the materials of the most universal of all *tools*—coined money. GOLD, owing, no doubt, to its low affinities for oxygen and sulphur, is exclusively found pure, or in alloy or mixture; all the alloys of a definite character, however, are very rare. In its *habitat* it occurs disseminated in nodules or threads in many rocks, but chiefly in quartz, and in the beds of rivers and alluvial deposits, the result of the degradaion of such rocks. The long-inhabited countries have been picked clean of

their alluvial gold, but in newly-occupied ones it is still abundant; confined, however, to the palæozoic rocks in the neighbourhood of porphyritic eruptions, and to the districts adjacent to such rocks, with an *especial preference* for those mountain chains which run north and south. Such are the Mexican and Peruvian Andes, the mountain ranges of California and North-Western America (including the newly-discovered gold districts on the Fraser River and Vancouver's Island)—such are also the mountains on the east coast of Australia, to which the gold districts of Sydney, Melbourne, and Adelaide, owe their wealth. Such, too, is the Ural chain, the chief source of the Russian gold. Gold also is found in Brazil, where almost all the rivers bring it down,—in mines at Matto Grosso, and in Minas Geraes—in the Altai Mountains—in Hungary and Transylvania—in Japan, Borneo, and in the province of Yunan in China, as well as at the base of the Kong Mountain, and in very extensive regions in the interior of Africa, where gold dust is obtained by washing, and where the closer exploration of its mountain chains will no doubt lead to the discovery of rich deposits. The largest mass of native gold yet discovered is that recently found at Ballarat, weighing 2217 ounces, greatly exceeding that of Miask in the South Ural (36 kilogrammes = 1158 ounces) found at Zarevo Alexandrofski in 1842.

(315.) Silver occurs in such immense abundance in Mexico and Peru, among the Cordilleras of the Andes, that it is hardly worth while to enumerate the localities of its feebler exhibition, such as Hungary and Transylvania, the Ural and Altai mountains, Armenia, Anatolia, Thibet, China, Cochin-China, and Japan. The most productive region of the Andes in silver is about Copiapo in Chili. In Peru, from Caxamarca along the whole range of the Andes to the desert of Atacama, it is very abundant. The most ancient mines are those of the "Knot of Pasco." At Potosi and at Chota the ore lies close to the surface. In the mines of Huantajaya a mass of pure silver weighing 800 lbs. has been found. Silver is a very general concomitant of lead, and a large quantity is extracted from that metal. This used to be done by cupellation, the lead being burned off and again recovered; but is now performed by the neater and far less wasteful and costly process of crystallization, by melting the lead, allowing it to cool and crystallize, and pouring off the last portions from the crystals formed, which portions contain all the silver much concentrated.

(316.) Platina is a rare but extremely useful metal. But for utensils formed of it, chemistry could not have attained its present state of improvement, either as a practical art or as a science. It is found in very few localities—in Brazil, at Matto Grosso, in Choco, New Granada, St Domingo, and the Ural Mountains, and always in alluvium.[1] According to the remark of Humboldt, the principal deposits of gold occur on the eastern, and of platina on the western side of the Ural chain. One of the most singular characters of this region is the frequent occurrence of the fossil bones of extinct pachyderms among the metalliferous sands. The largest "*pepite*" (nugget, *i.e.* ingot) of platina hitherto discovered is one of 25 oz. 1 dr., found in the gold mines of Condoto Choco, S. A. (*Phillips*).

(317.) Platina is *invariably* found associated with several other metals forming a family apart (the platinoids), of very singular chemical habitudes—viz., palladium, rhodium, iridium, osmium, ruthenium. Of these, palladium also occurs alloyed with gold and silver in Brazil, and iridium, or rather its osmiuret, occurs in almost all gold in a state of *mixture*, *not of alloy*, and is deposited by subsidence, by reason of its *much higher specific gravity*, at the bottom of the crucible whenever gold, fresh from the mines or diggings, is melted in large quantities. It sometimes settles *in the finest dust* from the melted gold!

(318.) Zinc and Antimony are chiefly useful as alloys tending to harden other metals, a quality which, in the case of zinc in union with copper (producing brass, or bronze), is of the highest importance in many of its applications, and in earlier ages enabled it, with the admixture of tin, to supply the place of iron, then unknown or unworkable. Bismuth is also used chiefly as an alloy, which is also the case with nickel. Zinc is chiefly found in the state of sulphuret or carbonate, sometimes in veins of tin or copper, as in Cornwall, but most frequently associated with lead in the lead-mines of Derbyshire, in the Mendip Hills; in Scotland, in those of Wanloch-head; in Wales, in Flintshire. It occurs also in the mines of Freyberg, in Saxony, Bleiberg, in Carinthia, Tarnowitz, in Silesia, and Medziana Goro, in Poland. Enormous masses of pure calamine are found in some of the North American mines—in New Jersey, and other parts. It is also found in the Siberian mines. Indeed, wherever lead occurs, zinc may be expected.

(319.) Antimony, which, besides its utility in hardening alloys, is also an important medicine, occurs in veins traversing gneiss at Allemont in Dauphiné. In Cornwall, in veins traversing those of copper and tin, at Andreasberg, in the Hartz—in Saxony, Bohemia, Hungary, Transylvania, Tuscany, in Mexico, and in Connecticut in North America. The chief deposits of Bismuth occur in the veins of primitive mountains. The chief localities are in the Cornish mines, Johan-Georgenstadt and Schneeberg in Saxony, Joachimsthal in Bohemia, in Transylvania, Swabia, France, Norway, and in Connecticut, N. A.

(320.) Nickel exists in considerable abundance in China and Japan, whence it reaches us in alloy with copper as tutenag; also in veins of primitive rocks in Saxony, Bohemia, the Banat, and in France; in rocks of the metamorphic and transition series in the Hartz. It occurs also in Swabia, at Saltzburg, in Spain; in veins traversing serpentine in Silesia, and in copper-mines in Frederick County, and at Chatham in Connecticut, N. A.; in Cornwall, and in Scotland. It is an essential ingredient in the so-called meteoric iron, which it effectually preserves from rust (*verb. sap.*)

(321.) Mercury occurs in few localities, the chief of which are the mines of Idria in Carniola, and Almaden in Spain, and it is prominent among the recent great metalliferous discoveries in California, where mines of it exist so extensive as to have given a new impulse to the working of the Mexican silver-mines, where its chief consumption takes place in the process of amalgamation. In medicine its valuable properties have been long recognized, and it has now taken its place among the essential materials of modern warfare, by reason of the detonating properties of one of its salts.

(322.) At the head of metals useful in the chemical arts, and in these only, stands Manganese, whose ores are very widely disseminated both in the primary and secondary rocks, where it occurs in veins, beds, or irregular masses, in the state of black oxide, in which alone it is of any utility. It is found, too, in Cornwall, at Upton Pyne and Tavistock in Devonshire, at Bristol, near Aberdeen in Scotland, at Howth near Dublin, in Ilefeld in the Hartz, in Nassau, at Christiansand in Norway, at Platten in Bohemia, at Johann-Georgenstadt in Saxony, and in several places in Hungary, Moravia, Silesia, and France.

[1] M. Boussigny found it in a syenitic rock associated with gold at Antioquia, in uth America.

(323.) ARSENIC is of almost universal occurrence in combination with the other metals, forming arseniurets and arseniates. CHROME, first discovered in Siberia in combination with lead, is now almost wholly obtained from the chromate of iron, which occurs in copious abundance in Unst, one of the Shetland Isles. These, with cobalt (which generally accompanies nickel), almost exhaust the list of metals useful in the manufacture of utensils, and in the chemical and medicinal arts.

(324.) *Objects of Conventional Value.—Gems.*—At the head of gems stands the DIAMOND, which, from its hardness, may also be reckoned among the useful materials as a tool. As is well known to chemists, it consists of pure carbon. It is found all but exclusively in alluvial detritus, and has never but in two or three instances been found forming an integrant part of any rock. As such, it was once observed to occur in scorodite, in a cavity of brown ironstone at Antonio Pereira, in Brazil, accompanied by micaceous iron, between Villa Rica and Sabara. Humboldt, or one of his companions in travel, detected it in the Ural, *in situ*. M. Harting (*Verh. der K. Akad der Wetensch.* Amsterdam. Deel vi. 1854) describes a diamond from Bahia, including in its substance definitely-formed crystalline filaments of iron pyrites—a fact unique in its kind, and, taken in conjunction with the affinities of iron and carbon at high temperatures, likely to throw some light on the very obscure subject of the ultimate origin of this gem.

(325.) Diamonds are found only in few localities. The principal are between Golconda and Masulipatam, in the peninsula of India, in Visapore, near Panna in Bundelcund, in the vicinity of Ellore, at Mallivully in the Mustapha-nagar Circar (in a peculiar fat white clay associated with ironstone), in the peninsula of Malacca, in Borneo, where the largest diamond known (367 carats=1130 grains) was found in Brazil, in the district of Cerro do Frio, in the country north of Rio Janeiro: also on each side of the Sierra Espenhaço, and on the affluents of the San Francisco river. The chief work is at Mandanga, on the river Jigitonhonha, where diamonds are found in an alluvium of pebbles called cascalhao; at Goyaz, Matto Grosso, and St Paul's. Diamonds are also found in the Ural, and especially in the rich mining district near Beresovsk.

(326.) The SAPPHIRE, ORIENTAL RUBY, and SPINELLE, are chiefly found in Ceylon, in the beds of streams; the finest in the Capellan Mountains near Sirian in Pegu. Sapphires also occur near Billin and Merowitz in Bohemia, in the sand of rivulets near Expailly in France, at Brendola in the Vicentine, and at St Gothard, but not in such quantity or of such value as to make their search remunerative. The Spinelle is not uncommon in Brazil, where also, in the Minas Geraes and at Villa Rica, the TOPAZ abounds. The finest EMERALDS are found in New Granada, in veins traversing a formation referable to the epoch of the greensand or lower chalk. They occur also in Upper Egypt, and in the valley of Tunca in Santa Fé, in granite. The BERYL occurs in the greatest purity and abundance at Nertschinsk in compact ferruginous clay, in Persia in a vein traversing granite, and in a similar *gisement* near Limoges in France. It is also found in Peru, Brazil, Saxony, and Elba, at Cairn Gorm in Aberdeenshire, and in Wicklow, Ireland. To enumerate the *habitats* of the inferior gems would be almost equivalent to giving a catalogue of mineral districts. The GARNET, however, may be mentioned as especially belonging to, and found imbedded in, the mica slate and gneiss formations. CORUNDUM, which, though not a gem, possesses the hardness, and consists of the same materials as one (the sapphire), and is on that account of great utility (in its form of emery), is found most abundantly in India, at Singraula near Sahapur, in Ava, on the Malabar coast, in Smyrna, and the isle of Naxos, in Italy and Spain, in Saxony in beds of steatite, in a schistose rock, and in Gellivara in Lapland. The ZIRCON is most abundant in Ceylon, in the districts of Matura and Suffragam, and is found also at Kalinovskoi near Beresovsk, and elsewhere in the Ural, and in the zircon-syenite rocks on the Aggers Elv in Norway. The CINNAMON STONE is peculiar to Ceylon.

(327.) ROCK SALT is commonly disposed in thick beds, either superficially, as in Africa, or at very great depths, as in the Polish mines at Wieliczka; sometimes at great heights above the sea, as in the Cordilleras and in Savoy. The greatest deposit in England is near Northwich in Cheshire. In Spain at Cardona it forms a rugged precipice four or five hundred feet high, of such purity as to require only pounding to be fit for use. At Lahore in India a similar mass occurs. In Affghanistan a road is cut out of solid salt at the foot of cliffs of that mineral 100 feet high. The island of Ormuz, at the entrance of the Persian Gulf, is a rock of salt. It is almost always found associated with gypsum.

(328.) PORCELAIN CLAY results from the decomposition of the felspar in granitic formations. Under the name of kaolin, it is quarried in China. It occurs also in great purity at Aue in Saxony, and at Meissen, in Austria near Passan, at Limoges and near Bayonne in France. The porcelain manufactories of Worcester are supplied from St Austel in Cornwall, at the foot of the granite range. In the granite districts of Ireland it also occurs abundantly.

(329.) COAL.—Happily for mankind this most useful mineral is very abundantly distributed over the world, though limited in its occurrence to those regions where the limestones of the (thence called) carboniferous series and their associated beds crop out to the surface, or underlie other superficial beds at accessible depths. Coal is generally deposited in "coal basins," or great concave depressions of the strata, partly owing, no doubt, to the general curve of the ocean beds in which the deposit was formed, but much more to their being broken up and dislocated by lateral upheavals, so that the parts no longer correspond—a circumstance extremely favourable to their working, since the great inclination which the beds assume would otherwise carry them down beyond the reach of the miner, were it not that their broken edges are thus brought up again and made to out-crop on the surface.

(330.) The "coal measures," or strata in which the beds of coal occur, usually alternating with clay and sandstone, are almost absolutely restricted to that group of the great geological series which used to be termed the transition series—that is to say, to the formations between the metamorphic rocks and the secondary limestones, &c., and more particularly to the upper Palæozoic formations between the Devonian and Permian groups, and in these, to the interval between the old red sandstone, the mountain or coral limestone and millstone grit below, and the new red sandstone and magnesian limestone above. From this circumstance (their coral substratum), from the nature of the fossils they inclose, and from the form and distribution of the carboniferous districts, it is inferred that their depositions took place in comparatively shallow seas, receiving the vegetable spoils of densely-clothed islands abounding in plants of a tropical character, and in particular, with arborescent ferns, flags, reeds, and large trunks of succulent plants. Few animal remains, and scarcely a single shell or coral, are found in the coal measures, while the vegetable forms, sometimes most beautifully preserved (though more ordinarily completely obliterated) which they contain, sufficiently prove their whole mass to con-

sis of vegetable matter consolidated by heat (after undergoing a specific peatifying action by long submersion in water) under a pressure sufficient to retain the more volatile portions of their structure in combination with the carbon, forming bitumen and all the varieties of hydro-carbon, which, as is well known, the distillation of coal yields in abundance. Where the heat has been very violent, the coal is converted into anthracite, or "blind coal," "culm," or "Welsh coal," which is almost pure carbon; and in some instances, in the neighbourhood of trap-dykes, into true coke, evidently from the effect of heat under insufficient pressure.

(331.) The coal measures would seem to mark an epoch of great interest in the geological history of the world, from the circumstance that whereas their strata bear every mark of great disturbance and violent dislocation, those incumbent on them are for the most part horizontal or comparatively little inclined. Such, at least, is the case in the great coal series of England and the Netherlands, and such is the impression strongly left by the moderate inclination and slight disturbance of the sandstones immediately incumbent on the great coal-fields of North America.

(332.) Coal occurs in immense abundance in all those parts of England, Scotland, and Wales where the strata above specified crop out, especially—(1.) In Northumberland and Durham, in a district the central point of which is somewhere about Jarrow at the mouth of the Tyne, in which it has been calculated that between five and six thousand millions of tons of *workable* coal exist (Phillips citing Thomson); (2.) In South Yorkshire, Nottingham, and Lancashire; (3.) In Staffordshire and Warwick, in a region having Ashby de la Zouche for its centre; (4.) In what may be called the western and south-western coal districts, comprising Anglesey, Flintshire, Shropshire, South Gloucester, Somerset, Monmouth, and Glamorgan; (5.) The Scotch coal-field occupying the great central lowland of Scotland; (6.) The Irish counties of Leinster, Tipperary, Munster, Connaught, and Tyrone. The larger portion of the whole area of Ireland, indeed, is occupied by the carboniferous formations.

(333.) On the continent of Europe coal occurs in Belgium in the district about Liège; in France in the neighbourhood of Vienne on the Rhone. The south of Europe is, generally speaking, destitute of coal. It has hitherto been found but very sparingly in Russia. It has been lately discovered, though of inferior quality, at a depth of 360 feet, near Moscow. By far the greatest system of coal deposits known, however, is that of the United States of America. It is considered that the state of Pennsylvania consists, in about one-third of its area, of coal-fields belonging to the great Appalachian system of coal measures, which extend altogether over upwards of 60,000 square miles. One of the seams in this formation, near Pittsburg, is worked through a large extent of its outcrop as an open quarry. The Illinois coal-field, which covers an area as large as England, in Illinois, Indiana, and Kentucky, consists of horizontal strata, and has numerous seams of excellent coal. Michigan, New Brunswick, Nova Scotia, and Vancouver's Island, all yield coal in abundance. It occurs at the height of 14,750 feet in the Peruvian Andes.

(334.) Coal is also found in a vast number of other localities both in Asia and Australia, in Asia Minor (on the coast of the Black Sea, near Trebizond), in Borneo, Formosa, Tasmania, and New Zealand. In India coal occurs on the Damoda river; also in Silhet and Cashar.

(335.) SULPHUR often accompanies salt and gypsum. It is produced in abundance, accompanying the latter mineral and sulphate of strontia (all three superbly crystallized) in the mines of Catolica in Sicily. The greater part of the sulphur of commerce is procured from "Solfataras" or volcanic half-extinguished vents, where, from "Fumaroles" and fissures in the soil, the sulphur is sublimed. The *Solfatara*, emphatically so called, near Naples, supplies an immense quantity. There exist also great masses of sulphur, constituting almost mountains, such as the Sulphur Island of the Luchu Archipelago. Great quantities occur among the volcanoes of Iceland, of Java, and of the Andes. It is one of the most universal of volcanic products.

(336.) *Distribution of Plants.*—Climate and soil are the elements which determine the abstract possibility of existence of all terrestrial and fresh-water vegetable productions. Their actual distribution over the globe involves, however, another element, which greatly limits the area over which particular classes and families of plants are found to prevail. Thus, while some not only will grow and flourish, but are naturally found indigenous, almost indiscriminately, wherever the soil and climate are suitable, there are others which are found native only in very limited districts, or even restricted to particular spots, removed from which they perish, or refuse to produce seed. Thus, the Disa grandiflora is found exclusively on the summit of the Table Mountain at the Cape of Good Hope, and no one has succeeded in getting it to grow elsewhere. The Coco-de-Mer (Lodoicea Seychellarum) is found only in the Seychelles Islands, and though it can be grown in Mauritius, can never be brought to produce fruit there. The Hymenophyllum Tunbridgense is found hardly anywhere but on the sand rocks of Tunbridge Wells. These, however, and such as these, are rare and exceptional cases, as are also those of plants usually of very low organization, which grow only under special, and even artificial conditions, as in the decaying hoof of a horse, or on the outside of *wine*-casks. They are, however, only the extreme exaggeration of a principle which may be considered as of universal application—that of the repartition of families, genera, and species, in districts or regions more or less extensive, in which only they are indigenously found in full development, though perfectly capable of flourishing and propagating elsewhere when artificially introduced. Indeed, it is found in many instances, that plants so introduced into a new soil and climate, not only rapidly adapt themselves to it, but flourish with singular exuberance of growth, as if their old and original *habitat* had become in some degree exhausted of their peculiar *pabulum*, and they were there in process of dying out. This has been singularly exemplified of late in the instance of the Anacharis alsinastrum, an American river weed, not remarkable for any great exuberance of growth in its native streams, but which, having been accidentally introduced into some English rivers, has spread into others, and is becoming a pest by filling and obstructing their beds in a way before unheard of. The thistles of the Pampas, of gigantic growth and immense extent of distribution, are said to be of European origin.

(337.) As the mean temperatures of the surface-soil and of the air change not only with the latitude, but with the height above the sea, the same limits of temperature which restrict the *habitat* of a plant to a definite zone of latitude, or to the interval between two isothermal lines, will also be marked out on mountains or highlands of sufficient altitude, whose lower parts are situated in an isotherm admitting of its growth, by zones of elevation. In such cases, the plant will be found flourishing at the base and up the slope, and gradually becoming more and more stunted, till it disappears altogether. Thus, on a

lofty equatorial mountain, every form of vegetation, from that of the equatorial to the polar regions, may exist, if the soil and water supply be fitting; each form occupying its appropriate zone. Of those which prevail on the Andes, and over the plains and lower elevations of Equatorial America, Humboldt has given a condensed view in a chart, from which our Plate IV. is copied, and which exhibits well the principle in question; and a reference to which will spare us much verbal explanation. The powerful influence which the element of moisture, as well as heat, has in determining the extent and limit of these mountain zones, is strikingly exemplified on the Peak of Teneriffe, where, at lower altitudes, the cloud-level determines a moist atmosphere, and where, at higher levels, the extreme of desiccation is gradually attained; here we find, according to the recent report of Mr. P. Smyth, that on descending from Alta Vista, where (at an altitude of 10,700 ft.) only lichens are found, we come, at the upper limit of 9800 ft., first on the Retama (Cytisus nubigenus), which occupies the whole zone, down to 5700 feet, to the exclusion of every other plant; then quite suddenly occurs the Erica arboracea, to the exclusion of the Retama, and of all other plants, except the Adenocarpus Frankenoides, which latter extends from 5900 ft. to 4200 ft., not, however, mixing in the upper portion of this, its zone, with the Retama, but occupying cinders, while the latter holds the rocky ground. The Erica descends to 1800 feet of altitude, but in the lower portion of its zone it encounters ferns from 5400 to 2300 feet, the Androscenum Webbianum (4900 to 1400), the laurel (5000 to 3500), and the vine (3700 to 2300). Three thousand feet is the lower limit of the perennial mountain cloud, which separates the under from the upper current of wind.

(338.) The decrease of temperature with increase of altitude, proceeding at an average rate of 1° Fahr. for about 350 feet of altitude (see METEOROLOGY), it will be easy to compute at what height above the sea, on a mountain slope, situate on a given isotherm, a plant, the mean temperature of whose most appropriate *habitat* is known, may be expected to be found, if at all. It is not, however, the mean temperature of the whole year, so much as the law of its distribution over the several months, and especially the temperature attained in the summer months, which principally determines the most vigorous growth of a plant, and the limits of its *reproductive* existence. The latter limit will, of course, be defined by the impossibility of its flowering and ripening its seed. When a plant cannot flower, it must, of course, die out, even if artificially introduced. Now, it has been laid down by botanists, that a plant flowers where the sum of the mean diurnal temperatures (or rather, as maintained by M. Quetelet, on apparently better grounds, that of the squares of those mean temperatures), from the epoch of the first movement of the sap in the spring, attains a definite amount, differing for each species of plant, but invariable for the same, under all circumstances. Wherever, then, on the globe, the climate is such, whether from the lateness of the spring, or the coldness of summer, that the appropriate sum is not attained up to the cessation of the annual cycle of the plant's activity, it cannot flower, much less fructify. This appropriate sum has hitherto been determined for very few plants. For the common lilac, it is 4264 square centigrade degrees (Quetelet, *Probab.* p. 164, Transl.) As the effect of each day's warmth progresses in a higher ratio than that of simple proportionality, it is easily seen that a short and hot summer may (as experience shews it does) far outweigh, in its influence on reproductive vitality, the rigour of a prolonged and severe winter.

(339.) The general influence of climate in accelerating or retarding the fructification of plants and the ripening of their seeds, will be best exemplified by the periods at which the wheat harvest commences on an average of years, in different latitudes, which we find stated by Dr Balfour as follows:—

Localities	Mean Period of Sowing.	Mean Time of Harvest	Difference in Days
Malta . . .	Dec 1	May 13.	162
Palermo . .	Dec. 1	May 20.	170
Naples . .	Nov. 1.	June 2.	195
Rome . .	Nov. 1.	July 2	242
Berlin . . .	...	...	299
Alps (3000 ft.)	Sept 12	Aug 7	329

Owing, however, to the comparatively higher summer heat in Sweden, and the more rapid vegetation than in England, the wheat harvest at Upsala is not later than that in the south of England; and barley ripens ten days earlier. According to M. Berghaus (*Alm. de Gotha*, 1840) the time of *flowering* of plants in general is retarded by 34 days, by an increase of 10° in latitude in the north of Europe, by 40 days in the more temperate countries, and by 74 days (for a similar increase of latitude) in south Europe and Asia Minor. M. Quetelet (*Probab.* 172) assigns 5 days for the general retardation of flowering due to 100 yards of elevation above the sea.

(340.) The local distribution of genera and species of plants over the globe tends very strongly to suggest the idea, now become prevalent among botanists, of specific centres in which they have had their origin, and from which they have spread, by divergence in all directions, till intercepted in their progress of propagation by some insuperable barriers, whether of climate, soil, or sea. The greater or less areas over which they have so spread have, of course, been determined by the natural facilities for the dissemination of their seeds by winds, by birds, or by water transport; while mountain ranges have in some cases supplied, as it were, stepping-stones for traversing regions, the plains of which are not adapted to their growth. This taking place at an earlier geological epoch, when much that is now sea was land, and when a continuity existed between countries now widely divided, affords a satisfactory explanation of many otherwise unaccountable phenomena. Thus, for example, we find the flora of Iceland to be nearly identical with that of the Scandinavian mountains. Europe and North America have many plants in common. The flora of the mountain districts of west and south-west Ireland, as Prof. E. Forbes has shown, is similar to that of the north and west of Spain; that of the loftiest British mountains refers itself to the same origin with that of the Scandinavian Alps. Thus, too, the chain of the Andes has afforded a line of communication of identical species from the equator to the very extremity of Terra del Fuego. The only question at issue is, as to the singleness or multiplicity of these specific centres in the case of one and the same species. Professor Schouw contends for the latter view of the subject, grounding his reasoning on the fact of identical plants appearing in regions so very far remote and separated by such natural obstacles, as to render the idea of migration untenable, as when, for instance, we find European plants, such as Phragmites communis, Alisma Plantago, and others, in America, New Zealand, and Van Diemen's Land, and not in intermediate countries. Sir W. Hooker has enumerated more than thirty antarctic species, as identical with European ones.

(341.) The total number of plants known to exist has been estimated by Dr Balfour at 120,000, and those ac-

tually described, at 96,000, viz., of acotyledonous plants 15,000, monocotyledonous 14,000, and dicotyledonous 67,000. These, however, differ in their relative proportions to each other widely in different quarters of the globe. The lower forms of vegetation, the acotyledons, bear a larger proportion to the others in polar and alpine regions. In equatorial regions, the monocotyledons are to the dicotyledons as 1 to 5 or 6, in temperate as 1 to 4, and in cold climates, as 1 to 3. In the extreme climates of the arctic islands, however, the proportion diminishes, while on the other hand, in the antarctic islands, they are comparatively much more numerous; the ratio in Kerguelen's island being as 1 to 2, and in Lord Auckland's group, according to Hooker, 1 to 2·2. In central and southern Europe the proportion is 1 to 4 on the plains, decreasing with increase of altitude up to 8500 feet, where it is 1 to 7. Among the monocotyledons gramineous forms especially flourish in temperate and cool climates.

(342.) Ferns bear the least proportion to phænogamous plants in the middle temperate zone, where they form about 1–70th of the whole flora, the ratio increasing both towards the equator and the poles. In the low plains of the great continents within the tropics they amount to 1–20th, while in their mountainous districts the ratio is as high as 1 to 7. The proportion of ferns attains its maximum in small islands situate in great oceans. Thus, in Otaheite their proportion to phænogamous plants is as high as 1 to 4, and in St Helena and Ascension as 1 to 2.

(343.) Among the phænogamous plants, the orders of gramineæ, cyperaceæ, and juncaceæ, increase in proportion to the rest as the latitude increases. The reverse is the case with the rubiaceæ, leguminosæ, euphorbiaceæ, and malvaceæ, while the natural orders of cruciferæ, umbelliferæ, and compositæ, are comparatively more abundant in the temperate latitudes, the proportion of the latter rising as high as 1 to 6 in the temperate regions of America.

(344.) The following classification of plants, according to their climatic distribution, specifying those families which are more especially characteristic in each zone, has been given by Von Humboldt, in illustration of the different aspects of vegetation presented in ascending a lofty equatorial mountain, in which the several zones are traversed in rapid succession. Here we find that the—

Region of	Corresponds to the
Palms and Bananas, ...	Equatorial Zone.
Tree Ferns and Figs, ...	Tropical Zone.
Myrtles and Laurels, ...	Subtropical Zone.
Evergreen Trees, ...	Warm Temperate Zone.
Deciduous Trees, ...	Cold Temperate Zone.
Pines, ...	Subarctic Zone.
Rhododendrons, ...	Arctic Zone.
Alpine Plants, ...	Polar Zone

The zones here in question are not limited by parallels of latitude, nor by the mean isothermal lines, but rather by those which we have called isotheral, or those which have an equal mean summer temperature, so as to present on the globe undulated outlines comprising between them plants which have a certain general resemblance. These therefore have been denominated Homozoic zones by Professor E. Forbes. Their limits, however, are necessarily ill defined, as they overlap or run into each other by a community of more or fewer genera and species, and in greater or less abundance of individuals of each such conterminous species.

(345.) The equatorial zone, according to Dr Balfour, besides the palms and bananas, which may be regarded as its most abundant characteristics (including the cocoanut and plantain), comprehends also arborescent grasses, orchidaceous plants and lianas, the coffee-trees, the ginger and its congeners, together with the cinnamon, the nutmeg, and other rich spices. The baobab (Adansonia digitata) of Senegal, the most massive, and supposed to be among the longest-lived of trees, is a native of this zone, as are also many others of gigantic growth, and of great commercial importance, as the mahogany-tree of Honduras and Cuba, the locust-tree of the West Indies, the logwood, the mora of Guiana, and the ebony; and among edible products, the pineapple, breadfruit, and the finest of all fruits, the mangosteen (Garcinia Mangostana), a native of Malacca.

(346.) In the tropical zones, besides the tree ferns and ficus family, to which the banyan of India belongs, which are its predominant characteristics, we find the piperaceæ (pepper and its congeners), melastomaceæ, and convolvulaceæ, among which the C. Batatas or sweet potato, is among the most useful. The yam also (dioscorea) belongs principally to this zone, as does also the teak, one of the most valuable of timber trees.

(347.) In the subtropical zones few palms occur; we find in it, however, the date palm of Egypt and North Africa, and the Chamærops Palmetto, which extends even into Sicily. These, however, are the zones *par excellence* of the euphorbias and cactuses, the magnolias, proteas, heaths (erica), and their Australian representative, the epacridaceæ. The zamia and cycas also occur. This zone is remarkable for the enormous growth of several of its timber trees. In California (included in it) has been discovered the Wellingtonia gigantea, the loftiest and grandest of trees, said to attain the almost fabulous height of 400 or even 500 feet, with a diameter of forty or fifty feet near the ground. The Californian pine (Abies Douglassii) is also of enormous stature, sometimes attaining 245 feet in height, with a circumference of fifty-seven feet three feet from the ground. The Araucaria imbricata of Chile also attains the magnificent altitude of 260 feet, the Norfolk Island pine (Eutassa excelsa) 224, the Snuglok (a species of tropical oak in the Valley of Teesta, in Sikkim) 200, &c.

(348.) Besides the evergreen oaks in the south of Europe, we also find in the warmer temperate zones, in perfection, the esculent fig, the orange, the pomegranate, and the vine, with numerous species of cistus, vaccinium, smilax, and melaleuca.

(349.) In the colder temperate zone we find the vegetation so familiar to us in England and in north Europe—the oak, the ash, the beech, the chestnut, and the walnut; great forests of coniferæ, the hemlock spruce, and the sugar maple of the American forests. In the southern hemisphere the blue gum-tree attains a gigantic size in Van Diemen's Land. Elwes (*Tour round the World*, p. 268) records a specimen in Lory Bay 27 feet in girth at five feet above the ground, a quite straight tree, which would square 2 feet 6 inches at 200 feet, and containing 5000 cubic feet of timber!

(350.) The subarctic zone is that of coniferæ, willows, birch, and poplar. In the valley of the Black Irkut, in Siberia, Atkinson found a ravine filled with ice, and large poplars growing in it, with their trunks imbedded 25 feet in snow and ice, while the branches were in full leaf. Around each stem was a hollow of 9 inches, thawed and full of water.

(351.) In the arctic zone the willow, the birch, and the alder are dwarfed. The Pinus sylvestris and Abies excelsa in north Europe; rhododendrons, azaleas, and andromedas in North America, with some grasses and numerous lichens and mosses also occur.

(352.) Finally, in the polar zone neither trees nor bushes, nor any cultivable esculent plants can exist. Yet Melville Island produces 67 species of flowering plants, and Spitzbergen 45. Kane found 22 species at Sylvia

Headland in 78° 41′ N. lat. Saxifrage, dryas, papaver, ranunculus, juncus, potentilla, salix, and some other genera, are enumerated as among the plants of these regions. In the southern hemisphere the vegetation of the subarctic zone is confined to a few cryptogamous plants, and that of the arctic and polar zones may be considered as *nil.*

(353.) Botanists, however, have considered the distribution of plants under another and more special point of view, taking account, not so much of the general contents of the zones of climate, as of those regions or districts over which particular families of plants prevail in their fullest state of development, or to which they are exclusively confined. Of these distributions, perhaps, the most generally received is that of Schouw, who divides the surface of the globe into regions, on the principle that, to constitute a botanical "region," at least one-half of the *species*, and one-fourth of the *genera*, of some one or more natural families of plants, should be peculiar to it, and that individual *orders* should either be peculiar to, or reach their maximum in it. Where this condition is either imperfectly fulfilled, or the flora of a district, though evidently peculiar, is not sufficiently known to afford a phytological designation to it, the "region" must be accepted as a provisional one.

(354.) The first botanical region thus marked out is nearly co-extensive with the polar and arctic zones of the former subdivision, including all the land within the polar circle and the northern parts of the two great continents, from the ice down to the zone of trees; and the upper parts of the European mountains and those of North Asia, down to the arborescent belt. *Saxifrages* and *mosse* are the especial characteristics of this region, gentianaceæ, caryophyllaceæ, cyperaceæ, and salicaceæ, also abound. In the northern portion of this region carices predominate. On the more southern alpine heights primroses and campanulas appear. On the warmer borders of this region forests of fir and birch, to the exclusion of other trees, begin to present themselves.

(355.) The region which extends in northern Europe and Asia from the warmer limit of the former down to the Pyrenees, Alps, the Balkan, and Caucasus, and the Altai range of mountains, is especially characterized by the predominance of *umbelliferous* and *cruciferous* plants. In this region also (which is nearly conterminous, in the quarters of the globe to which it belongs, with the zone of deciduous trees) coniferous and amentaceous trees abound; and of shrubs and other plants, the families rosaceæ, ranunculi, carices, and fungi, are largely developed. In its north European portion, chicoraceous plants abound (the dandelions and their congeners), while in southern Asiatic Russia and the countries bordering on the Caucasus, cynarocephalæ (the thistle and artichoke tribe) and astragali, as well as many saline plants, appear as prominent features. The cultivated plants are those of the temperate zones.

(356.) The next botanical region may be considered as including the Mediterranean flora, that is, of south Europe, Asia Minor, and north Africa, down to the Desert, the Canaries, and Madeira, with exception, of course, of the Alpine heights, which belong to the first region. Here stand prominent the *labiatæ* and *caryophyllaceæ* (families of which the blind nettle and pink afford instances). This, within its limits, coincides with the zone of evergreen trees, and nourishes those fruit-bearing trees enumerated in our account of that zone. Rice also and millet, cotton, guinea corn, and the almond, are here cultivated. The cistus abounds in Spain and Portugal; the aromatic labiatæ and scabiosæ in France and Italy; the shrubby labiatæ in Greece and Asia Minor; the oleander adorns the Mediterranean coast, and many balsamiferous and gum-yielding trees and shrubs flourish in Asia Minor and North Africa. In the Canary Isles the family of houseleeks (sempervivum), and in Madeira arborescent heaths are common. Four-fifths of the Azorean species are European, the remainder are peculiar to the Atlantic islands. A specimen of the Dracæna Draco, on Teneriffe, in the Canaries, is said to be the oldest existing tree.

(357.) The flora of the eastern portion of North America, from the limits of the arctic region to the 36th parallel, differs from that of the corresponding district in Europe in the paucity of umbelliferous, cruciferous, and cynoracephalous plants; in the absence of heaths; and in the predominant abundance of *asters* and *solidagos.* Maize is much cultivated in the southern part of this region. Among its forest trees the hemlock, spruce, and the sugar maple, the hickory, the tulip-tree, and the liquid amber, as well as many peculiar and magnificent oaks and others, which in autumn assume the most vivid tints of red and yellow. Kalmias, azaleas, rhododendrons, hydrangeas, and other richly flowering shrubs, occur also in great abundance.

(358.) The western flora of North America, down to the same parallel, is less known, and constitutes a region apart—that of California, Oregon, Vancouver's Island, and Russian America. It is remarkable for the beauty and brilliancy of colour of its flowers, among which the eschscholzia would seem to have imbibed the quintessence of the Californian gold. The nemophilas, clarkias, and innumerable others of this region, have become the pride of our gardens. But it is chiefly in the grandeur of its timber trees that this region stands conspicuous. The Wellingtonia, or "Mammoth tree," has already been mentioned (art. 347), and a vast number of peculiar coniferæ, such as the Abies balsamea, grandis, alba, canadensis, Douglassii, the Pinus ponderosa, Lambertiana, insignis, Fremontiana, and many others, of which A. grandis attains the height of 224 feet, A. alba 160, P. Fremontiana 224, and Lambertiana 235. The Thuyia gigantea of the Rocky Mountains attains 200 feet. Many of these thrive well in England.

(359.) The southern region of North America, which may be called, *par excellence*, the region of *magnolias*, is distinguished from the corresponding region of the old continent by the paucity of labiatæ and cayrophyllaceous plants. Its trees have broad shining leaves and beautiful flowers. The tulip-tree here attains 120 feet in height. Here, too, we have the long-leaved pitch pine (one of the most picturesque of trees), clothing the "pine barrens," while the swamps of the southern states produce the deciduous cypress, the aquatic oak, and the swamp hickory. Among the more beautiful and curious of the flowers are the Nelumbium luteum and the Dionæa Muscipula. The forests of Florida and Alabama are hung with air-plants (Tillandsia usneoides). In this region also many tropical forms occur—zinziber, cycas, cactus, anona, &c. Of 2891 species of phanogamous plants in the United States, only 385 occur in northern or temperate Europe.

(360.) In the subtropical, or warm temperate region of east Asia, from the 30th parallel northward, comprehending Japan, the north of China, and Chinese Tartary, plants of the order *ternstræmiaceæ* (tea and its congeners) and *celastraceæ* chiefly abound. Camellia, thea, citrus, rhamnus, and lonicera, occur abundantly, the two latter in Mantchouria so much so, as to give a peculiar character to the vegetation, and to merit for it the name of the region of *rhamni* and *caprifoliaceæ.* The flora of this region is, in many respects, intermediate between that of the Old and New World. The loquat, the tallow-tree (Stillingia sebifera).

the camphor-laurel, and the Westaria sinensis, are natives of this region. The south of China forms a distinct region, having many peculiar plants, among which the rice-paper plant of Formosa, and that delicate fruit, the litchi, may be mentioned.

(361.) The flora of India, Ceylon, and the south-eastern Asiatic peninsula, to the height of 4000 or 5000 feet, is more expressly marked by the number of *zinziberaceous* plants, by leguminosæ, cucurbitaceæ, and tiliaceæ. Here also we find the cocoa-nut, the mangosteen, cinnamon, cloves, turmeric, indigo, cotton, and pepper. Teak is abundant in the Birman empire and on the Malabar coast. The varnish-tree and that which produces the stick-lac; mangroves, casuarinas, immense bamboos, the satin-wood, (Chloroxylon Swietenia), the Borassus flabelliformis, a magnificent palm, said to grow 100 feet high, and to produce leaves large enough to shelter twelve men, and the Amherstia nobilis, the most magnificent of flowering trees belong to this region.

(362.) The mountain country south of the Himalaya, to the height of 10,700 feet, including the Sub-Himalayan provinces of Upper India, form a region which has some European plants. Ranunculus, nasturtium, veronica, and polygonum, mix with a rich vegetation peculiarly Indian. Here occur the Cedrus deodara, supposed by Hooker to be a variety of that of Lebanon, sometimes attaining 200 feet in height and 36 in girth; the Pinus excelsa, Webbiana, longifolia, and others. In the higher portions of this region are found species of oak, rhododendron, berberis, and primula; in the lower, many tropical plants. In the valleys of the Central and East Himalaya, arborescent ferns and orchids occur in great luxuriance. The Saul wood too, (Shorea robusta), that dreadful poison the Aconitum ferox, and that most beautiful of magnolias (M. insignis), are natives of this region. India abounds with urticas (nettle), the sting of some of which, as U. crenulata, is most formidable in its effects.

(363.) To the region of the Asiatic islands, including those of the Indian Ocean and those between the Eastern Peninsula and Australia, below the altitude of 5000 feet, belong most of the plants of tropical India, with many peculiar ones, as the Carica papaya (papaw-tree), which occurs also in Central America, the Jatropha manihot, the bread-fruit, coco-de-mer, the poisonous upas of Java, and a nettle even more formidable than the Urtica crenulata, whose sting sometimes produces death (the Daoun Satan or Devil's leaf of Timor), as well as that of Sumatra, called tenacissima, which makes excellent cordage. The Rafflesia Arnoldi of Sumatra, a parasitical plant, bears the largest of flowers, being 3 feet 6 inches in diameter. Orchideæ and other parasites load the trees in the rank forests of Java, and ferns also are abundant. This is especially the region of spices. The forests produce an infinite variety of useful and ornamental woods. In Borneo are found the Dryobalanops camphora and the Pandanus odoratissimus or screw pine, a tree with buttress-like roots, every branch of which terminates in an enormous head, like the pine-apple plant. The sugar-cane is cultivated in Mauritius, and the whole character of the vegetation of this region is rich and luxuriant beyond imagination.

(364.) The higher portions of this district, where it exceeds 5000 feet in altitude, has a flora of its own, nearly allied to that of the higher elevations of India, in which extra-tropical forms replace the tropical, and where we find forests of various species of oak, podocarpus (a species of yew), plantagos, gentians, and vaccinia, and other genera of colder regions.

(365.) The islands of the Pacific (Oceanica) form a region the character of whose vegetation partakes of the Asiatic and Australian. Of their 214 genera, 173 are found in India. In the Sandwich Islands nearly one-third of the vegetation consists of ferns. No less than 50 varieties of bread-fruit, the paper mulberry, the Dracæna terminalis or ki, which supplies food and an intoxicating drink, the Tacca pinnatifida or Otaheite saleep, which produces a starch, with several other peculiar fruit-bearing trees and esculents are found here. Lobelias, grapes, sedges, myrtles, and arums also abound. In common with the Australian flora, we find in this region species of casuarinæ, proteaceæ, epacridaceæ, and acacias.

Physical Geography

(366.) The Arabian region, which includes that part of the Asiatic continent stretching across Persia and Afghanistan to the plains of north-west India, is more especially characterized as that of balsamic trees, mimosæ, acaciæ, balsamodendron, and amyris. The coffee, the sensitive plant, numerous species of ficus, senna, &c., are also products of this region. The Boswellia serrata produces frankincense. *Coffee* is supposed to be originally a native of Abyssinia, where in *Kaffa* it forms dense thickets.

(367.) The Desert region, comprising the sandy wastes of Africa and Syria, as may easily be supposed, is poor in plants. It has no peculiarly characteristic genera, and the species which chiefly inhabit it are those of acacia, mimosa, cassia, and zygophyllum or caper-bean, the date, palm, and the dourra (sorghum) supply food, and the pennisetum grass and Alhagi maurorum form the chief support of the camel.

(368.) The flora of tropical Africa is but imperfectly known. Leguminous, rubiaceous, and cyperaceous plants abound throughout. On the west coast we find the baobab and the palm-oil plant (Elais guineensis), ground nuts, and the akee (Cupania sapida), the envelope of whose seed is eaten, the kola nut, the Pentadesma butyracea, the butter and tallow tree of Sierra Leone, and the poison bean of Calabar. On the east coast the distinguishing genera are danais, ambora, dombeya, and senacia. Cotton, indigo, tobacco, the sugar-cane, ginger, yams, cassada, bananas, cocoa-nuts, papaws, oranges, pine-apples, and many others, form the rich catalogue of vegetable delicacies and commercial treasures furnished by this important region.

(369.) Central America (including Mexico and South America to the Amazon river, from the sea level to 5500 feet in altitude) is the region especially characterized by *cactuses and piperaceous plants.* In the West Indian isles, ferns and orchideous plants also prevail. In Panama, besides these, we find abundant leguminosæ, melastomaceæ, compositæ, and cinchonaceæ. That noble flower, the Victoria Regia, occurs in this region, and in all the warmer parts of south-eastern America. The lower parts of Mexico, Guiana, New Granada, and Peru, abound in palms. The vegetable-ivory palm is a native of the last-named province. The Anona Cherimolia, or Peruvian pine-apple, is celebrated. Indeed this region is the original *habitat* of the pine-apple. The fragrant vanilla, and that kind of vanilla called chica, are cultivated in this province, with the Theobroma cacao or chocolate. The sugar and tobacco culture of the West India islands is too well known to need mention. The agave, or American aloe, which yields the pulque wine, the custard-apple, and guava, the cassava or manioc, and the capsicum; among woods, the Hymenæa Courbaril, or copal tree, logwood, mahogany, &c.; and among poisons, the ourali or woorara (Strychnos toxicaria), are also indigenous in this most rich and productive region.

(370.) The Mexican highlands (above 5500 feet) offer, of course, the prevailing families of the colder countries. Many peculiar coniferæ, as the Pinus religiosa Apul-

censis, Hartwegii, and Montezumæ, sixteen species of quercus, and the deciduous cypress (which here attains a height of 120 feet, and 30 or 40 feet in girth) grow here.

(371.) Between 5° and 20° S. lat., and the altitudes 5000 and 9600 feet in the Cordilleras of the Andes, the *cinchonas*, which yield the medicinal alkaloids, quinine and cinchonine, are found almost exclusively. The Ceroxylon andicola, which produces wax on the surface of its stem, and the Chenopodium Quinoa, a Peruvian plant affording a nutritious meal from its seeds, are native here.

(372.) The still loftier elevations of the Andes are particularly rich in *escallonias* and *calceolarias*, associated with many alpine plants. The cultivated vegetation of the warm temperate zone is not altogether absent from this region, since we find the vine, the orange, and the olive succeeding well in La Paz, on the plateau of Bolivia, 12,200 feet above the sea-level. (K. Johnston.)

(373.) The basin of the Amazon river, and the upper part of that of the Parana, comprising the portion of South America east of the Andes from the equator to the southern tropic, is rich beyond description in every form of forest vegetation. *Palms* and *melastomas* are its more characteristic forms. We have reeds of 100 feet high, grasses of 40, and tree ferns. The magnificent forest trees are covered, and, in some cases stifled, with overwhelming masses of parasitical creepers, with orchideæ, araceæ, tillandsias, epiphytic cactuses, peperomias, and gesneras, or with lianas, including bignonias, passifloras and aristolochias, &c. The Eriodendron saumauma (which, from its habits, ought to be called Excelsius), puts forth no branches till it has overtopped every other tree of the vast Amazonian forests, over which it then predominates unrivalled. The Siphonia elastica, which yields caoutchouc, is indigenous in Brazil. That wonderful product, the coca leaf or ipadu (from the Erythroxylon coca), is obtained from the tropical valleys of the eastern slope of the Andes. The yerba maté, or Paraguay tea, represents in its general use, as it partakes in its properties, and in the presence in it of *theine*, the tea plant of China.

(374.) Extra-tropical America, from the southern tropic to 40° S., including South Brazil, La Plata, and Chili, is more especially the region of *arborescent compositæ*. Its flora exhibits an approach to those of South Africa and Australia, in the families of protea, polygala, oxalis, araucaria, and goodenia. That superb tree, the Araucaria imbricata, which may be also considered as a valuable fruit tree, is a native of Chili, as are also some species of arbor vitæ. The chief approximation of this region is European, more than half its genera being common to both. The vine and peach are cultivated. The potato is found wild both in Peru and Chili. The loasa, a stinging climber, has been introduced into our gardens from the latter.

(375.) The portion of America south of this, with the Falkland and other antarctic islands, constitutes another region, in which the forms of the northern and arctic zones prevail. A greater number of plants, in Terra del Fuego, identical with, or nearly allied to those of Britain, occur here, than in any other part of the southern hemisphere. Some of the beech trees are peculiarly beautiful. The flora of the higher mountains is European. Evergreen plants prevail, and the fuchsia, in winter, presents a singular spectacle—arborescent, and covered with snow, while still green, and frequented by humming birds (King.) The Falkland Isles are treeless, but rich in the vegetation of the tussac grass and bolax globaria, which forms dense round balls, or sometimes a dense bushy mass, along the top of which it is practicable to walk when impenetrable to the traveller at the ground level. The character of the antarctic islands, south of these, is one of utter desolation. In Kerguelen's Land only eighteen species of flowering plants exist.

(376.) South Africa has a very peculiar and striking character of vegetation. The *mesembryanthemum* and *stapelia* families are especially abundant, but little conspicuous in comparison with the heaths which there luxuriate in astonishing profusion, as well as the geraniums and pelargonia. Innumerable bulbous genera and everlastings clothe the sandy flats and mountain terraces with beautiful flowers; and the proteaceæ form a rich and peculiar feature, especially the P. (leucodendron) argentea, with its silver-silky leaves. The heaths and proteas are chiefly abundant in the most southern districts. Northward, thorny acacias abound, among which the "wait-a-bit" (A. detinens) is the traveller's plague, with a profusion of aloes and great succulent euphorbias, which attain a tree-like development. In the desert plains of Latakoo, Burchell describes scanty plants not two feet high, with hard woody stems, and two or three centuries old, which abide their time to put forth a transient life on the few and far-between occasions (sometimes several years asunder) when rain falls. The flora of South Africa is connected with that of Australia by the links of the proteæ, restiaceæ, iridaceæ, diosmas, and others.

(377.) The vegetation of Australia is also exceedingly peculiar. Taken as a whole, it has been characterized as the region of *eucalypti* and *epacridaceæ*, which latter represent, in this continent, the heaths of the old world. "Several entire orders of plants are known only in Australia, and the genera and species of families which grow elsewhere assume new and singular forms. Persistent-leaved trees, with hard, narrow leaves of a sombre, melancholy hue, are prevalent, and there are whole shadowless forests of leafless trees, the footstalks of the leaves, dilated and set edgewise on the stem, supplying their place. Plants in other countries have glands on the under-side of the leaves, but in Australia there are glands on both sides, and the changes of season have no influence on the unvarying olive-green of the Australian forests. Even the grasses are distinguished from those of other countries by a remarkable rigidity."—(Mrs. Somerville.) Among the Australian forms are many proteaceæ. Nearly half the known species of this order grow in the parallel of Port Jackson on both coasts. There are 100 species of eucalypti, and 93 leafless acacias. Casuarinas, with long-jointed, drooping branches, afford the principal timber; and the Norfolk Island pine (Eutassa excelsa) is one of the most superb of trees. The roses of the old world are replaced by banksias, which are already naturalized in our gardens.

(378.) New Zealand furnishes another, and the last, of those botanical regions. Its flora connects itself with that of Australia, South America, and the Pacific islands. Out of 1900 or 2000 species of plants it contains, only 730 are flowering ones, and of these, two-thirds are absolutely peculiar to it. Of the rest, according to Hooker, 193 species are Australian, 89 South American, 60 European, and 50 antarctic. The Phormium tenax (New Zealand flax) is a very valuable product. 120 ferns, some arborescent, rising to a height of 40 feet, occur. The forest trees are peculiar, and furnish excellent timber, the Kauri pine being one of the most remarkable. One palm only grows here, the Areca sapida, and, among flowering trees, the Metrosideros tomentosa is remarkable for its rich crimson blossoms.

(379.) *Marine Vegetation.* It would lead us too far to enter into any particular account of marine botany. Like

that of the land, it has its regions:—1. Northern; 2. North Atlantic; 3. Mediterranean; 4. Tropical Atlantic; 5. Antarctic; 6. Australian and New Zealand; 7. Indian Ocean and Red Sea; 8. Japan and China Seas; 9. Pacific. The sargasso, or gulf-weed, forms a mass of almost continuous vegetation in the Atlantic, covering 260,000 square miles. The Macrocystis pyrifera is of universal distribution; wherever the sea is exempt from ice, it occurs in immense masses, at a mean depth of 6 to 9 fathoms. Individual plants attain 700 feet in length. Fucoideæ abound in the higher north latitudes, and cystophora in southern. The lavers of the British seas (as if to carry out the general resemblance noticed in art. 375) occur at the Falkland Isles, where also is found the Durvillæa utilis, "a vegetable cable several hundred feet long, and as thick as the human body."

(380.) In depth, according to Professor Forbes, one great zone lies between the high and low water marks; a second (the region of fuci and laminariæ), from low-water mark to 7...15 fathoms. Ordinary algæ exist only within 50 fathoms of the surface. In the Mediterranean and Ægean seas, marine vegetation occurs at the depth of 100 fathoms.

(381.) *Cerealia.* WHEAT has been lately referred by M. Fabre, as its origin, to the Ægilops ovata, a native or the south of France and the Mediterranean coasts, which by careful culture he finds to shoot into varieties, and these again into others more and more nearly resembling wheat, till, after fifteen or sixteen years, a true wheat results. The conclusion, however, has been still more recently more than called in question by Dr Godron, who considers the case one of hybridation from neighbouring wheat fields (*Jour. R. Agricult. Soc.* xix. 108). Wheat will not yield produce within the tropics at the sea level, at least during the hotter season, though, in the colder months, it may be grown a few degrees nearer the equator. Its northern limit is 58° N. in Britain, 64° N. in Norway, 60° in Russia, and lower in Siberia. In Chili and Peru it grows luxuriantly at 8500...10,000 feet above the sea. Humboldt saw a wheat plant in Mexico with 70 stalks, some bearing ears of 100 grains. BARLEY can be grown as far north as 70° in Lapland, and 68° in Siberia; on the Alps, as high as 3500 feet, and on the Himalayas, up to 12,000. RYE has its northern limit in Norway at 67°; in Siberia, perhaps 68. Fraser found large fields of it, and of BUCKWHEAT, at 11,405 feet, near the temple of Milun, in the Himalaya. RICE can only be cultivated where a high mean summer temperature (not under 73°), and such an excess of moisture as actually to flood the fields, combine; for which artificial irrigation is almost always resorted to. In India and China it is the universal food and chief support of their teeming populations. In Ceylon alone there are one hundred varieties of rice used, and thirty of MILLET, which is cultivated, for the most part, in southern and western Asia and north-eastern Africa; also to some extent in Italy, and even so far north as Bagneres de Bigorre, in the Pyrenees, where we have seen it growing. MAIZE was brought from America by Columbus, in 1593, and has since been propagated very extensively: its colder limit is the isotheral line of 65°.

(382.) *Distribution of Animals.*—The distribution of animals on the earth, like that of plants, is far from being solely determined by the conditions of a suitable climate and sufficient food. The evidence of radiation or dispersion from local centres or primary *habitats,* is of the same nature, and equally cogent as in the case of plants, though modified by the locomotive powers of animals. We find the indigenous Faunas of the Old and New Worlds, of Australia, and of many islands, separated from each other by quite as strong lines of demarcation as their Floras; and that not by reason of any peculiarity rendering the soil or climate of the one unsuited to the indigenous animals of another. On the contrary, the animals of one region, when introduced by man into another not too different in climate, are usually found to multiply with extraordinary rapidity. The Pampas of South America swarm with wild cattle and horses, the descendants of European breeds. Strayed oxen in Australia have been found multiplied into vast herds; the sheep has proved prolific there beyond the most sanguine hope; and already the song of the nightingale and the lark has begun to be heard in its woods.

(383.) Another point of resemblance in the distribution of these two great divisions of organic creation is found in the fact that, though the species differ, yet many families and genera are represented in the several zoological regions, even those most independent, by genera and species, bearing a certain considerable parallelism or representative relation to them. Thus the lion and tiger of the Old World are represented by the puma and jaguar of the New, both belonging to the same genus (felis); the crocodile of the Nile by the cayman of the Orinoco; and the seals of the Arctic Ocean by other seals resembling them in general form and in all their habits, though specifically different, in the Antarctic. In the New World we find, it is true, no pachydermata provided with trunks like the elephant, but an approach to that form is preserved in the tapirs, of which South America produces two species, strongly allied in form and habits to the Malayan tapir, though specifically distinct. Even in the Old World we find species distinctly localized, to the mutual exclusion of each other. Three species out of four of the African rhinoceros have two horns, the Asiatic only one. The Asiatic and African elephant are quite distinct from each other, and both from the Siberian elephant (primigenius), which, though now extinct, evidently existed there during the geological epoch in which we are now living. In the inferior forms of animal life we find examples of a similar and almost startling kind. In the Mammoth Cave of Kentucky occur three genera of *eyeless* insects (anophthalmus, adelops, and bathyscia), members of a subterranean fauna, whose common character consists in *blindness*. And these generic forms are found to be reproduced in the limestone caverns of Carniola, and that in the case of anophthalmus, with an approximation almost amounting to specifical identity (*Schiödte Specimen Faunæ Subterraneæ*). We find, too, cases of restricted localization quite as marked as any afforded by the vegetable kingdom. That the chamois and ibex should be peculiar to the Alps, and the llama to the Cordilleras and high plateaus of the Andes, may not appear extraordinary when the habits of these animals, in keeping to the loftiest summits, are considered; but the limitation of an active insect, well formed for flight (Glossina morsitans, the Tsetze fly), to a limited district of small extent in South Africa, marked out by no apparent natural boundary, yet so definite, that for a horse to cross a well-known line is certain death (the trial has been deliberately made—*Livingstone*, p. 81, 82), assuredly does seem very astonishing.

(384.) The great majority of animated beings are confined to zones of temperature more or less restricted according to their organization, few only (man and those domestic animals which he has succeeded in acclimatizing) being capable of resisting the two extremes of temperature. And within these limits, among herbivorous animals, the botanical limits which restrict the growth of their habitual food constitutes another boundary, which may or may not be conterminous with the former,

though few animals of higher organization than insects are restricted in their range of food to a single or to a very few species of plants. The carnivora have, however, in this respect a wider range, their limit of food being no other than that placed by the absence of animal life itself. Thus we find in the neighbourhood of the Baikal lake both the Fauna and Flora of hot and cold regions intermixing. At Nertschinsk the wild peach grows near the dwarf birch, and the tiger and the bear range the same forests. The former finds his way even to Barnaoul, crossing the Kirghiz steppes and the Irtisch river for prey.—(*Atkinson.*)

(385.) The total number of species of animated creatures known to exist in the present state of the world may be roughly stated at about 155,000, which zoologists have classed as follows:—

	Species.
1. Vertebrata, viz.:—	
Mammalia, about	1,700
Birds,	6,000
Reptiles,	1,500
Fishes,	6,000
	15,200
2. Mollusca,	10,000
3. Articulata, including insects,	120,000
4. Radiata,	10,000
	155,200

Of these the number of existing mammalia may be considered as pretty accurately known, and of birds with some approach to certainty. The number of reptile species, whose *habitat* is determined, and of which scientific descriptions have been published, is set down by K. Johnston at 657, and 1500 is perhaps a somewhat large estimate for what may be considered as *known* reptiles. The articulated animals, which are all, in common parlance, classed as worms and insects, are no doubt as yet but very inadequately known, and such large additions to them are yearly made, that it is very likely the real number may be double of that set down. As for the last class, comprehending, as it does, the countless multitudes of infusoria and polypes, the number here assigned is doubtless a most inadequate one. In stating the species of existing animated organisms at 200,000 we are probably within the mark, and if fossil species be included, even this large number may perhaps be doubled.

(386.) It will be impossible, within the limits of this article, to do more than indicate some of the leading facts relative to the distribution of the more interesting to man among these classes of animated beings. Of these the MAMMALIA claim the first place. They are divided by naturalists into eight orders: Quadrumana, Marsupialia, Edentata, Pachydermata, Carnivora, Rodentia, Ruminantia, and Cetacea. The *Quadrumana* (apes, monkeys, baboons, gibbons, &c.) are divided between the Old and New World in the proportion of 14 genera and 111 species in the former, to 9 genera and 91 species in the latter, none of the genera being common to both. They are all tropical animals, the great majority being denizens of the torrid zone. One species only, the Barbary ape, is found in Europe (Gibraltar), one only so far north in East Asia as the Isle of Niphon, in lat. 38°; two south of the Orange River, in South Africa, while, in South America, a few extend as far as 38° S. Australia possesses none. The small monkeys, called *makis*, or Prosimiæ (the lemurs, lorises, &c.), are chiefly natives of Madagascar and the neighbouring Mozambique coasts. The ourang-outang is a native of Sumatra and Borneo, and its African congener, the chimpanzee, the most gentle, human, and intelligent of them all, inhabits the forests of south-western Africa between Cape Negro and the Gambia. The brown monkeys of the New World (the sapajous and sajuans) are, for the most part, smaller and less ferocious than the Simiæ of the Old, and differ from them in their system of dentition and the absence of cheek-pouches. Their chief *habitat* is in the forests of Brazil and Guiana.

(387.) The *Marsupials* (or those which carry their young in pouches, including the opossums, kangaroos, wombats, phalangers, &c.) constitute 14 genera, including 123 species. Of these only one genus, the opossum, is found in America, distributed, in 21 species, over the whole continent, from Canada to 36° S. All the other genera belong exclusively to Australia, Van Diemen's Land, and the islands of the Asiatic archipelago as far as Java. In Australia they constitute an immense majority of the mammalian species, in which, with this exception, that singular continent is exceedingly poor. In the islands of the archipelago only seven species are enumerated, among which one kangaroo is said to occur (in Java). In no other part of the Old World are any marsupial animals belonging to this class found living; and if we would seek for indications of them, singularly enough it is in the fossil remains in the oolites of the south of England, the antipodes of the region which they now almost exclusively possess.

(388.) The genera of edentata, or toothless animals (the sloths, armadillos, ant-eaters, manises, &c.), eight in number, are equally distributed between the Americas and the rest of the world; the former, however, being richer in species in the proportion of 20 to 8. The sloths live entirely in trees, chiefly in the Brazilian forests; the armadillos range through Central and Southern America, as far as the 43d degree of S. lat. That rare and most curiously formed little animal, the chlamyphorus, is found only in the provinces of Cuyos, in Mendoza —(*Sir W. Parish.*) The ant-eaters (myrmecophagi) extend no farther south than Buenos Ayres (of which the largest is the M. jubatus, remarkable for his enormous mane). Among the Asiatic and African edentata, the manises, or scaly ant-eaters, have the widest range, being found in Senegal, North-east India, and the Eastern and Southern Asiatic isles. Australia possesses two genera, the echidna or porcupine ant-eater, and that most extraordinary animal, the ornithorhynchus paradoxus; the only mammal which lays an egg. It is found in the Murrumbidgi and other rivers in S.E. Australia.

(389.) Of the 39 species of pachydermata, arranged in 9 genera, none are Australian, one only (the wild boar) European. The elephant is limited to Southern Asia, Scythia, the Archipelago, and Central and Southern Africa; the hippopotamus is exclusively African; the rhinoceros conterminous, or nearly so, with the elephant. The swine and the horse (including the wild ass and zebra) are the most numerous in species of this class, nine species of the former being scattered over Europe, and Asia, three (the wart-hogs) in Africa, and two (peccaries), being South American representatives of this family. The wild ass frequents the deserts and high plateaus of Asia, and the zebra is exclusively African. The tapirs have been already noticed.

(390.) The *carnivora* form a very large class, consisting of 514 species, arranged in 61 genera, and divided, by strong natural characteristic distinctions, into five families, viz., the *digitigrades*, or those clawed beasts of prey, which spring and leap on their prey, and which comprehend, as *cats* (feles), the lion, tiger, leopard, panther, &c.; and as *dogs* (canes) the wolf, fox, &c., and which comprise the most active and formidable. The *plantigrades*, as bears, badgers, racoons, &c., which use the whole lower joint of the leg as their

support, and (in the bear) stand often erect on it as a broad basis. The insectivorous (hedgehogs, moles, shrew-mice, &c.), a family little formidable: the *flying cats*, a small family confined to tropical Asia: and the *bats*. We find by far the majority of species, and, with exception of the bears and wolves, all the larger and most formidable ones, confined to the tropical countries. This is so marked, that, if we divide the world into austral, tropical, north temperate, and arctic (understanding by austral the extreme South America, from 40° S., with Australia and its connected islands), we shall find the *mean density* of species inhabiting each of these *seriatim*, to stand in proportion nearly as follows, viz.:—[1]

Austral,	3
Tropical,	26
North Temperate,	9
Arctic,	7

The disproportion in the southern division would be still greater were it not for the comparatively large proportion of bats found in the Australian and Oceanic islands, the greater number of which, however, it should be observed, belong to the "frugiverous" bats, which only by courtesy of structure belong to the carnivora.

(391.) Among animals of this class a few only can here be specially noticed. The *lion* is found over all Africa, Egypt and the Libyan Desert excepted; and in Asia, only in the districts bordering on the Euphrates, in Persia, and the jungles of India. The *tiger*, whose migrations, as we have seen, take a wide, extratropical range, has its chief *habitat* in the forests and jungles of Bengal, the southern mainland of Asia, Java, and Sumatra. The *puma* ranges over both Americas, from 50° N. to 53° S.; the jaguar is principally found in Brazil and Paraguay. The wolf, though now nearly driven out of the more populous portions of Europe, is indigenous (with its American congeners) over the whole northern hemisphere, from the arctic latitudes down to the tropical ones. The bear is largest and most formidable within the arctic circle, as the white or polar bear, and in the North American forests, as the grisly bear of the Rocky Mountains and Western Savannahs. Within the tropics their species are not numerous, and in the austral region none occur; neither is any species of the *insectivora* native in these regions, though otherwise pretty equally distributed over all the others. The *bats* are chiefly tropical, 55 species occurring in the tropical region of America, 41 in that of Africa, and 67 in that of Asia. Of these the only formidable one is the vampire, a West Indian and South American species, which sucks the blood of animals during sleep, and occasionally of man. The immense numbers of the bat tribe, which suspend themselves, head downwards, in caves in tropical regions; and, when disturbed, rush forth, rendering the darkness hideous with their ill-omened flappings; are always dwelt on with peculiar emphasis by those who have visited such scenes.

(392.) The *Rodentia*, though a very numerous class, will not detain us long. They consist of, 1. *Sciuridæ*; 2. *Muridæ*; 3. *Hystricidæ*; 4. *Leporidæ*, or animals allied to the *squirrel*, *mouse*, *porcupine*, and *hare*, divided as follows:—

	Genera.	Species.
Sciuridæ,	14	169
Muridæ,	47	306
Hystricidæ,	30	99
Leporidæ,	2	46
	—	——
	93	620

Of these genera 44 belong exclusively to America, and 5 exclusively to Australia (the total number of Australian species being only 21, and those confined entirely to the muridæ). Excluding these, the *mean density* of species in the temperate to that in the tropical regions of the globe is the ratio of 16 : 19.[2]

(393.) Among the rodentia the most remarkable are the beavers and the porcupines. The former (classed by a rather strained analogy among the squirrels) are represented in North America by the genus Castor, in Europe by Fiber. This latter form of beaver, within the records of history, inhabited Britain. Of the porcupines, 77 species belong to America, and only 6 to the Old World. The common porcupine is a native of south Europe: we remember to have picked up the quill of one, which seemed to have freshly dropped from the animal, in the immediate neighbourhood of Rome. The flying squirrels are natives of the Malayan peninsula and Java.

(394.) Of all the mammalia, and, indeed, of the whole animal creation, the *Ruminantia* are the most important to man. Of these there are 8 genera and 180 species, divided by Mr Waterhouse as follows:—

	Species.	Old World	New World.
Camels,	2	2	0
Llamas,	3	0	3
Musk Deer,	7	7	0
Deer,	51	37	14
Giraffes,	2	2	0
Antelopes,	48	47	1
Goats,	20	18	2
Sheep,	27	25	2
Oxen,	20	18	2

Of *camels*, the African and Asiatic (or Bactrian) are distinguished by having respectively one and two humps. Both inhabit arid regions, and are singularly provided with an additional stomach for the retention and conveyance of water in their long wanderings in dry places. The *llama* was the only beast of burthen known in Peru in the time of the Incas. It is the American representative of the camel, and has no hump. It is described as the "characteristic quadruped of Patagonia" by Mr Darwin. Among *deer*, the rein-deer is by far the most important, as an animal of wonderful endurance, speed, and docility—the special gift of Providence, as it would seem, to the inhabitants of the regions bordering on the arctic circle. The *cameleopard* is exclusively African; and of its two species, the one belongs to North, the other to South Africa. The *antelope* also, though represented in Europe by the chamois, in America by the prongbuck, and in Asia by eleven other species, is yet, *par excellence*, an African animal, both in respect of the number of the species, and of the countless multitudes of individuals which, in their migrations in search of water, are described as covering the whole surface of extensive tracts of country like the waves of the sea. Among the *goats*, the ibex frequents the loftier regions of the Swiss Alps. The Asiatic species frequent the Taurus mountains and Kamschatka. The *sheep*, domesticated in Europe, would appear to be traceable to Western Asia, where, as well as in Africa, the wild species frequent the more inaccessible mountain districts. Of the two American species, the argoli of the Rocky Mountains is remarkable for the enormous horns of the ram. Among *oxen*, the South African buffalo is wild and ferocious, the Indian domesticable. The American congener, the bison, exists in immense herds on the north-western American prairies,

[1] This estimate is founded on the enumeration of species in particular districts, given in the *Physical Atlas*, and is so framed as to be, as far as possible, independent of overlapping.

[2] These numbers are concluded from Mr Waterhouse's statement of the number of species in the *Physical Atlas*.

from California to 60° N., a huge, ugly, and terrible animal, the very type of blind brute force. It is in rapid process of extermination. The musk-ox is the only considerable ruminant of the arctic region of America. Australia produces no ruminant animal.

(395.) The *Cetacea* are a very peculiar class, numbering among them many forms which never leave the water, and have the external aspect and general attributes of fishes, as the whales, the cachalots, and the narwhals (balænæ, physeters, and delphinidæ), as well as the lamantin of the Orinoco, the dugong, and the porpoises, but they also comprehend two genera of animals, bearing little resemblance to fishes, and which are properly amphibious—the seal (phoca), and walrus or morse (trichecus), the latter of which is exclusively confined to the polar seas, unless drifted southwards on floating ice. The former has a considerably wider range; sometimes reaching the Orkneys and Hebrides, and even the Isle of Wight, where, within our own recollection, a specimen has been captured in Freshwater Bay.

(396.) *Distribution of Birds.*—Six thousand species of birds are said to exist in the Museum of Berlin alone, but of those which are accurately described and classified, and of which the *habitat* is satisfactorily known, the number is much smaller. Not much above half that number are enumerated as such by Mr K. Johnston, and of these the mean densities of species in the several great divisions of the globe, concluded from the data of his enumerations, are, in proportion to each other, as follows, viz.:—

Europe,	15
Asia,	5
Africa,	6
America,	6
Australia and Oceanica,	4

As regards the mean density of species, then, we see that, of these divisions, Europe far exceeds any of the others. As is the case with the mammalia, the mean density of species increases on approaching the equator. The distribution in zones of temperature, calculated on the same principle as before adopted, will give for the several zones the following proportions:—

Northern Frigid Zone,	3
Northern Temperate do.,	8
Northern Warm do.,	5
Tropical do.,	11
Southern Warm do.,	5
Southern Cold do.,	1

Where the abundance of European species is again apparent is the disproportionate percentage of the northern temperate zone, which here includes the whole of Europe. In this statistical view, the *habitat* of the migratory birds is assumed to be that in which they settle during their breeding season. Wide as the range would seem to be which the power of flight gives to birds, they appear to be retained to particular regions, independent of temperature, chiefly, no doubt, by the condition of their finding their appropriate insect and vegetable food; but partly also by local association of another kind, which seems to be strong in this class of animals; since we find instances of migratory birds identified as returning to the same spots for breeding in successive seasons.

(397.) The paucity of species in the arctic regions, both north and south, is compensated, especially in the former, by the multitude of individuals, which, mostly living on fish or other marine products, find there abundant food. Thus we find that even in so extreme a latitude as 80° 17′ N., at Cape Andrew Jackson, Dr Kane reporting, that "never had they seen the birds so numerous. The water was absolutely black with dovekies, and the rocks crowded" with these and with ivory gulls, mollemokes, eider-ducks, brent-geese, &c. In 71° 56′ S. on Possession Island, in like manner we find the penguins assembled in countless multitudes, and fringing every ledge of rock.

(398.) Birds are divided into the orders of Rapaces (birds of prey), Scansores (climbers), Oscines (singing birds and perchers, including the humming-birds), Gallinaceæ (poultry), Grallatores (waders and long-legged birds), and Natatores (swimmers). Of *rapacious* birds, the eagle is the noblest. The golden eagle inhabits the higher grounds of Central and Southern Europe, extending his range across the Crimea to the Caucasus, and being also a denizen of the Scotch and Scandinavian mountains. The condor, the largest of vultures (spanning 15 feet across the wings), soars far above the highest peaks of the South American Andes, but never crosses the isthmus to the northern range. The albatros disdains the land, and sleeps on the wing over the widest extratropical oceans, above which he seldom rises to any great height. Swan-like in apparent size, his wings extend 10 or 11 feet. The vulture of the Old World is a native of Africa and India, and sometimes visits Sardinia.

(399.) Among the climbers, the most beautiful and interesting are the parrots, cockatoos, and lories. They are chiefly tropical, but in South America range to the extremity of the continent, and are abundant in Australia. Birds of paradise are found exclusively in New Guinea and the neighbouring islands, with the Moluccas and Aroo islands. Toucans are confined to the tropical region of South America. The tropical region of Africa is poor in climbers, the species being to those in the corresponding region of America only as 21 to 122, or about as 1 to 6.

(400.) In the number and variety of its singing birds, Europe stands pre-eminent—110 species are especially so characterized; and the total number of birds of this order in Europe is 186. The nightingale (of which there are nine European species) sings, in England, nowhere north of the Tees and nowhere west of Exeter. Whatever the richness of European bird-song, however, North America can produce its single mockbird, the very embodied spirit of woodland melody (a native of Louisiana and Carolina), which, besides possessing an unrivalled song proper to itself, imitates in perfection, and even surpasses, that of every other species. The humming-birds also belong to this order. They are chiefly restricted to tropical America, but a few species range very widely. One has even been found on the shore of Behring's Straits, in 61° N., and others in Terra del Fuego, flying about in a snow-storm; so that, so far as climate goes, there is no reason why they should not be naturalized in Europe. In the Cape Colony they are represented by the "Sugar-birds."—(Certhia).

(401.) Of *Gallinaceous* birds, the peacock is a native of India; the pheasant is indigenous through Asia, from the Caucasus to Sumatra. That beautiful bird, the Argus pheasant, is a native of China, and the lyre-bird, the most elegant of the whole order, is the Australian representative of the pheasant family. The turkey, in its wild state, is peculiar to North-west America. The pigeon family is equally indigenous, both in the Old and New World, there being 6 European and 8 American species. They are found in countless myriads in the North American forests, where, in congregating to roost, they cover every tree, over large tracts, to crowding, and even break down great limbs by their weight, producing all the havoc of a storm. Flocks, consisting of millions, pass, twice in the year, over Canada and the northern states in their migrations north and southward. The dodo, a large galli-

naceous bird of Madagascar, which has become extinct within the memory of man, is considered, from the structure of some of its bones, to have been a gigantic pigeon, too heavy for long flights, and thus, as in a similar case in the Isle of Rodriguez (that of the solitaire), to have fallen an easy prey to man.

(402.) The order *grallatores* or waders, besides storks, flamingoes, herons, &c., which really wade, is made to take in many long-legged birds which frequent the dry places of the earth, as the ostrich, the emu, the cassowary, &c. The two-toed ostrich, the largest existing bird, is at present nearly confined to Africa, in the Old World, being, however, represented in South America by the three-toed ostrich Suri or Tuju (Rhea). Though unable to fly, its wings assist it in running, in which it is the fleetest of animals. In ancient times, its range extended through Asia Minor, Persia, and South Asia, to the farthest East, but it has become exterminated except in Arabia. The cassowary, which has hair for feathers. inhabits south-east Asia, and the Indian archipelago, as far as New Guinea. The emu (remarkable for its long, narrow double feathers) affords another instance of the singular bizarreries of Australian organization, as does also the Deinornis of New Zealand, which should it be (as is barely possible) not yet entirely extinct in the unknown interior of the Australian continent, must take the precedence of the ostrich as the giant of living birds, its skeleton standing 11 feet in height.

(403.) To the *swimming* birds belong the swan (which in Australia is black), the pelican, the eider-duck, and the penguin, besides innumerable geese, ducks, &c., which people the colder lakes and sea shores of Arctic Asia and of Northern America. Of 112 European species, 44 belong to this family, and 33 to the gulls. The pelican is a native of Eastern Europe, and is not uncommon on the Danube, and very common in Africa, in the tropical islands of Asia, at Siam, and in China. It occurs also, very widely diffused, in North America, and even in South Australia, so that it is one of the most widely distributed of birds. The eider-duck is exclusively confined to the northern seas, though it has been known to breed as low as the coast of Northumberland. The penguin, on the other hand, haunts the desolate islands of the South Seas, the Straits of Magellan, and the Falkland Isles, and is unknown in the northern hemisphere.

(404.) *Distribution of Reptiles.*—Of the 1000 or 1500 species known to exist, those described and well ascertained as to *habitat* amount to 657, divided into families and genera as below, viz.—

Families.	Genera.	Species.
Testudines (tortoises),	3	69
Sauria (lizards),	9	203
Ophidia (serpents),	9	265
Batrachia (frogs),	5	120

And the proportions (in respect of the mean densities of species) in which these are distributed over the great divisions of the globe, and the zones of temperature are these, viz.—

Europe,	3
Asia,	5
Africa,	5
America,	8
Australia and Oceanica,	3

And in zones, in the proportions (*inter se*) of the numbers :—

Temperate,	11
Tropical,	29
Austral,	2

It is chiefly to the forests and swamps of Brazil and Guiana, which swarm with reptile life, that the marked disproportion between America and the other divisions of the globe is owing. The tortoises (including the turtles) are almost entirely tropical, very few land species existing anywhere beyond 30° or 40° of latitude, and the turtles frequenting only the tropical seas. The alligators or caymans occupy tropical America, frequenting the rivers from 30° south to 32° north. Of these, some species during the dry season bury themselves in mud, and remain encrusted and torpid till the first rains, when they at once start up, shake off their crust, and rush down to the first indication of a stream. Humboldt was, one rainy night, surprised by such a resurrection of one, over whose dormitory he had unknowingly made his own. The true crocodile is African and Syrian, and is found in the Nile and in all the rivers of tropical Africa, as well as the Euphrates. The gavial infests the Ganges. Chameleons abound in Africa, both north and south, and are even found occasionally in Spain and Italy. The iguana is eaten in the West Indies and in Central Africa (Livingstone), and considered very delicate food. Among the frogs, the most remarkable seem to be a species, called Matlametlo, described by Dr Livingstone as inhabiting the Kalahari district of South Africa; whose instincts, like that of the cayman above mentioned, excite him from torpor on the first symptom of rain, and one of which furnishes an excellent repast. In the case of the Surinam toad or pipal, the female hatches her eggs on her back, the young from which, when produced, bury themselves in her skin, and there undergo their transformations. This toad is 8 inches, and the bufo agua of Brazil 10 or 12 in length.

(405.) Of 265 known species of serpents, only 58 are venomous. The serpents of America are, without exception, *specifically* different from those of the Old World; and in the latter, they are entirely absent in all the Pacific islands, while in those of the Indian archipelago they abound, though with singular and capricious exceptions. Thus in Java 56 species occur, in Borneo not one; in Australia 10, 7 of which are venomous. Of 6 species found in Japan, none exist elsewhere. In no class of animated beings is the localization of species so marked. In general, however, in common with nearly all others, the abundance of species increases with proximity to the equator. Sea serpents, of which 7 species are known, all venomous, are found only in the Indian Ocean, and the seas of the Indian and Oceanic Archipelago. As regards particular and remarkable serpents, the rattle-snake (Crotalus horridus) is North American, where it represents the European viper. The cobra-capello, or hooded snake (the dancing snake of the Indian jugglers) is common everywhere, from Malabar to Sumatra. The boas are peculiar to the tropical forests of South America; their representatives in the Old World, the pythons (one species of which attains 20 feet in length) range over North Africa, through tropical Asia, to China and Japan. This snake (which is not venomous) is probably that which gave rise to the extravagant exaggeration, in the accounts handed down to us, of Regulus's invasion of Africa. Lucan's description of the serpents which annoyed Cato's army is not less extravagant. Africa, in fact, as regards species, is not comparatively rich in serpents.

(406.) *Distribution of Fishes, Molluscs, and the Lower Aquatic Organisms.*—The *habitat* of Fishes, like that of land animals, is necessarily limited by the condition of their supply of appropriate food, as well as by that of an appropriate temperature, which for them is that of the surface water, since very few fishes are capable of sustaining the pressure of a greater depth of water than a

100 or 150 fathoms, and in these the air-bladder is either entirely absent or in an imperfect or rudimentary state of development, such an apparatus being useless under the heavy pressure of 20 or 30 atmospheres. The way in which surface temperature may set a limit to the excursions of marine animals, even those of the widest range, is curiously exemplified in the case of the whale. The "right whale" (Balæna mysticetus), according to Lieutenant Maury, is incapable of crossing the equator, and the whales of this class taken in the Southern Ocean are specifically different from those of the Arctic and North Seas. Yet, as we have seen (art. 49), the temperature of the tropical seas is superficial, and at a depth of two or three thousand feet would be so much mitigated, that but for the necessity of rising to the surface for air, which is common to all cetacea, there is no reason why he might not pass, since the whale habitually plunges down to immense depths, and seems quite unaffected by a pressure sufficient to "waterlog" the wood used in constructing whaling boats.

(407.) The ultimate food of such fishes as do not prey on one another is either the soft parts of marine vegetables, or such animal organisms of inferior orders as either draw their food from these, or extract it chemically from the water. Such are, of course, far more abundant, or at least more varied, in the neighbourhood of the shores, or upon shoals affording marine vegetation, or the estuaries of rivers bearing supplies from the land; and it is therefore to the vicinity of these that a very large portion of fishes is confined. The widest oceans, it is true, abound in organic life at and near their surfaces. Even in very cold latitudes countless millions of creatures of the genus Beroe exist, and others of a larger size, medusæ (or jelly fish), zoophites, &c., swarm to such an extent, as to convert the surface water in some places almost into a kind of soup, which furnishes food not merely to small fish but to cetaceæ of the largest growth; and in tropical regions the sea teems with minute forms of animal life in infinite variety—small mollusca, crustacea, and luminous creatures, as salpæ, pyrosomas, &c., many of them gelatinous; and where the sea is covered with floating weeds, these become the haunts of a numerous population of species, crabs, sea-slugs, &c., peculiar to them. Thus, whatever be the distance from shore, food is not wanting for such fish as are fitted for its assimilation, and the fish of prey (as is also the case with land animals) are confined by no limits but those which temperature sets to their range.

(408.) The cetacea are not properly fishes, but belong to the class of mammalia; and inasmuch as many of them breathe air, and are obliged to come to the surface for its renewal, border on, and, in the cases of the seals and walrus, really are *amphibia;* in those of the lamantin and dugong, nearly such (art. 395). The larger whales, as a family, have a very wide range, and some of the species are found in almost every sea. The Balæna mysticetus, as we have seen, does not appear between the tropics, nor does the narwhal, which is specially arctic. The Rorqual (which furnishes whalebone, and is said to attain 100 feet in length) is a denizen of high latitudes (70°—80° N.) The Cachalot (Physeter macrocephalus), on the other hand, does not visit the colder seas, but wanders over the whole of the temperate and torrid ocean, affecting always the central and deepest parts. The grampus, porpoise, and dolphin occur in almost every sea.

(409.) Among fishes of prey, the sharks, though not confined to the tropical seas, are there by far most abundant. Some occasionally visit our own seas. The largest of the family (Squalus maximus), the Basking Shark, visits pretty high latitudes. It has been seen off the north-west coast of Scotland, where it has been taken for the "sea serpent." It attains 50 or even 60 feet in length, and one of the former size was lately taken at Kuraci, at the mouth of the Indus. Happily its voracity is not in proportion to its size, as it lives chiefly on medusæ and sea-slugs, small fishes, &c.

(410.) The localization of those fish which live near the shore, and furnish the principal part of the marine contribution to human food, is often very limited, and we find almost as many littoral "provinces" of fish as there are lines of coast characterized by some common feature either of soil, rivers, or climate. In general it may be noted as a universal feature that the colder waters furnish those species best fitted for food, and that even in the same species the individuals taken in cold waters are far superior in flavour and nutritious quality to those in warmer seas. According to Lieutenant Maury, the excellent fish with which the Atlantic cities of the United States are supplied owe all their value to the stream of cold water which sets down the coast out of Baffin's and Hudson's Bay, between it and the Gulf Stream (art. 55.) "The 'Sheep's-head' (? species), so much esteemed in Virginia and the Carolinas, when taken on the warm coral banks of the Bahamas, loses all its flavour, and is held in no esteem. The same is the case with other fish. When taken in the cold water of that coast they have a delicious flavour, and are highly esteemed; but when taken in the warm water on the other edge of the Gulf Stream, though but a few miles distant, their flesh is soft, and unfit for table." "A current of cold water from the south sweeps the shores of Chili, Peru, and Columbia, and reaches the Gallapagos Islands under the line" (art. 64.) "Throughout this whole distance the world does not afford a more abundant or more excellent supply of fish. Yet, out in the Pacific, at the Society Islands, where coral abounds and the water presents a higher temperature, the fish, though they vie in gorgeousness of colouring with the birds, plants, and insects of the tropics, are held in no esteem as an article of food. I have known sailors, even after long voyages, still prefer their salt beef and pork to a mess of fish taken there" (*Phys. Geog. of the Sea*, p. 55.)

(411.) The phenomenon of coloration referred to in the last sentences of the above extract is a general one. The arctic and northern fishes have little colour, and as the zones of temperature ascend in the scale towards the equator, the species, not only of fishes, but of all marine animals in all seas, become more highly and more variously coloured. The brilliancy of colour of the fishes, shells, and sea-weeds of tropical, and especially of the Indian and the Caribbean Seas, is spoken of with admiration by every voyager, and is enhanced by the purity of the water in those bays and recesses which are kept clean and scoured by the indraft of currents from the deep ocean.

(412.) A bare enumeration of the several "littoral provinces" of marine life (and our limits would allow little more) would be of small interest, and it will suffice to observe that, with exception of arctic forms, which have a common origin in the polar seas, and are, therefore, propagated downwards in both oceans, scarcely any forms of littoral marine life are specifically identical in the Atlantic and the Pacific, and that even on opposite sides of the Atlantic itself but few species are common to both.

(413.) Of migratory fish, some resort to rivers to spawn. The principal of these is the salmon, which is found in most of the rivers of cool temperate coasts down to the 45th degree of latitude; and so definite are the habits of the fish in this respect, that in adjacent rivers, on the N.W. coast of Ireland, abounding in salmon, the fish of each river are known to the fishers by some peculiarity sufficient to ground a recognized claim on the

part of one proprietor to fish accidentally straying into the precincts of another. On the other hand, such fish as migrate seaward, as the cod, the herring, and the pilchard, appear to be driven southward by the cold of winter, or by the failure of their food resulting from it, and descend in immense shoals, and at fixed periods, like the birds. Thus the cod arrives annually on the banks of Newfoundland, along the cold current inside the Gulf Stream, and also in the North Sea, descending by the coast of Norway in February to the Dogger Bank in shoals so dense that the sounding-line can hardly pass between them. The herring also visits our coasts in winter, its migrations being very definitely limited to water of a certain precise temperature, a circumstance which, taken in conjunction with the fluctuations known to exist from year to year in the limits of the Gulf Stream, and the surface-drift currents from the S.W. (art. 55), may serve to explain the seemingly capricious desertion of certain bays and haunts of these fish in some years, and their appearance in others not previously frequented by them.

(414.) About 853 species of European fishes have been described, of which 643 are marine, 210 live entirely in fresh water, and 60 of the marine species resort to fresh water to spawn. Of the marine species 444 inhabit the Mediterranean, 216 are found off the British coasts, and 171 are peculiar to the Scandinavian seas.

(415.) It would be wrong, in speaking of fish, to omit all mention of that remarkable and very curious power manifested only in this class of animated beings—the power of giving forth a voluntary electric shock. This is possessed by several distinct species: among sea-fish, by the torpedos, four species of which are found in the Mediterranean, and others in the Indian seas. They occur also in Table Bay at the Cape of Good Hope. The Isle de Rhe, on the French coast, is remarkable for the frequency of the occurrence of one species. The Gymnotus electricus, whose shocks are most formidable, and even dangerous, is a species of eel which inhabits the Orinoco, but is more common in pools and marshes on the eastern bank of that river. It is also found in other rivers of the eastern part of South America; and Humboldt calculates that each square league of the Planos de Caracas contains two or three ponds filled with these creatures. It is caught also in Guiana.

(416.) The distribution of the marine mollusca and other animals of the invertebrate classes is very powerfully influenced by the element of vertical depth. In that of vegetable life we have seen how increase of altitude in the air acts with all the influence of increased latitude, as bringing the plant into a colder region; but the influence of depth in marine life is one of a quite different kind. As regards temperature, no doubt the water in the shallow sea-bords is subject to diurnal and annual fluctuations of temperature to a considerable extent, though much less than the air, and this affords a condition of existence which cannot but be very influential in determining the species which can exist at the extreme borders of the sea. But the amount of this fluctuation diminishes very rapidly with the depth. Not so, however, another very important element of all life, viz., light. The light which penetrates to great depths is not merely much less in quantity, but very different in its photo-chemical qualities, from the entire solar light of the surface, and this, though at present we are ignorant of the mode and laws of its agency on the animal economy, we are very sure is an element of exceeding importance. The food, &c., afforded by submarine vegetation is different—the texture and constitution also of the sea-bed, as consisting of finer particles carried out far to sea, affects its quality as a nidus for habitation; so that we find the zones of habitable depth in the water to succeed one another with far greater rapidity, and to be confined within far narrower limits than those of atmospheric altitude on land.

(417.) Professor E. Forbes, to whose researches we owe a very large portion of our knowledge of this part of natural history, has discriminated the zones of depth affected by marine animals into, 1*st*, Littoral, between high and low water-marks—a zone which might, *à priori*, be expected to be very strongly characterized, as we find it to be, by species capable either of maintaining an active existence in air as well as water, such as crustaceous animals, crabs, &c., of various families, or of such testacea and shell-less animals as close themselves up, or seal themselves hermetically on the rocks, and remain dormant during the recess of the water, of which the patellas, mytili, littorinas, purpuras, &c., and, among the zoophites, the common sea anemone, afford examples: 2*d*. The "circumlittoral zone," with a depth from low-water mark to about 15 fathoms. 3*d*. The "median zone," from 15 to 50 fathoms. 4*th*. The "infra-median;" and, 5*th*. The "abyssal zone," the former from 50 to 100 fathoms, the latter from thence to the lowest depth at which life is possible, which in some of the minuter forms would seem to include almost the lowest deeps that the sounding-line has reached (see art. 118). Each of these zones is characterized by species which belong to no other, and each passes into the other by the intermixture of species common to several. It would carry us quite beyond our limits to enumerate these, and without specific detail the mere enumeration would afford no instruction. Suffice it to observe, that in these, as in other departments, proximity to the tropics carries with it increase in the number and variety of species and genera, greater development in size, form, and colour. The shells of the Indian Seas, and the Eastern Archipelago in particular, are prized not merely by the zoologist as illustrative of animal organization, but by collectors for their exceeding beauty, brilliancy of colour, and elegance of form. It is in these seas also that the pearl fisheries are conducted, the true pearl oyster being confined to them, though pearls of inferior quality are produced also by certain species of mytilus; and Suetonius has recorded that Cæsar's first idea of invading Britain arose from the report of pearls being found on its coasts (*Britanniam petiisse spe margaritarum*). The depth, moreover, has quite as marked influence on the colour of shells as the warmth of the water on the flavour of fish. Below the level, where light can penetrate copiously, the colours of shells wax faint and dilute, and even individuals of the same species taken at different depths exhibit a marked difference in their intensity of colour. The circumlittoral zone, it may be generally observed, is that of the reef-building corals (art. 87), of star-fishes, sea-urchins (Echini), and cuttle-fishes—the medial of sponges, corallines—the infra-medial of the deep-sea corals—and, in particular, of the valued red corals of the Mediterranean. As respects all the zones, also, it is remarked by Professor Forbes, that as we descend, the regions of depth characterized by the same species become of greater extent, *and the range of species (in a horizontal direction) wider.*

(418.) *Distribution of Insects.*—All nature seems to swarm with insect life; but here, as in all departments of natural history, we find fewer species inhabiting the colder regions; and their maximum of development, both in variety, richness of ornament, and what may be termed *intensity of quality*, is found in the hottest countries. There it is that the greatest singularity of form and habit, the greatest pungency of bite, and every other mode of insect annoyance, are found in perfection. The only exception

seems to be in the case of coleopterous insects, which are specifically more abundant in temperate climates.

(419.) According to Mrs Somerville, the rate of increase of insect life, in proceeding from either pole to the equator, is very various in different longitudes. Their numbers are small in both the polar regions—more abundant in Tasmania and New South Wales—more so in Southern and Western Africa, Columbia, and a maximum in Brazil; but North America has fewer species than Europe in the same latitude; and Asia is comparatively poor in species, in proportion to its great extent. The horrors of insect annoyance in the swamps of the great rivers of tropical America are vividly described by Humboldt. The air is one dense cloud of poisonous insects to the height of 20 feet. In Brazil the vivid colours and metallic brilliancy of many of the beetles is extraordinary. Among the more remarkable varieties of insect life deserve special mention, 1*st*, the bees and ants. Of the former each country has peculiar species; but it is singular that the honey bee of North America has been introduced from Europe.[1] The ants, of which the species are almost innumerable, are found chiefly in hot and dry climates, and are, perhaps, of all insects the most remarkable in their habits. The termite of tropical Africa builds pyramidal nests ten or twelve feet in height, hollowed into chambers of elaborate structure. The white ant of India devours everything of animal and vegetable origin, ascending by covered galleries (for they cannot bear the light) to the sap of furniture, beams, &c. But perhaps the most singular species of all is that of the parasol ants of Trinidad, in the West Indies, which walk in long procession, each carrying a cut leaf over its head, as a parasol, in the sun, and these they deposit in holes 10 or 12 feet deep under ground, apparently with no other object than to form a comfortable nest for a species of white snake, which is invariably found coiled up among them on digging out the deposit (Mrs Carmichael's *Domestic Manners, &c. &c., in the West Indies*, ii. 327). The scorpion extends in Europe to the north coasts of the Mediterranean, but is more abundant in Africa, both north and south, where its bite has the singular peculiarity, that, although excessively painful on the first occasion of its infliction, and even dangerous to life, the constitution becomes hardened to it, the suffering is less on every subsequent occasion, and at length comes to be little regarded. Brazil produces a scorpion six inches in length. The locust, one of the most formidable scourges in countries infested by it, migrates in such masses as to darken the air for successive days, and when driven into the sea is sometimes thrown up as banks on the shore, poisoning the air by their decomposition for many miles in length. They are frequent in Syria and Barbary, whence they occasionally migrate to Italy, and within this last summer (1858) several individuals have even been taken in England, and one or two in London. They are even said to cross the Mozambique Channel from the African coast to Madagascar.

(420.) *Fossil Organic Remains.*—Buried in the strata of which the earth's crust is composed, we find in every part of the world, and in all the strata properly so called (excluding thereby granitic and other igneous formations, and the metamorphic rocks in which the evidences of stratification appear to be obliterated by partial fusion, or softening at least, by heat), either the actual harder exuviæ, such as shells, bones, scales, &c., or impressions of the softer and more destructible parts of animals, and the remains of vegetables silicified or otherwise fossilized, affording evidence of the abundant existence of organic life in every stage of the world's history. It is only in the newest and most superficial strata, however, that we find imbedded the remains of any species, either animal or vegetable, now existing in a living state, and these consist almost exclusively of the shells of marine and some freshwater mollusca. As we go deeper in the order of stratification, existing species rapidly become rarer, existing genera thin out, and we find ourselves very soon landed in an order of things where the Fauna and Flora have nothing in common with the present, or rather in a succession of such (art. 11).

(421.) The strata in which we find this gradually decreasing community of organic life with that now in existence, are those which lie wholly above the chalk formations, and which have been termed by Sir C. Lyell, Tertiary, drawing the line between these and the secondary deposits at this point, and they have been subdivided by him into three stages or epochs, the Pleiocene, or that *more* nearly approximating (πλειων) to the present *new* state (καινος); the Meiocene, or that *less* recent (μειων), or in which the number of species, common to them with the present epoch is less; and *Eocene* (ἠως), that in which, as it were, only a *dawning* of the present state is visible. The upper of these three has been subdivided into *older* and *newer* pleiocene or pleistocene, that which approaches nearest, by the abundance of fossilized species identical with living ones, to the modern state. Now in these, if we reckon only the fossil shells as compared with those recent, we find, according to Sir C. Lyell, in the newest or pleistocene strata, nearly 96 per cent. of recent, and only about 4 per cent. of extinct species; in the older Pleiocene, the recent species still predominate, varying from 50 to 66 per cent. of the whole number, while in the Meiocene, the proportion falls already as low as 18 per cent., and in the Eocene, does not exceed 3½.

(422.) In the strata forming under our eyes, in estuaries, lakes, and shoal deposits, of course the remains of all existing animals and vegetables become imbedded; but already in the Pleistocene strata an immense majority of the existing mammalia and birds has disappeared, and those few species which can be identified with now existing ones are confined mainly to the *very newest* of these formations, designated by some geologists as Post-pleistocene, or in "Bone caverns" in some of the older formations still open to day, and which have served as dens for carnivora, or places of refuge for other animals during all that period which may have elapsed since those formations were raised above the ocean. It is in the Pleistocene and these Post-pleistocene beds that we find the remains of a few terrestrial animals which have become extinct during the present geological epoch, and which either certainly have, or may reasonably be presumed to have, been contemporary with man, such as the Dodo, and the Solitaire (art. 401), the Deinornis of New Zealand (art. 402), six species of which have been discovered, and Opyornis of Madagascar, second only to the Deinornis in size, whose *egg-shell* has been found equal in bulk to six of that of the Ostrich, and which has only recently become extinct. Such also are those remains of gigantic elephants (art. 220) preserved in ice in Siberia, the Mastodon of North America, so slightly covered as to have been known to the aborigines, and to have given rise to obviously fabulous and mythological traditions of its contemporary existence,[2] those gigantic Sloths of the Pampas of Brazil (art. 238)

[1] We take this fact on the report of Mrs Somerville (*Phys. Geog.*, p. 307), but is there not some mistake? At all events, the search for wild honey has, from the earliest settlement, been a feature of American forest life, but the indigenous species is, perhaps, undomesticable.

[2] At Bigbone Lick, in northern Kentucky, the *contents of the stomach* of the Mastodon Giganteus have been found, consisting of crushed branches, leaves, and a species of reed now well known in Virginia (De la Beche.—*How to Observe*, p. 365).

and the fossil Elks (Cervus Megaceros) of the Irish peat mosses, which are found in soft muddy deposits just below the peat, where they would seem to have perished by becoming embogged, a group of eleven of their skeletons having on one occasion been discovered in a standing position, and without signs of violence.

(423.) If we take in the whole range of the tertiary formations, we embrace nearly the total extent in time of the full development of Mammalian existence, as well as that of birds, though the latter would seem (as might indeed be expected from their power of migration and readier escape from destructive events, to take a somewhat wider range through past time than the others. In the cretaceous strata we find no mammals, and only a few indistinct vestiges of one or two genera of birds. Below the chalk in the Oolitic beds (art. 387) only two or three genera of Marsupial animals have been detected, and the footprints of birds even as low as the Permian series; while, on the other hand, we find in the Eocene formations, enumerated by Prof. E. Forbes, 25 genera of mammals and 8 of birds; in the Meiocene and Pleiocene, 81 genera of mammals, and many birds of existing genera, and in the Pleistocene and Post-pleistocene, no less than 88 extinct mammal generic forms, besides those still existing, and among the birds, many of the now existing *species*.

(424.) The distribution of these extinct forms over the globe affords matter of highly interesting and important remark. A marked and almost complete separation subsists between the fossil Faunas of the Old World, America, and Australia; while, on the other hand, subject to that condition, the range of genera and species within those limits appears to have been much wider than it is at present. And what is still more striking is the fact, that the types which, in their several divisions, are more especially characteristic of them in the recent epoch, or what is equally so, the absence of particular types, are found no less to prevail in the fossil Faunas. Thus Australia is especially characterized (art. 387) by the exclusive prevalence of the marsupial type, which is altogether absent in other parts of the Old World, and represented only by a single genus in the New. And in its fossil Fauna we find an equally striking prevalence of the same singularity. According to Professor Owen, whose views in this and the following articles we adopt from the striking address pronounced by him from the chair of the British Association at Leeds, on the formations of the more recent tertiary periods, and in the limestone caverns of Australia, abundance of mammalian fossils have been found, but *except a single tooth of a mastodon*, all of marsupials. Among them are fossil kangaroos, potoroos, wombats, dasyuri, &c., equalling the lion and leopard in size, a wombat (phaseolomys gigas) equalling the tapir, and others of peculiar characters, rivalling the ox and rhinoceros in bulk. The skull of one of these great marsupials (the nototherium) from the "Darling Downs," presents the strangest peculiarities hitherto seen among mammalia; and that of the diprotodon, from the same locality (remarkable for two large and strong tusks projecting horizontally, straight forward from the lower jaw), is hardly less extraordinary. On the other hand, Europe, Asia, and Africa have not offered a single marsupial fossil in the pleiocene and pleistocene deposits, and those in America are limited to the genus didelphis (opossum), species of which at present exist there. In the meiocene and eocene deposits, however, didelphidæ are found both in France and England (from which it would seem reasonable enough to conclude that in those periods a land communication existed between the continents).

(425.) The distinction between the fossil Faunas of America and the Old Continent is not less marked. "All the fossil remains of quadrumana in the Old World belong to the family (Catarhina), which is still exclusively confined to that great division of dry land;" but the quadrumanous fossils of the New World exhibit exclusively platyrhine forms—those, *i. e.*, of a family peculiar to South America, among which is one larger than any now known to exist, found in Brazil.

(426.) So again of the camels. The camel and dromedary, the two European genera of that family, are represented in America by genera (the llamas and vicugnas) characteristically distinct. And the fossil camels of Asia are referable to the same type (camelus) as those there now existing, while those of America belong to the llama type (auchenia).

(427.) The giraffe and hippopotamus are at present African. Fossil remains referable to these families are, however, found in the pleiocene strata, both of Asia and Europe, but none have been met with in the New World; neither has any form of rhinoceros been discovered in its strata, though Europe, which is now deprived of that form, anciently possessed several species, one destitute of the nasal horn, and three provided with two of those weapons, one of these being fur-clad, adapting him for a cold climate.

(428.) As regards the elephant family, the case is somewhat different. This family, according to Professor Owen, has been more "cosmopolitan" than any other hoofed herbivorous quadruped. Yet even here the distinction between the Old and New World type is by no means obliterated. Especially corresponding to the representative of the elephant in America is the mastodon. Of elephants we have *now* an African and an Asiatic species, and no American. But while we find in a fossil state one North and two South American mastodons, and one elephant at least, it appears that double that number of species, both of elephant and mastodon, all specifically distinct from each other and from the American, inhabited Europe during the pleiocene epoch. Of these elephants, the largest ever found, which appears, by the only remaining bone, to have been of at least twice the *linear* dimensions of the large mastodon exhibited in the British Museum, was found in making a railway cutting, in the Valley of the Thames, at Grays, in Essex, through the upper pleiocene. The skeleton, when found, was nearly complete, but was *broken up* by the workmen. and sold as bone manure to a neighbouring farmer, one only metatarsal bone finding its way to our national collection! In further illustration of this wider range of the elephant family in past epochs, Professor Owen observes, that not only China (in which at present there are no elephants), but even Australia (witness that single tooth before alluded to) has furnished evidence of the fact.

(429.) The distribution of fossils of the class of edentata furnishes additional evidence of the same laws. The manis or pangolin of Asia and Africa corresponds in South America to the ant-eaters; and at present neither does the one form exist in Europe nor the other in North America. In the European tertiary beds, however, a large pangolin has been discovered, while the domain of the armadillos and sloths, as well as the ant-eaters, in the same geological epochs, is now ascertained to have extended over North as well as South America, though still confined to that continent. Their present peculiar *habitat*, however, Brazil; and the neighbouring regions of South America, were then, as now, the head-quarters of the family, the sloths being represented by the gigantic genera of megatherium, megalonyx, mylodon, &c., (of which the megalonyx, an animal as large as the rhino-

ceros, ranged at least as far north as Virginia), and the armadillos by the glyptodon, hoplophorus, pachytherium, chlamydotherium, &c. The mylodon, an animal of the most enormous strength, and which probably lived by uprooting large trees and feeding on their branches, though found near Buenos Ayres, was probably floated down by the Parana or Uraguay; but the glyptodon, which was discovered by the horse of a gaucho striking his hoof through its huge carapace (Parish, *Buenos Ayres*, &c., 222), must have lived and died on the spot during the recent epoch.

(430.) One of the most remarkable features of the Mammalian fauna and birds of the tertiary world is the gigantic size attained by many of the species. Several instances of this have been noticed in the preceding articles, and many more might be added; in particular, the Deinotherium, the largest of terrestrial mammals, a creature 18 feet long, with two enormous tusks curving downwards from the extremity of the *lower* jaw. This animal has been of wide distribution, during the Meiocene period, having been found in strata of that age at Eppelsheim, in Hesse-Darmstadt, in France, Switzerland, and the Sivalik Hills in India; several reasons exist why, supposing all the species of a genus to have been at one time coeval, and to have ranged to the utmost extent to which the then existing impassable barriers restricted them, the larger species should have died out first, and the limits of the genus (especially it of non-migratory habits) have become restricted. "In proportion to its bulk," observes Prof. Owen, "is the difficulty of the contest which, as an organized whole, the individual of such species has to maintain against the surrounding agencies, which are ever tending to dissolve the vital bond, and subjugate the living matter to the ordinary chemical and physical forces. Any changes, therefore, in such external agencies as a species may have been originally adapted to exist in, will militate against that existence in a degree proportioned, perhaps, in a geometrical ratio, to the bulk of the species. If a dry season be gradually prolonged, the large mammal will suffer from the drought sooner than the small one; if such alterations of climate affect the quantity of vegetable food, the bulky Herbivoræ will first feel the effects of stinted nourishment. If new enemies be introduced, the larger and conspicuous quadruped" (and we may state the more helpless birds, if provided with none, or only rudimentary wings) "will fall a prey, while the smaller will conceal themselves and escape; smaller animals are also usually more prolific than larger ones. The actual presence, then, of small species of animals in countries where larger species of the same natural families formerly existed, is not the consequence of any gradual diminution of size of such species. . . . . . The smaller and feebler animals have bent and accommodated themselves to changes, which have destroyed the larger species."—*Zool. Trans.* iv., p. 15.

(431.) *Bone Caves and Osseous Breccias.*—The caves noticed in art. 420 exist in great abundance over most parts of the world in which limestone, of whatever age, abounds (art. 197), and they are peculiarly important in respect of this inquiry, by reason of the vast abundance and variety of fossil remains they contain of animals, which we may be assured inhabited the surface while they were open and accessible. The most remarkable of such caves in Britain, are the Kirkdale cave in Yorkshire, examined by the late Dr Buckland, Kent's Hole near Torquay, the cave of Paviland or Goat's Hole near Swansea, and that of Yealm Bridge near Plymouth. In Belgium such caverns occur at Chockier near Liége. In France we find the Grotte de Fouvent, and the caverns of Miallet near Anduze (dep. du Gard) in dolomite, that of Bize (dep. de l'Aude), those near Lunel-viel (dep. du Herault), and the Grotte d'Osselles near Besançon. In Germany a tract of country nearly 200 miles in extent has been pointed out by Cuvier as full of such caves, and those of Gaylenreuth are particularly celebrated for the number of extinct bears, hyænas, &c., they have yielded, and for the singularly inaccessible situation (at present) of some of them. In Sicily several bone caverns have been examined within a few miles of Palermo. But perhaps those that have yielded the most striking results are the Brazilian bone caverns examined by Mr Lund, and others which have been found full of those strange and wonderful forms which especially characterize the South American fossil fauna, large Amadillos, Glyptodons, Megatheria, Scalidotheria (nearly equalling the rhinoceros in bulk), &c.; and those in Wellington Valley, 200 miles N.W. from Sydney in Australia, where were found the principal among those extinct marsupials above mentioned.

(432.) In these bone caves, not unfrequently two or three layers of bones, separated from each other by stalactitic floorings, are found; and when this is the case, the upper usually contains remains of living, or *very* recently extinct species, and not seldom human skeletons. But wherever this has been the case, there has also been reason to conclude, from circumstantial evidence, that the caves have been used as places of sepulture or of refuge; and though, in many instances, such remains are doubtless of great antiquity (using the term as referring to human history), there has never been discovered any fossil human bone so embedded in even the most recent geological *stratum*, other than the merest superficial alluvium, as to afford the slightest ground for believing the earth to have been inhabited by man during the epoch of its formation. On penetrating through the stalactite beneath the first loose layer of bones, the species found in the lower beds are usually found to belong to genera of earlier epochs.

(433.) Not less remarkable than the accumulation of bones in caverns, is the frequent occurrence in all parts of the world of osseous breccias, or beds of bones either reduced to fragments or entire, cemented together by calcareous stalactite. Such are found in great abundance all along the north coast of the Mediterranean—at Gibraltar, Montpellier, Nice, &c. Some of the Greek isles, too, as Cerigo, abound in such breccias, the bones from the latter being crushed and comminuted in the most extraordinary manner. To any one who reflects on the destructive effects of sudden inundations, in sweeping away and drifting together the drowned carcasses of tens or hundreds of thousands of animals (as recorded in the floods of the South American rivers), the causes of such accumulations will offer no difficulty.

(434.) Among the Mammals of the earliest tertiary or eocene period, the most remarkable are those discovered by Cuvier in the Lacustrine formations of the Paris basin, and especially in the gypsum quarries of Montmartre, scarcely a block taken from which does not disclose some fragment of a fossil skeleton. Here, among extinct species of extinct genera, we find the Palæotherium, Anoplotherium, Cheropotamus and Adapis, and among extinct species of genera still existing, bats, wolves, racoons, genettes, dormice, squirrels, and several birds, besides a small didelphis allied to the American opossum. The Deinotherium belonged to the Meiocene, and the Machairodon to that and the Pleiocene, the latter being a genus of very wide distribution, species of it having been found at Buenos Ayres, in Britain, in France, in Germany, and in the Sivalik hills in India.

(435.) Among the fossils of the tertiary epochs, occur many reptiles, the most remarkable of which is the

gigantic tortoise discovered in India by Messrs Falconer and Cautley, the colossochelys; but the greatest development of reptile life appears to have taken place during the deposition of the secondary strata. Thus, we find enumerated by Professor E. Forbes, in the Cretaceous formations, 8 genera of reptiles; in the Oolitic and Wealden, including the Lias, 24; and in the Triassic beds, 16. They extend, indeed, somewhat lower in the scale, as in the Permian members of the upper Palæozoic rocks four genera are enumerated; and even below the coal, in the Devonian strata, two genera are found among these animals. The most remarkable forms are those of the Saurian family, most of them aquatic lizards furnished with paddles in lieu of legs, and many of them marine (Enaliosauria). Among them occur several of gigantic dimensions or monstrous form, as the Mososaurus of the upper chalk, near Maestricht, a species allied to the Monitor, 25 feet in length; the Hylæosaurus, of equal dimensions; the Icthyosaurus and Plesiosaurus of the Oolite and Lias, and others. In the Stonesfield slate occurs the Megalosaurus an amphibious or land lizard, carnivorous like the crocodile, and from 40 to 50 feet in length; in the newer Oolite or Wealden, the still more gigantic but herbivorous iguanodon, which, according to Dr Mantell, attained 70 feet. In the strata below the Lias, in the upper red sandstone, we find that extraordinary gigantic Batrachian, the Labyrinthodon, and the Cheirotherium, whose footmarks only have been discovered. But the most singular reptile form of the whole series is that of the Pterodactyl or flying lizard, with bat's wings and crocodile jaws, furnished with 60 pointed teeth, which first appeared in the epoch of the Lias, and became extinct in that of the chalk, and of which several species have been found.

(436.) Comparatively few fossil serpents have been discovered, and those only in the tertiary formations—the Eocene deposits of England have afforded some of the largest, forming two genera, Palæophis and Paleryx—the largest of which was equal in size to the largest boa constrictor of the present day. Some small snakes have been found in the Meiocene and Pleiocene formations of France.

(437.) Among the fishes, no existing genus is found below the chalk. In the inferior chalk there is one living genus, Fistularia; in the true chalk, 5; in the tertiary strata of Monte Bolca, 39 living and 38 extinct, according to M. Agassiz, to whom we owe a system of classification of this order of vertebrata by their scales, a character peculiarly adapted to fossil fish, of which frequently only the scales and a few of the harder bones remain, according to which they are divided into four great groups, Placoid, Ganoid, Ctenoid, and Cycloid. Of these four great families, the two latter are found only in the cretaceous and tertiary strata, and not a single species is of older date. In the cretaceous strata, they occur mixed with species of the two former classes. The epoch when the chalk began to be deposited forms therefore a very decided break in the history of this class of animals. And again, of the two more ancient orders, the Palæozoic rocks contain almost exclusively the remains of that class of fishes known as heterocercal, in which the upper lobe of the caudal fin is much more developed than the lower; while the secondary rocks contain the homocercal, in which the lobes are equal. The most remarkable deposits of fossil fishes are those of the Monte Bolca limestone near Verona—the coal formation of Saarbrück in Lorraine, the bituminous shale of Mansfield in Thuringia,—the blue slate of Glaris, and the marl stones of Oëningen in Switzerland, and of Aix in Provence, and our own old red sandstone. The distribution of genera, according to Professor E. Forbes, is as follows:—Newer Tertiary, 40 genera; Older Tertiary, 38; Cretaceous, 61; Oolitic, 61; Triassic, 15; Permian, 14; Carboniferous, 31; Devonian, 43; and Silurian, 2. (?)

(438.) The mollusca, from the durability of their shells, have left behind them almost a complete record of the ancient zoology of this class of animals. Their remains furnish the chief and most available practical means of determining the relative ages and order of superposition of strata, and are thus the main stay of geological science. As such, then, their study assumes a technical aspect, and can only be followed up in professedly geological works (see the article on that subject in this work, and every geological treatise of note). The same evidence is afforded of the continual introduction of new genera and species, and dying out of old, as in every branch of zoology, the range, however, being far wider than in any before treated of. In fact, these, and the forms of radiata and articulated animals, and of zoophytes, occur as the first vestiges of animated existence in the earliest fossiliferous strata. As might be expected, from the greater probable uniformity of condition afforded in marine over terrestrial life, the families have been much more persistent than those of the higher organisms. Thus the lingula, a brachiopodous genus of the very earliest silurian epoch, has its generic representatives still living. The nautilus, a cephalopod of the older palæozoic series, has still its place among living genera. We have also natica, eulima, solarium, and capulus among the gasteropods, and cardium, mytilus, arca, isocardia, avicula, and terebratula among the acephalous molluscs; while, on the other hand, some of the genera of earliest appearance (as orthoceras, cyrtoceras, phragmoceras, gomphoceras, and lituites) died out before the commencement of the secondary period. The ammonites, a most extensive and characteristic genus of the secondary period, in like manner died out before its close, as was also the case with the belemnitic, scaphytic, and turrilitic forms. This is the more remarkable in the case of the ammonites, as there is scarcely any generic form of organized life which seems to have luxuriated into so vast a variety of species. Bivalves are rare in the older formations.

(439.) Among the articulata, the trilobite, a form long since extinct, is highly characteristic of the earliest formations. They extend up to the carboniferous epoch. Crustaceous animals, gradually approaching recent forms, commence from the oolitic and cretaceous epoch. Insects are of comparatively rare occurrence. Fossil scorpions are recorded in the coal formation of Chomle, in Bohemia. Among the radiated animals and zoophytes (to which belong the very earliest vestiges of animated being) are a great variety of very remarkable and exquisitely beautiful forms, those, for instance, of the encrinites, apiocrinites, and actinocrinites, which have more resemblance to plants than animals, whence their name of "stone lilies." They seem to have attained their maximum in the carboniferous period. The pentacrinites of the lias are particularly beautiful. Sea urchins (echini) first appeared in the lias period, became abundant in the oolitic, continued so during the cretaceous epoch, and are still denizens of our seas. Corals and corallines belong to every age in which limestones have been formed.

(440.) *Fossil Plants.*—The lowest palæozoic strata exhibit indications of what may be taken for sea-weed, and in the grauwacke strata (which belong to these and to the lower devonian), fucoid plants occur abundantly. In Pennsylvania a hundred layers of them have been found in a thickness of 20 feet (Buckland, *Bridgw. Tr.* i., 452), but it is not till the carboniferous period that fossil vegetation assumes any notable proportions. There, however, it stands forward in most singular and wonderful promi-

Physical Geography.

nence, as there is no doubt that the whole of the immense deposits of coal in every part of the world owe their origin entirely to the fossilization of vegetables. "The most elaborate imitations of living foliage," says Dr. Buckland, "upon the painted ceilings of Italian palaces, bear no comparison with the beauteous profusion of extinct vegetable forms with which the galleries of the Bohemian coal mines are overhung. The roof is covered as with a canopy of gorgeous tapestry, enriched with festoons of most graceful foliage flung in wild profusion over every part of its surface. . . . Trees of forms and characters now unknown, are presented to the spectator almost in the beauty and vigour of their primeval life. Their scaly stems and bending branches, with their delicate foliage, are all spread before him, little impaired by the lapse of countless ages." The plants thus wonderfully preserved are equisetaceæ, ferns, mostly arborescent (indicating the prevalence of a tropical climate and insular arrangement of the land), lepidodendra, sigillaria, calamites, and stigmaria, the lepidodendra offering a transitional step between cryptogamous and flowering plants of high botanical interest. Above the carboniferous series the vegetation undergoes a great change. Cycadeæ occur in abundance, associated with peculiar ferns, but now coniferous plants, such as pines, araucarias, &c., begin to appear in the lias and oolite; and it is singular that the genera in our own lias approximate rather to the recent species of the southern than the northern hemisphere. It is worthy of remark, that where the stumps of these trees are found rooted in strata now inclined at a high angle to the horizon, the direction of the remaining portion of the stem is similarly inclined to the vertical. The pandaneæ, or screw pines (now confined to the Indian archipelago and tropical Pacific islands), are also found in our oolitic beds.

(441.) In the tertiary strata, the Dicotyledons assume nearly the same ratio to the Monocotyledons as at present, and the greater number of fossil plants, though of extinct species, bear much resemblance to living genera. Great deposits of Brown Coal or Lignite (as those of Poole in Dorset, Bovey Traccy in Devon, Soissons in France, the Surturbrand beds in Iceland, and those on the banks of the Rhine, belong to the Eocene epoch, those of Oeningen in Switzerland to the Meiocene. Independent of these, we find fossil palms in the British tertiary beds, and even the date and cocoa-nut in the isle of Sheppey, as well as at Brussels, where also the fruit of the areca-nut is found fossil, but with abundant evidence of having been drifted thither by oceanic currents from a warmer climate.

(442.) As we approach the recent epochs, the remains of vegetables are assembled in *submarine forests,* such as we find at Hastings, on the coast of Sussex, and indeed along the shores of western Europe, from Scandinavia to Spain and Portugal. They stretch sometimes inland under gravel sands and clays to a considerable distance, usually on slopes dipping slightly seaward. In the Baltic, trunks of oaks, pines, &c., the roots in their natural position, several layers one above the other, and four or five feet under water, occur at Griefswald, in the island of Usedom, and near Colberg. In the submarine forest of Minehead, Somerset, the bones and antlers of the red deer (which are still found wild in Exmoor) are found among the still upright oak stumps. In one of these forests in South Wales, near the mouth of the Neath river, among the stumps are found footmarks of a gigantic species of ox in the clay, apparently of the "*Bos primigenius,*" whose horns and skull have been discovered near the spot.

(443.) A great portion of the fossilized plants which occur in various parts of the world, are found silicified, the vegetable matter having been, as it were, extracted molecule by molecule, and silex deposited in its place, and that without destroying the cells, fibres, and tissues of the organization, which remains perfectly distinguishable under the microscope, in sections thin enough to be transparent. The chemical or electro-chemical process by which this change has been accomplished, is ill understood. Whatever the nature of the process, it goes on, as it were, under our eyes in siliceous springs; as in the Azores, where wood and reeds are found to become silicified; in the Geysers of Iceland; and even in the waters of certain streams not usually considered siliceous, as in the case of Trajan's bridge, the piles of which, still extant in the Danube, are externally converted into silex. But other cases occur where the mode of change is much more mysterious. Thus in the sand of the Isthmus of Suez, an immense abundance of silicified palm-trees makes its appearance, which would seem never to have undergone submergence in water. At Ober Dollendorf, on the Rhine, occurs a deposit of silicified wood, in which not only the living organization of the wood is preserved, but when the wood has become decayed, and almost disintegrated by decomposition, the silicifying process has arrested the progress of decay, and preserved every fibre in *loose spiculæ* of most wonderful delicacy and beauty.

(444.) *Ethnology.*—Our limits oblige us to be very brief on this part of our subject, and in this we acquiesce the more readily—1st, Because the reader will find, under that heading, an elaborate article in another part of this work; and 2dly, Because whatever *properly* belongs to the scope of the present essay, may be comprised in a very small compass. And first, then, as to the date of the introduction of the human species on earth. So far as geological research has hitherto gone, there can hardly be said to be any absolute unequivocal proof that men have been coeval with any one quadruped now extinct, or any bird but the dodo and the solitaire or bluebird, whose extinction is distinctly referable to his agency in times comparatively recent. The geologist, however, needs not to be reminded that this admission leaves a margin wide enough for any, even the most extravagant interpretations, of sacred chronology or traditional history. 3dly, That the unity of the human species, as a matter of natural history, rests upon quite as valid physiological arguments as that in the case of several other animals, as the dog among quadrupeds, or the domestic fowl among birds (to say nothing of the sheep and ox, in which the varieties are less marked), and in which the "races" are distinctly referable to the influence exercised by their domestication and *association with man;* not only as to varieties of stature or form (which go to an infinitely greater extent than anything observable among different races among men), but as to the development of new and peculiar psychological qualities.[1] Of all the merely physiological arguments which have been adduced in support of this unity, the most satisfactory seems to be that drawn from the identity of the period of gestation in all the races of mankind. 4thly, That, nevertheless, the difference between the human and all other species of animals is so vast, that it is impossible to ground a perfectly secure inductive argument or any such analogies. Our definition of "species" breaks down; and 5thly, That though we have absolutely no measure whatever, and cannot even conjecture what time or what number of

[1] It is probable that the full value of the Elephant as an *intelligent* servant of man has never been developed, owing to the neglect of all rational and persevering attempts to breed them in captivity. An absurd prejudice has too long been suffered to prevail as to its impossibility, but this has been distinctly disproved, and is now, we believe, exploded.

generations would be required to convert the descendants of (say) a Georgian or a Circassian pair, established in Congo or Guinea, and cut off from all communication with the rest of mankind, into negroes, or *vice versâ*, we are very sure that the change would require an immense period; and yet that such transformation, if it ever took place at all, must have taken place antecedent to all history. The negro was as much a negro in the time of the Romans as at the present day. The fair hair and blue eyes of the Germanic races were as much matter of general notoriety and contrast with the dark standard of South Italian beauty (*nigris oculis, nigroque crine*), in the days of Juvenal,[1] as now. If, therefore, we accept the idea of a single creation, and of the divergence of the human race on the world from a single centre; since we must then make up our minds to accept with it whatever consequences, as to the great duration of man's denizenship on earth, the existing diversity of races shall carry with it, we must not be surprised if those should be found who maintain that every trace of the primeval language has been totally obliterated indefinite ages ago, and that, whatever clue language may afford us in tracing out migrations and affiliations during the last few thousands of years, it can give us absolutely none towards the discovery of that point or that region on the surface of our planet first inhabited by man. All that the division recognized by ethnologists of the existing population of the globe into three, or five, or more races differing by marked peculiarities (a Caucasian or Aryan, a Mongolian and a Negro, or these, with an American or Polynesian type), can teach us is, that certain great districts, having certain features more or less influential in determining moral and physical habits, have remained for a sufficient number of ages in a state of comparative insulation from each other. On this subject we must refer our readers emphatically to the great work of the late Dr. Pritchard on "the Natural History of Man."

(445.) We cannot conclude this article without acknowledging our obligations to the authors of several valuable and excellent works on this general subject which we have consulted, and which have furnished us with useful guidance, especially the Physical Atlas of Mr Keith Johnston, a perfect treasure of compressed information; Mrs Somerville's "Physical Geography," and the unpretending but most useful treatise on the same subject by Professor Ansted, in the "Manual of Geographical Science." To cite the special authorities from which we have drawn the great mass of our statements, or to which the reader must be referred for further information, would be almost equivalent to giving a *catalogue raisonée* of voyages, travels, and works on geology, geography, and natural history. (J. F. W. H.)

APPENDIX A.

Table of the Heights of Mountains.—I. *Mountains of Europe.*

N.B.—When the heights in the table differ from the text, the former are to be preferred. (V) denotes an active volcano.

Mountains of Europe.	Height in English feet.	Country or District.
Mont Blanc	15,744	Sardinia.
Monte Rosa	15,151	Sardinia.
Mont Cervin	14,836	Sardinia.
Finsteraarhorn	14,026	Switzerland.
Jungfrau	13,716	Switzerland.
Kleine Mt. Cervin[2]	13,703	Sardinia.
Monte Viso	13,599	Sardinia.
Grande Jorasse (Mt. Blanc)	13,496	Sardinia.
Pic des Ecrins or Arsines	13,467	France.
Aiguille Verte (Mt Blanc)	13,432	Sardinia.
Schreckhorn	13,397	Switzerland.
Mt Iseran	13,272	
Aiguille du Geant (Mt. Blanc)	13,099	Sardinia.
Oertler Spitz	12,822	Tyrol.
Breithorn	12,800?	Sardinia.
Gross Glockner	12,431	Austria.
Mulhaçen	11,664	Spain.
Pico de Veleta	11,398?	Spain.
[illegible]	11,168	Pyrenees.
[illegible]	11,063?	Austria.
Mont Perdu	10,994	Pyrenees.
Muschelhorn	10,948?	Tyrol.
Cylinder of Maburé	10,897	Pyrenees.
Etna (V)[3]	10,872	Sicily.
Maladetta	10,866	Pyrenees.
Vignemale	10,820	Pyrenees.
Sierra de Gredos	10,552	Spain.
Hochspitze	10,330	Vorarlberg
Dreyherrn Spitz	10,122	Austria.
Monte Corno (Gran Sasso d'Italia)	10,144	Apennines.
Mt. Buet	10,112?	Sardinia.
Sharah Tagh	10,000?	
Ruska Poyano	9,912	E. Carpathians.
La Marmolata	9,802	Tyrol.
Olympus in Europe	9,749	Thessaly.
Gross Kogl	9,700?	Carinthia.
Monte Santo	9,628	Greece.
Mt. Budosch	9,594	Transylvania.

Mountains of Europe.	Height in English feet.	Country or District.
Mt. Surul	9,593	E. Carpathians.
Pic du Midi	9,439	Pyrenees.
Mt. Terglou	9,366	Austria.
Mt. Butschetje	9,256	Transylvania.
Mt. Legnone	9,206	
Cima d'Asta	9,191	Tyrol.
Canigou	9,138	Pyrenees.
Mte. Amaro di Majella	9,113	Apennines.
Mount Kom	9,000?	Illyria.
Great Balkan (Hæmus)	8,874	Balkan Mts.
Lomnitzer Spitz	8,862	Carpathian
Monte Rotondo	8,767	Corsica.
Monte d'Oro	8,701	Corsica.
Mt. Tatra	8,524	W. Carpathians.
Mt. Tornavacas	8,500?	Spain.
Mt. Kesmark	8,500?	Hungary.
Pic d'Abrizon	8,344?	Pyrenees.
Mt Csabi	8,316	W. Carpathians.
Rilodagh (Rhodope)	8,313	
Mt. Guiona	8,241	Greece.
Peña Laza	8,222	Spain.
Mont Spinal	8,203	Tyrol.
Schneehätten[4]	8,102	Scandinavia.
Skagtoltind	8,101	Scandinavia.
Parnassus	8,068	Greece.
Schlern	8,045	Tyrol.
Taygetus (Mt. St Elias)	7,904	Greece.
Monte Gazza	7,898	Tyrol.
Mte. Velino	7,851	Apennines.
Mt. Kelmos	7,726	Greece.
Cima di Portole	7,416	Tyrol.
Mt. Olonas	7,293	Greece.
Siete Picos	7,244	Spain.
Koldetina	7,224	Scandinavia.
Termenillo Grande	7,212	Apennines.
Sognefield	7,182	Scandinavia.
Pindus	7,000	Greece.
Monte Cimone	6,975	Apennines.
Pighätten	6,788	Scandinavia.

[1] Cærula quis stupet Germani lumina, flavam Cæsariem.

[2] By a barometrical measurement in 1821 by the author of this article.

[3] By a barometrical measurement in 1824 by the author of this article.

[4] K. Johnston makes the Schneehatten 7520. We follow the Annuaire du Bureau des Longitudes.

Table of the Heights of Mountains—(Continued).

Mountains of Europe.	Height in English feet	Country or District.
Mt. Athos	6,776	Greece
Langfield	6,598	Scandinavia.
[illegible]	6,584	Jura
El Gador	6,575	Spain.
Mt. Priel	6,565	Austria
Pizzo di Cane	6,509	Sicily.
Monte Genargentu	6,293	Sardinia. (Isl.)
Mont Ventoux	6,263	France.
Pic de Sancy (Mt d'Or)	6,238	France.
Sulitelma	6,178	Scandinavia.
Plomb du Cantal	6,096	France
Mont Rigi	6,050	Switzerland.
Aetscher	5,990	Austria
Mont Mezen (Cevennes)	5,794	France.
Monte Amiata	5,794	Tuscany.
Mount Helicon	5,738	Greece.
Delphi	5,725	Greece.
Mont Lozere	5,535	Central France.
Puy Mary	5,435	Central France.
Riesekoppe	5,394	Germany.
Wechselsberg	5,352	Styria.
Mt. Hussoko	5,328	Moravia.
Schneekoppe	5,376	Bohemia.
Puy de Violan	5,229	Central France.
Kasberg	5,215?	
Mt Adelat	5,145	Sweden.
Tschatir Dagh	5,000	Crimea
Riesenberg	4,961	Bohemia.
Melderskin	4,859	Scandinavia
Gross Arberg	4,832	Bavaria.
Puy de Dome	4,807	Central France.
Schneeberg	4,784	Riesengebirze.
Ballon des Vosges	4,688	France
Feldberg (Schwartzwald)	4,675	Germany.
Belchenberg (Schwartzwald)	4,642	Germany.
Rachelberg Bohmerwald	4,561	Germany.
Seisser Alp	4,553	Tyrol.
Mt. Celeno	4,500?	Greece.
Ben Nevis	4,406	Scotland.
Lyngen Mountains	4,300	Scandinavia.
Ben Macdui	4,296	Scotland.
Kammkoppel (Schwartzwald)	4,265	Germany
Cairn Tuol (Aberdeen)	4,225	Scotland.
Puy de Longchamp	4,190	Central France.
Puy de Come	4,173	Central France.
Kandelberg (Schwartzwald)	4,160	Germany
Sonnenwerbel (Erzgebirge)	4,124	Germany.
Cairn Gorm	4,090	Scotland.
Puy de Pariou	4,012	Central France.
Puy de Cliersou	3,992	Central France.
Ben Lawers	3,984	Scotland.
Vesuvius (V) [1]	3,922	Italy
Puy de Chopine	3,910	Central France.
Mt. Eryx	3,894	Sicily.
Mte. Somma	3,869	Italy.
Ben Avon (Aberdeen)	3,821	Scotland.
Grand Sarcouy	3,799	Central France.
Brocken (Hartz)	3,740	Germany.
Sierra de Foya (Algarve)	3,609	Portugal
Mt. Rona	3,593	Shetland.
Snowdon	3,590	N. Wales.
Schehallion [2]	3,547	Scotland.
Steinberg (Moravia)	3,511	Germany.
Cairn Llewellen	3,471	N. Wales.
Schneeberg (Fichtelgebirge)	3,461	Germany.
Mte. Cuccio (Palermo) [3]	3,435	Sicily.
Ben Wyvis	3,422	Scotland.
Curran or Cairn Tual (Kerry)	3,405	Ireland.
Hymettus	3,378	Greece.
Gross Bier (Thuringia)	3,361	Germany.
Cuchullin (Skye)	3,242	Hebrides.
Ben Lomond	3,192	Scotland.
Ben More (Mull)	3,185	Hebrides
Mte. Cavo (Campagna)	3,130	Italy
Helvellyn (Cumberland)	3,115	England.
Skiddaw (Cumberland)	3,058	England.
Cader Idris	2,959	N. Wales
Chicciola (V) (Stromboli)	2,957	Lipari Islands
Cross Fell (Cumberland)	2,928	England.
Shebh Donard	2,788	Ireland
Gross Feldberg (Taunus)	2,775	Germany.
Blessberg (Thuringia)	2,748	Germany.
Cheviot	2,669	England.
Coniston Fell (Lancashire)	2,649	England.
Nephin (Mayo)	2,638	Ireland.
Morne Mountains (Down)	2,493	Ireland.
Schunner Fell (Yorkshire)	2,348	England.
Soracte (Sorretto)	2,271?	Italy
Skaling Fell (Stromoe)	2,172	Feroe Islands.
Ben More (South Uist)	2,035	Hebrides.
Lowenberg (Siebengebirge)	2,024	Germany.
Hecla (South Uist)	1,992	Hebrides
Mt Ronas (Shetland)	1,475	Scotland.
Gibraltar	1,439?	Spain
Volcano Island (V)	1,304	Lipari Islands.
Valdai Mountains (culm)	1,100	Russia.
Arthur's Seat (Edinburgh)	822	Scotland.

II. *Mountains of Asia.*

Mountains of Asia.	Height in English feet.	Country or District
Deodunga or Chingo-pamari	29,002	Nepal.
Kinchinjunga (W peak)	28,178	Sikkim.
——— (E peak)	27,826	Sikkim.
Dwalagiri	26,861 [4]	Nepal
Nandadevi	25,749	Himalaya.
Juwahir	25,669	Kemaon.
Jumnotri	25,660	Nepal.
Jumnu	25,313	Sikkim.
Setghur	25,261	Nepal.
Daibhun	24,740	Nepal.
Gossain Thau	24,700	Himalaya.
Khabru	24,005	Sikkim.
Chumalari	23,929	Thibet.
Momonangli or Gurla	23,510	Thibet
Webb's Peak, No 12	23,263	Himalaya.
Powhunri or Donkiah Lah	23,175	Sikkim
Webb's Peak, No. 3	22,832	Himalaya.
Api	22,799	Nepal.
Webb's Peak, No. 23	22,727	Himalaya.
——— St. Patrick	22,638	Himalaya.
——— St. George	22,500	Himalaya.
——— No 13	22,313	Himalaya.
——— No. 25	22,277	Himalaya.
Kanchangow	22,000	Sikkim.
Jownili	21,940	Kemaon.
Zwillingo	21,600	East Himalaya.
Gangoutri Pyramid	21,219	Himalaya.
Kailas	21,000	Thibet.
Hindu Koh (summit N. of Cabul)	20,232	Affghanistan.
Bolor Mountains	19,000	
Elbruz	18,493	Caucasus.
Kohibaba	17,905	Hindu Kho.
Ararat (Agridagh)	17,112	Persia
Kasbek	16,532	Caucasus.
Klieutschewsk (V)	15,763	Kamschatka
Savalan	15,750	Caucasian Mts.
Demawend (V)	14,695 [5]	Persia
Argæus (Argisch Tagh)	13,197 [6]	Asia Minor.

[1] By a barometrical measurement by the author of this article.

[2] We follow the Annuaire du Bureau des Longitudes.

[3] By a barometrical measurement by the author, June 23, 1824.

[4] We follow the Annuaire du B. des L. K Johnston makes it 27,600.

[5] Humboldt (Kosmos, iv. 385) makes Demawend more than 19,000 feet. Mr Thomson and Lord Schomberg Kerr are said to have determined its height by recent barometrical measurement at 21,500 feet. (*Times Newspaper*).

[6] Humboldt makes it 12,600. We follow Mrs Somerville.

Table of the Heights of Mountains—(Continued).

Mountains of Asia.	Height in English feet	Country or District.
Opalinski (V) 51 21 N	12,000	Kamschatka.
Jebel el Makmel	12,000	Syria
Uschinskaia (V)	11,721	Kamschatka.
Koriaskaia (V)	11,210	Kamschatka.
Belouka	11,062	Altai.
Takt-i-Suleiman	11,000	Affghanistan
Tangnou Mountains (Oubsa River)	11,000	Central Asia.
Kronozkaia (V)	10,609	Kamschatka.
Schiwelutsch (V)	10,544	Kamschatka.
Hermon	10,000	Syria.
Taurus (culminating point)	9,800	Asia Minor
Krestowskaia	9,592	Kamschatka.
Libanus	9,517 ?	Syria.
Um Shomah	9,300	Syria.
Jupanowa (V)	9,055	Kamschatka.
Awatscha or Gorelaia (V)	8,910	Kamschatka.
Dodabetta Peak	8,760	Nilgheri Mts.
Horeb	8,593	Syria.
Kudiakad Peak	8,502	Nilgheri Mts
Bevoybetta Peak	8,488	Nilgheri Mts.
Murkurti	8,402	Nilgheri Mts.
Daversolabetta Peak	8,380	Nilgheri Mts.
Kundah	8,353	Nilgheri Mts.
Tolbatschuskaia (V)	8,313	Kamschatka.
Poworotnoi (V)	7,931	Kamschatka
Kundamaya	7,816	Nilgheri Mts.
Sinai	7,498	Syria.
Wiljutschinskaia (V)	7,373	Kamschatka.
Utacamund Peak	7,361	Nilgheri Mts.
Tamburbetta Peak	7,292	Nilgheri Mts.
Hokulbetta Peak	7,267	Nilgheri Mts
Bonasson	7,000	Western Ghauts.
Urbetta	6,915	Nilgheri Mts.
Kodanad	6,815	Nilgheri Mts.
Jebul Serbal	6,760	Syria.
Wilutschinskaia (V)	6,746	Kamschatka.
Davebetta	6,571	Nilgheri Mts.
Kotagiri	6,571	Nilgheri Mts.
Kundabetta	6,555	Nilgheri Mts.
Olympus in Asia	6,332	Asia Minor.
Dimhutti	6,330	Nilgheri Mts.
Cunur	5,886	Nilgheri Mts.
Tandiamole	5,781	Western Ghauts.
Pupugiri	5,682	Western Ghauts.
Koniakofsky Kamen	5,397	Ural.
Tremel or Iremel	5,075	Ural.
Mount Abu	5,000	Aravulli Mts.
Constantinow Kamen	5,000	Ural.
Jatara	4,800	Affghanistan.
Mahabuleshwar	4,700	Western Ghauts.
Purundar	4,472	Western Ghauts.
Singhur	4,162	Western Ghauts.
Hurrechundernagur	3,894	Western Ghauts.
Taganai	3,592	Ural.

III. *Mountains of Africa and the Atlantic Islands.*

Mountains of Africa and the Atlantic Islands.	Height in English feet.	Country or District
Kilimanjaro	20,000	Equatorial Africa
Mount Woso, 6 30. N.	16,350	Ethiopia.
Mount Dajan, 13. 15. N.	15,740	Ethiopia.
Abba Jarrat, 13. 10. N.	15,008	Abyssinia.
Geesh	15,000 ?	Abyssinia.
Buahat, 13. 12. N.	14,362	Abyssinia.
Mont Fatra, 10. 42. N.	14,350	Abyssinia.
Cameroon Mountains	13,000	Bight of Biafra.
Pico de Teyde (V) (Teneriffe)	12,205	Canary Islands.
Atlas (Miltsin)	11,400	Morocco
Lamalmon	11,200 ?	Abyssinia.
Fez Mountains	10,000 ?	Morocco
Chahorra (V) (Teneriffe)	9,885	Canary Islands.
Peak of Fogo (V)	9,152	Cape Verde Is.
Peak of St Antonio	8,815	Cape Verde Is.
Gondar Mountains	8,450 ?	Abyssinia
Tristan d'Acunha (V)	8,236	T d'Acunha Is.
Taranta	7,800 ?	Abyssinia.
Pico de Cruz (Palma)	7,730	Canaries
Pico (Peak of Azores)	7,613 [1]	St Michael's, Azores.
Trigo	7,400 ?	Canaries.
Blue Mountains (culmination of)	7,277 [2]	Jamaica.
Montano del Cobre	6,890	Cuba
Beerenberg	6,871	Jan Mayen's Is.
Los Rexas (Gt Can)	6,400	Canaries.
Morne Diablotin (V)	6,075	Dominica.
Pico Ruivo	6,059	Madeira.
Mount Chaco	6,000	Hayti.
Oraefa Jokul (V)	5,927	Iceland.
Eyafialla (V)	5,685	Iceland.
Hecla (V)	5,117 [3]	Iceland.
Snaefell Jokul	5,112	Iceland.
Morne Garou	5,007 [4]	St Vincents.
Souffriere (Guadaloupe)	4,867 [5]	
Montagne Pelée or Carbet	4,432 [6]	Martinique.
Alto Geraona (Gomera Is)	4,400	Canaries.
Swart Spitz (Pte. Noire)	4,399	Spitzbergen.
Mount Parnassus	3,917	Spitzbergen.
San Anton (Ferro)	3,907	Canaries.
Table Mountain	3,816	Cape of G. Hope.
Mount Misery (St Kitts)	3,720	Antilles.
Pico de Vara (St Michaels)	3,570	Azores.
Caldeira de S. Barbara (Terceira)	3,560	Azores.
Pico de S Jorge	3,198	Azores.
Morro Gordo (Flores)	3,087	Azores.
Asses' Ears (Fuentaventura)	2,770	Canaries.
Diana's Peak	2,692 ?	St Helena.
Caldeira de Corvo	2,460	Azores.
Lion's Head	2,166 ?	Cape of G. Hope.
Santa Lucia (V)	1,920	Antilles.
Mount Esk (V)	1,600	Jan Mayen Is.
Morne Rouge (V) (Granada)	640	Antilles.

IV. *Mountains of America.*

Mountains of America.	Height in English feet.	Country or District.
Aconcagua	23,910	Chile.
Sahama (V)	22,350	Peru.
Parinacota	22,030	Peru.
Tupungato	22,016	Chile.
Gualatieri	21,960	Peru.
Pomarape	21,700	Peru.
Chimborazo	21,424	Equatorial Andes.
Sorate	21,288	Bolivian Andes.
Ilimane	21,148	Bolivian Andes.
Chaquibamba	21,000	Bolivian Andes.
Viejo	20,500	Peru.
Concae	20,386	Chile.
Chachacomani	20,355	Bolivian Andes.
Huaina (Potosi)	20,260	Bolivian Andes.
Angel Peak (16. 10. S.)	20,115	Bolivian Andes.
Chipicani	19,745	Peru.
Charcani (V)	19,708 ?	Peru.

[1] Keith Johnston makes this mountain 7808 feet. We follow Humboldt.
[2] K. J. gives 6000. We follow the Annuaire du B. des Long.
[3] The Annuaire makes Hecla only 3314. We follow Humboldt.
[4] Mrs Somerville makes Mt Garou only 4370. We follow Keith Johnston.
[5] According to St Clair Deville. K. J makes it 5110.
[6] Dupuger makes this mountain 4706 feet high. We follow K. J.

Table of the Heights of Mountains—(Continued).

Mountains of America.	Height in English feet.	Country or District.
Coyambe	19,535	Equatorial Andes
La Mesada	19,356	Bolivian Andes.
Antisana (V)	19,137	Quito.
Sierra de Santa Marta	19,000	Venezuela.
Cotopaxi (V)	18,877	Equatorial Andes
Arequipa (V)	18,876 ?	Peru.
Queñuta, 17. 41. S.	18,765	Peru.
Nevado of Anaclache	18,500	Peru
Cacaca, 16. 25. S.	18,210	Bolivian Andes.
Tolima	18,120	Quito.
Cololo	17,930	Bolivian Andes.
Orizaba (V) or Citlaltepetl	18,879	Mexico.
Mount St Elias[1]	17,850 ?	N W. America.
Popocatepetl (V)	17,726	Mexico.
Maypu (V)	17,644	Chile.
Apu Cunaranu	17,590	Peru.
Vilcañota	17,525	Peru.
Ilinissa	17,380	Equatorial Andes
Sangay (V) or Macas	17,124	Quito.
Puracé (V)	17,006	N Granada.
Mount Hooker (Rocky Mountains)	16,730 ?	N W. America.
Chorolque	16,550	Bolivian Andes.
Tunguragua (V)	16,491	Quito.
Sinchulagua	16,434	Quito
Cerra de Potosi	16,152	Bolivian Andes.
Muiquiri	16,100	Bolivian Andes.
Dona Aña Peak	16,070	Bolivian Andes.
Nevado de la Vinda	16,000	Peru.
Uvinas	16,000	Bolivian Andes.
Mount Brown	15,990	Cascade Mountains, N. W. A.
Pichincha (V)	15,923	Quito.
Iztacihuatl (V)	15,705	Mexico.
Carguairazo	15,673	Quito.
Cumbal (V)	15,680	Quito.
Mount St Helens	15,500	Cascade Mountains, N. W A
Mount Hood	15,500	Cascade Mountains, N. W. A
Sierra Nevada	15,170	Mexico.
Toluca (V)	15,168	Mexico.
Tupungate (V)	15,100	Chile
Agua (V)	15,000	Guatemala.
Cerro di Buen Tempo	14,710	N. W. America.
Monte de las Litanias	14,500	Bolivian Andes.
Inchocaio	13,656	
Fremont's Peak, Rocky Mountains	13,568	N. W. America.
Pasto	13,450	Quito.
Monte de Azupe	13,450	
Cope de Perote	13,416	Mexico.
Amilpas, 15. 10. N.	13,160	Guatemala.
Colima (V)	13,003	Mexico.
Tuqueres (V)	12,821	Los Pastos.
Atitlan (V)	12,506	Guatemala.
Mont Regnier (V)	12,320	Cascade Mountains, N. W. A
Mount Taylor	12,256	Rocky Mountains, N. W. A
Iliämän (V) 60. N.	12,066	N. W America, Cook's Inlet.
Wrangell's Volcano	12,064	N. W. America, Coppermine R.
Cerro de Azusco	12,052 ?	Mexico.
Irasu (V. de Cartago)	11,478	Guatemala.
St Nicolaus, 60. 40. N.	11,270	N. W. America.
Pico de Tancitaro	10,498 ?	Mexico.
Orosce or Papagajo	9,976	Guatemala.
Votos (V)	9,848	Guatemala.
Viejo (V)	9,600	Guatemala.
Mount Pitt or Laughlin	9,549	Cascade Mountains, N.W.A.
Antuco (V)	8,918	Chile.
Silla de Caraccas	8,600	Venezuela.
Mount Aquarius	8,526	Rocky Mountains, N W.A.
Yanteles (V)	8,030	Patagonia.
Minchinmadeva (V)	8,000	Patagonia.
Sierra de Guayraima	7 600	Venezuela.
Osorno or Lanquihue (V)	7,549	Chile
Corcobado (V)	7,510	Patagonia.
Congrehoy Peak	7,482	Honduras.
Roraima	7,450	Guiana.
Melimoya	7,400	Patagonia.
Duida[2]	7,149	Venezuela.
Mount Omoa	7,000	Honduras
Mount Sarmiento	6 910	Terra del Fuego
Mount Darwin	6,800	Terra del Fuego
Mount Washington	6,428	Appalachian Mts, N.A.
Mount Stokes	6,400	Patagonia.
White Mountains, Massachusetts	6,230 ?	N. America, U S.
Mount Werner	6,000 ?	East Greenland.
Blaaserk	6,000 ?	East Greenland.
Itambe	5,960	Brazil.
Mount Adams	5,960	Appalachian Mts
Mount Jefferson	5,860	Appalachian Mts
Sierra da Piedade	5,830	Brazil.
Mount Burney	5,800	Patagonia.
Itacolumi	5,750	Brazil.
High Peak (Adironbeck)	5,467	Adironbeck Mts, N A.
Mount Katahdin	5,360	Maine, U. S, N. A
Itabira	5,250	Brazil.
Monte Giganta	4,600	California.
Jorullo (V)	4,265	Mexico.
Mount Buckland	4,060	Terra del Fuego.
Cockscomb Mountain	4,000	Honduras
Monte del Diablo	3,672	Sacramento River
Sierra Ventana	3,500	Buenos Ayres.
Kaatskill Mountains	3,454 ?	New York, U.S.
Mount Jacinto, 57. 1. N.	3,000	N America.
Guanacaure	3,000	Guatemala.
Mount Edgecumbe, 57. 3. N.	2,920	Lazarus Island, N.W.A.
Izalco (V)[3]	2,132	Central America.
Cosiguina (V)	1,000	Guatemala.
Mount Bridgeman (V)	400	South Shetland.

V. *Mountains of Polynesia, Australia, and Pacific Islands.*

Mountains of Polynesia, Australia, and Pacific Islands.	Height in English feet.	Country or District.
Singalang (V)	15,000	Sumatra.
Mowna Kia (V)	13,951	Sandwich Isls.
Mount Terror	13,884	South Victoria.
Mount Ophir (Gunong Passama) (V)	13,840	Sumatra.
Mowna Roa (V)	13,758	Sandwich Isls.
Merapi (V)	13,200	Sumatra
Mount Erebus (V)	12,366	South Victoria.
Rindjani (V)	12,363	Sunda Islands.
Tobreonou	12,250	Otaheite.
Semeru Gunong (V)	12,235	Java.
Fusi-no-yama (V)	12,443	Japan.
Sesarga (V)	12,000	Solomon Islands.
Alaid (V)	12,000	Kurile Islands.
Gunong Dempo (V)	12,000	Sumatra.
Mount Ambotismene	11,506	Madagascar.
Gunong Slamat or Tegal (V)	11,116	Java.
Gunong Ardjuno (V)	11,030	Java.
Sumbing or Sunding	11,028	Java.
Mount Luse	11,000	Sumatra.
Mowna Wororai or Hualai (V)	10,790	Owyhee.
Gunong Lava (V)	10,727	Java.
Walierung (V)	10,300	Java.
Merbabu (V)	10,220	Java.
Gunong Raon (V)	10,180	Java.
Sindoro (V)	9,880	Java.

[1] According to Captain Denham, Mount St Elias is only 14,968 feet in height.
[2] Mrs Somerville makes Duida 8280 feet. We follow K. J.
[3] K. J. assigns 1500 feet for the height of Izalco or Sonsonate. We follow Humboldt.

Table of the Heights of Mountains—(Continued).

Physical Geography

Mountains of Polynesia, Australia, and Pacific Islands.	Height in English feet	Country or District.
Gedee (V)	9,850	Java.
Merapi (V)	9,708	Java.
Mount Edgecumbe	9,630	New Zealand.
Schischaldinskoi (V)	8,953	Aleutian Islands.
Mount Egmont	8,840	New Zealand.
Gunong Api (V)	8,800	Sumatra.
Gunong Tengger (V)	8,700	Java.
Lombock Island (V)	8,688	Sunda Islands.
Wielis (V)	8,480	Java.
Mount Pedrotallagalla	8,280	Ceylon.
Tchermai (V)	8,280	Java
Bourbon Island (culm.) (V)	8,001	Indian Ocean.
Patuha (V)	7,907	Java
Bukit Tunggul (V)	7,800	Java.
Tomboro (V)	7,600 [1]	Sumbawa.
Adam's Peak	7,420 [2]	Ceylon
Sulak (V)	7,204	Java.
Ungarang (V)	7,100	Java.
Papandjam (V)	7,039	Java.
Dasar (V)	7,034	Java
Klut (V)	7,000	Java.
Mount Koschiusko	6,500	Australia.
Pogromnoi (V)	6,500	Aleutian Islands
Tankuban Prahu (V)	6,427	Java
Agung (V)	6,400	Java
Tongararoro	6,200	New Zealand.
Wayang (V)	6,149	Java
Tilu (V)	6,062	Java
Mount Seaview	6,000	New South Wales
Tombak-ruyung (V)	5,896	Java
Idjem or Taschem (V)	5,800	Java
Gunong Lama Lama (V)	5,755 [3]	Ternate
Mount Lindsay, 28. 20. S.	5,700	Australia.
Burungrang (V)	5,690	Java
Sumbung (V)	5,582	Java
Mount Humboldt	5,520	V. Diemen's Land
Ben Lomond	5,502	V. Diemen's Land
Mount Dargal	5,490	New South Wales
Talaya Boda (V)	5,490	Java
Makutschinskaia (V)	5,474	Aleutian Islands
Langle	5,350	Japan.
Gunong Lamongan (V)	5,339	Java.

Mountains of [illegible] and [illegible]	Height in English feet	Country or District
Golgatha (V)	5,263	Java.
Volcano of East Sitkin (V)	5,036	Aleutian Islands
Atka Island (V)	4,852	Aleutian Islands.
Cradle Mountain	4,700	V. Diemen's Land
Mount Canoblas	4,610	New South Wales
Sarytschew (V) Matua Island	4,505	Kurile Islands
Mount Wellington	4,195	V. Diemen's Land.
Tchikura (V)	4,144	Java
Mount Mitchell	4,120	New South Wales
Wunzen (V)	4,110	Japan.
Mount Pinnabar	4,100	New South Wales.
Mount Arrowsmith	4,075	V. Diemen's Land
Mount Bathurst	4,000	New South Wales
Valentine Peak	4,000	V Diemen's Land
Ben Nevis	3,910	V Diemen's Land.
Mount Arthur	3 900	V Diemen's Land
Kirauia	3,870	Owyhee.
Mount Sturt	3,735	New South Wales
Mount Adine	3,726	New South Wales
Narborough (V)	3,720	[illegible]
Mount George	3,620	[illegible]
Mount York	3,440	[illegible]
Ringitt (V)	3,400 [4]	Java.
Akutan (V)	3,332	Aleutian Islands
Squall or Sugarloaf Hill	3,288	New South Wales
Mount Blaxland	3,256	New South Wales.
Mount Tomah	3,240	New South Wales
Saddle Hill	3,001	New South Wales.
Strzlecki Peak	2,550	Flinders' Island.
Mount Hundawar	2,515	New South Wales.
Mount Munro	2,500	Bass's Strait
Mount Hay	2,425	New South Wales.
Stony Hill	2,400	New South Wales
Cockatoo Hill	2,356	New South Wales
Mount Wilson	2,350	New South Wales
Mount St Patrick	2,227	V. Diemen's Land.
Assuncion (V)	2,096	Mariana Islands.
Gunung Api (V)	1,948	Banda Island.
Barren Island (V)	1,700	Sunda Islands
[illegible] (V)	1,502	Aleutian Islands.
[illegible]	1,200	V. Diemen's Land.
Kosima (V)	746	Japan Islands.

APPENDIX B.

Lengths, &c., of the Principal Rivers of the World.

N.B.—O. S. G. B R. are used as contractions of the words Ocean, Sea, Gulf, Bay, River.

Name of River.	Length in Statute Miles.	Length in Geographical Miles	Area of River basin in thousands of square Geographical Miles.	Sea, Lake, or River into which it flows
Albany	644	560	...	Atlantic Ocean.
Amazon or Maranon	3545	3080	1512	Atlantic Ocean.
Amur	2739	2380	583	Sea of Japan.
Anadir	460 ?	400 ?	63	S. of Kamschatka.
Arkansaw	1840	1599	...	To Mississippi.
	2370	2727	...	To the Sea
Churchhill	976	848	74	Hudson's Bay.
Colorado	921	800	170	Gulf of California.
Columbia	1565	1360	194	Pacific Ocean.
Connecticut	310	270	8	Atlantic Ocean.
Danube	1722	1496	234	Euxine Sea.
Delaware	304	265	9	Atlantic Ocean.
Dnieper	1243	1080	170	Euxine Sea.

Name of River.	Length in Statute Miles.	Length in Geographical Miles.	Area of River basin in thousands of square Geographical Miles.	Sea, Lake, or River into which it flows.
Dniester	505	440	23	Euxine Sea.
Don	1104	960	168	Sea of Azof.
Douro	505	440	29	Atlantic Ocean.
Duna	644	560	33	Baltic Sea.
Dwina	1041	864	106	White Sea.
Ebro	483	420	25	Mediterranean S.
Elbe	787	684	42	German Ocean.
Essequibo	483	420	62	Atlantic Ocean.
Euphrates	1716	1492	196	Persian Gulf.
Forth	120	104		German Ocean.
Francisco, St	1551	1400	187	Atlantic Ocean.
Gambia	700	608	90 ?	Atlantic Ocean.
Ganges	1938	1680	432 [5]	Bay of Bengal.

[1] Humboldt makes Tomboro only 5862 feet.
[2] Mrs Somerville sets down Adam's Peak as 6152 We follow K. J.
[3] As stated by Humboldt. K Johnston sets down the Volcano of Ternate Island at 4093 feet (? if same).
[4] According to K. Johnston. Humboldt makes it 2845 only.
[5] This includes the basin of the Brahmaputra.

Lengths, &c., of the Principal Rivers of the World—(Continued).

Name of River.	Length in Statute Miles.	Length in Geographical Miles	Area of River basin in thousands of square Geographical Miles.	Sea, Lake, or River into which it flows
Garonne	368	320	24	Bay of Biscay.
Gihon or Amu	1611	1400	194	Sea of Aral
Glommen	340	296	..	German Ocean
Godavery	861	748	93	Bay of Bengal
Gogra	830	725	...	To the Ganges
	1440	1250	...	To the Sea
Guadalquivir	299	260	15	Atlantic Ocean.
Guadiana	483	420	19	Atlantic Ocean.
Hoang-ho	2624	2280	537	Pacific Ocean.
Humber	190	165	...	German Ocean
Illinois	500	434	...	To Mississippi R
	1360	1241	...	To the Sea
Indigirka	1045	908	86	Arctic Ocean.
Indus	2256	1960	312	Arabian Sea
Irawadi	2532	2200	331[1]	Indian Ocean.
Jordan	104	90	...	Dead Sea
Jumna	780	898	...	To Ganges.
	1550	1783	...	To Sea
Katanga	442	384	...	Bay of Katanga.
Kistna	791	688	82	Bay of Bengal
Kolyma	921	800	107	Arctic Ocean.
Kour	736	640	65	Caspian Sea
Lawrence, St	2072	1800	298	G. St Lawrence.
Lena	2762	2400	594	Arctic Ocean.
Loire	598	520	34	Bay of Biscay.
Mackenzie	2440	2120	442	Arctic Ocean.
Magdalena	983	828	72	Caribbean Sea.
Maritza	320	278	...	Euxine Sea.
Maykan or Mekong	2417	2100	216[2]	China Sea
Menam	1182	940		Gulf of Siam
Minho	221	192	12	Atlantic Ocean.
Mississippi	1930	1677	...	Gulf of Mexico
Missouri	2310	2008	...	To the Mississippi.
	4096	3560	982[3]	To Sea
Motagua	299	260	7	Gulf of Honduras
Nerbudda	760	660	...	Arabian Sea.
Neva	506	440	67	Gulf of Finland.
Niemen	529	460	32	Baltic Sea.
Niger	1010	878	?	Atlantic Ocean.
Nile	2578	2240	520	Mediterranean S.
Obi	2670	2320	925	G of Obi, Arctic O
Oder	552	480	39	Baltic Sea.
Ohio	1200	1043	...	To the Mississippi.
	2270	1973	...	To the Sea.
Olenek	1151	1000	77	Arctic Ocean.
Orinoco	1556	1352	252	Atlantic Ocean.
Oural	771	670	83	Caspian Sea.
Paraguay	1133	984	...	To Parana River.
	1864	1620	...	To the Sea
Parana	1500	1304	...	To the La Plata R
	2265	1968	...	To the Sea
Paranahyba	857	744	115	Atlantic Ocean
Petchora	690	600	49	Arctic Ocean.
Piasina	449	390	...	Arctic Ocean.
Plata, La	2210	1920	186	Atlantic Ocean.
Pilcomayo	967	840	...	To Parana River.
	1871	1626	...	To the Sea
Po	405	352	30	Adriatic Sea
Potomac	410	357	...	Atlantic Ocean.
Pregel	115	100	6	Baltic Sea
Pruth	620	538	...	To Danube River.
	740	643	...	To the Sea
Red River	1500	1293	...	To Mississippi R.
	1800	1564	...	To the Sea
Rhine	690	600	65	German Ocean.
Rhone	644	560	28	Gulf of Lyons.
Rio del Norte, or Bravo	2138	1840	180	Gulf of Mexico.
Salado	829	720	...	Parana River.
	1119	972	...	Sea
Saskatchewan	1915	1664	360	Hudson's Bay
Scheldt	180	156	...	German Ocean
Seine	391	340	23	British Channel.
Senegal	960	834	?	Atlantic Ocean.
Severn	240	191	...	
Sir or Sihon	1390	1208	237	Sea of Aral.
Susquehanna	630	547	...	Atlantic Ocean.
Tagus	552	480	22	Atlantic Ocean
Tarim Ergeugol	940	816	177	Lake of Lob
Tay	120	104	...	North Sea.
Tchekiang	1105	960	99	China Sea
Thaluain or Martaban	2152	1870	[4]	Indian Ocean.
Thames	220	191	5	British Channel
Tigris	1010	878	..	To Euphrates River
	1100	956	...	To the Sea
Tocantins	1289	1120	285	Atlantic Ocean.
Tonquin	552	480	92?	Gulf of Tonquin.
Vardoc	270	235	...	Medit., Archipel
Vistula	598	520	57	Baltic Sea.
Volga	2762	2400	397	Caspian Sea.
Weser	322	280	13	
Yana	483	420	...	Arctic Ocean.
Yangtsekiang	3314	2880	548	Pacific Ocean.
Yenesei	3222	2800	785	Arctic Ocean.

PHYSICS (*φυσικόν, natural*, from *φύσις, nature*), is, in its most general signification, the science of nature. Modern usage, however, has limited the acceptation of the term to those sciences which treat of *body* or *matter*, thus standing distinguished from the mental sciences on the one hand, and from mathematics, or the science of quantity, on the other. Physics, or physical science, thus understood, falls to be divided into the two great heads of ABSTRACT PHYSICS and CONCRETE PHYSICS. The former is co-extensive with *natural philosophy*, and treats of mechanical philosophy, including under it mechanics, hydrostatics, and hydraulics, on the one hand; and with *chemical philosophy*, including under it optics, electricity, and magnetism, on the other. The latter includes natural history, descriptive and philosophical, embracing physiology, geology, and physical astronomy, on the one hand, and concrete chemistry, analytical and explanatory, on the other; as well as zoology, botany, descriptive astronomy, meteorology, mineralogy, and physical geography. Auguste Comte, in his classification of the sciences given in his *Philosophie Positive*, restricts the term *physics* to what, in ordinary language, is loosely termed *natural philosophy*. Physics, according to him, have for their object the discovery of the general laws of the inorganic world. "In physics we study the laws which govern the general properties of bodies ordinarily viewed in their mass, and constantly placed in circumstances capable of maintaining intact the composition of their molecules, and most frequently even their state of aggregation."

PHYSIOGNOMY (*φυσιογνωμονία*) is the art of determining the mental character of an individual by an examination of his countenance. (See PHRENOLOGY.)

[1] Including the basin of the Martaban River.

[2] The joint basin of both rivers.

[3] The joint basin of the whole Mississippi–Missouri river system.

[4] The basin of the Martaban is included in that of the Irawadi.

PHYSIOLOGY.

Physiology. THE word PHYSIOLOGY, derived from φύσις, *nature*, and λόγος, *a discourse*, means literally the doctrine or the history of nature, and, strictly speaking, would comprehend a knowledge of all the physical and natural sciences. But as these in the course of time came to be more particularly studied, they received distinct names,—such as, on the one hand, astronomy, chemistry, and natural philosophy, and on the other, mineralogy, geology, botany, zoology, &c. That science which treats of the functions of living beings, however, still retained the old name, although even now its meaning is every day more and more restricted, as other branches of knowledge become better defined. At present, by physiology is generally understood a knowledge of vital actions in a state of health, as distinguished from pathology (παθος, *disease*), which means a knowledge of the same functions when unhealthy. Again, the modern term histology (ἱστός, a *tissue* or *web*), which is limited to an acquaintance with the functions of the elementary textures of a living body, as distinguished from the study of organs and organisms, also encroaches upon physiology. Thus, vital action, as manifested in the ultimate fibre of a muscle, may be considered histological, as appertaining to elementary structure; vital action as exhibited in a group of muscles, for the purposes of speech, deglutition, respiration, locomotion, and so on, may be called physiological, as belonging to the functions of organs; and vital action in muscle, as shown in perversion of those functions during spasm, convulsion, or paralysis, is more properly called pathological.

It must be evident, however, that these distinctions are altogether arbitrary, and that the three subjects constitute one study. Thus, our knowledge of muscular action is derived from an acquaintance with its ultimate structure and the contraction of its individual fibres, and from an observation of its diseased conditions. Where health terminates and disease begins has never yet been settled; nay, more, what is health to one man would be disease in another, just as the degree of strength which is natural to a delicate frame would be considered weakness in a strong one: histology, physiology, and pathology, then, are closely allied, and are only different divisions of the same subject. The facts of one are available for the study of all; and any theory deduced from this branch cannot be correct unless in accordance with the data furnished by the others. In the present article, therefore, we shall employ the term physiology in the enlarged sense of comprehending the doctrine of life, whether in health or disease,—which would, perhaps, more properly be denominated biology (βίος, *life*),—and avail ourselves of all the knowledge put within our reach by its modern investigators.

THE DOCTRINE OF LIFE IN GENERAL.

In order to understand the general doctrine of life, we must first attend to the characters of the bodies which manifest it. These may be arranged under five heads. All living beings possess,—1. A peculiar arrangement of matter, called *organized*, consisting of a combination of solid and fluid parts, which exercise a reciprocal action on each other.—2. Origin from parents in the form of a germ, which afterwards becomes separated to enjoy an individual existence.—3. The power of taking in from, and giving out substances to, the external world, or what is called assimilation and excretion.—4. The property of passing through certain definite changes, constituting the ages of a living being.—5. Certain derangements from which they may recover, constituting disease. These characters are not possessed by inorganic or brute matter.

Organized or living beings may be further distinguished from inorganized matters, or such as are incapable of living,—1*st*, *By their form.*—An organized being is of a definite form, presenting convex or concave surfaces, and bounded by curved lines. It is of determinate bulk, and invested by a general envelope. Whereas an inorganized body is of indefinite form, or of one presenting flat surfaces bounded by straight lines, such as a crystal. It is of indeterminate bulk, and without any general envelope. 2*d*, *By arrangement of parts.*—An organized being consists of an aggregation of heterogeneous parts, each of which bears a certain relation to the rest. An inorganized body consists of an aggregation of homogeneous parts, no one of which bears any certain relation to the rest. 3*d*, *By the substances of which they are composed.*—An organized being is composed of solid, liquid, and aeriform substances conjointly, constituting the tissues and fluids,—the fluid parts being included within the solid. An inorganized body is composed exclusively of a solid, liquid, or aeriform substance, the particles of which are merely either superimposed upon, or intermingled with, each other. 4*th*, *By their chemical composition.*—An organized being is composed of several elements, associated, at least after the cessation of their vitality, into ternary or quaternary compounds, called *proximate principles*, which, as the result of nutrition, are not capable of being imitated by art, and which are prone to spontaneous decomposition. An inorganized body is composed but of few elements, associated into binary compounds; which are formed by common chemical attraction, are easily imitated artificially, and are not prone to spontaneous decomposition.

The eggs of birds and seeds of plants do not possess all the characters of living beings, and yet they live. Once place them in conditions favourable for the development of their existence, and they become transformed into animals or plants. Such bodies are regarded as collections of organic matter possessing dormant vital properties, which, under certain circumstances, waken up and become active.

Numerous efforts have been made to define life. Without entering upon a criticism of these, it may be said that they are all faulty. Most authors have felt the necessity of presupposing some organized structure, the existence of which is taken for granted in their definitions. Bichat says, "Life is the sum total of the functions which resist death;" Treviranus calls it "The constant uniformity of phenomena with diversity of external influences;" Lawrence says it consists "in the assemblage of all the functions or purposes of organized bodies, and in the general result of their exercise;" Duges calls it, "The special activity of organized bodies;" and Béclard, "Organization in action;" which last gives us, as far as a short phrase can, what is understood by life.

With regard to the nature of life itself, two opinions have been held concerning it:—1. That life is an independent entity, a vital principle—an idea which has come down to us from the ancients, and is founded on the notion that the union of this principle with the body caused it to live, and its separation to die. 2. That life is the collection of phenomena in organized beings, dependent partly on a certain structure and chemical composition, and partly on the existence of external agencies which stimulate them into action. We do not think it worth while to enter into the long arguments by which both these theories have been supported. It is sufficient to say that the latter is the view

which has been adopted by modern physiologists, who believe that the various tissues of an organized body are endowed with various properties, some physical and some vital; that the latter require what are called stimuli to bring them into action; and that a knowledge of the tissues, their properties, their stimuli, and the forces evolved from them, is the true method of arriving at just conclusions concerning life as manifested in health, and as modified by disease. Before, then, we can arrive at a just theory of life in general, we must acquaint ourselves with the structure, chemical composition, and vital properties of the tissues themselves.

PART I.—HISTOLOGICAL PHYSIOLOGY.

Histology comprehends the functions, mode of development, and chemical transformations of the ultimate textures of the body, and has become the recognised basis of our physiological knowledge since the important generalizations of Schleiden and Schwann as to the cell theory were published in 1841. These ultimate or elementary textures are only made visible by means of the achromatic microscope, and have been variously arranged by physiologists. We shall describe them under four heads,—viz., 1*st*, Molecule Tissues; 2*d*, Cell Tissues; 3*d*, Fibre Tissues; and 4*th*, Tube Tissues.

MOLECULE TISSUES.

On examining the different textures under high magnifying powers, we invariably observe a greater or less number of molecules and granules. A molecule is a minute body, presenting optically the appearance of a point or minute dot. A granule is a larger body, in which we can discover a centre and an external ring or margin, which are alternately dark or light according to the focus it is examined with. Molecules may become granules by magnifying them, and granules may appear as molecules by diminishing the magnifying power; so that structurally they are the same bodies. In composition they may be various, consisting of albuminous, fatty, pigmentary, or mineral matter, which may be determined by the action of re-agents. In shape they are usually round, although mineral molecules may be angular or many-sided. They may be isolated and equally diffused, or collected together in groups or masses. In size they may be uniform, but more generally vary from a point scarcely visible up to a magnitude of considerable but varying size, when they are often called globules, as in the milk.

Molecular Fluids.—All fluids in which organization is proceeding, and out of which the higher tissues are formed, are rich in molecules, as may be well seen among plants in the embryonal sac and in the extremity of the pollen tube. The chyle of all animals contains a molecular basis (Gulliver), which gradually becomes cleared up after it has joined the blood, and perfect blood corpuscles are formed. There can be little doubt that the floating molecules enter directly into the substance of nuclei and cell-walls. Molecules are also numerous in the fluid within cells, sometimes being the commencement of new germs, at others the deposits of secreted or effete matter.

Molecular Fibres.—The molecules formed in organic fluids frequently assume a fibrous arrangement. This is well observed in *mucin*, the viscous substance of which frequently exhibits, especially on the addition of acid, a multitude of fibres, composed of molecules aggregated end to end. Similar fibres are formed in the coagulum of blood, the fibres being deposited as molecules, which rapidly assume a fibrous arrangement.

Molecular Membrane.—Albuminous fluids may frequently be observed to contain shreds, which can be spread out into a membrane, and are composed of molecules aggregated closely together. Such membranes may readily be produced artificially by shaking the fluid, adding slight heat, or mixing them with acids or oil. If a fluid drop of oil and another of liquid albumen are brought together, a membrane is immediately produced (*haptogen membrane* of Ascherson). If the two drops are mechanically rubbed together, an emulsion like milk,—containing granules and globules,—is produced; and the latter may readily be shown to be composed of an envelope of this membrane containing a drop of oil. Numerous membranes in the animal body are formed directly by the deposition of albuminous matter, originally in the form of minute molecules, which subsequently melt into a homogeneous layer. Amongst these the substance of cell-walls is perhaps the most important.

Molecular Movements.—All molecules floating in a fluid have distinct movements, which were first described by Robert Brown; hence called Brunonian movements. They may be vibratile, circular, spiral, serpentine, or irregular in character, but seem to be governed by certain laws of attraction and repulsion, which have not yet been minutely investigated. In the interior of cells they frequently pursue certain directions, hence assuming the nature of a circulation, well seen in large vegetable cells. Within the salivary cell they may be seen to move in minute circles, and present a trembling character; in the vibriones so common in putrid fluids, they are vibratory or serpentine.

The Molecular Theory of Organization.

When we consider that all embryonic forms are developed from molecular fluids, and that in adult animals all organizable matter used as food is first reduced to minute molecules, in order that it may become organized, it must be evident that the primary source of vegetable and animal forms must be sought in the molecular element. When, moreover, we know that essentially different fluids, as oil and albumen, when brought into contact, immediately precipitate molecules that assume a globular, fibrinous, or membranous form, and that such a process is facilitated by numerous chemical re-agents, acids, or alkalies, acting on albuminous, fibrinous, or mineral solutions, we readily observe one way in which histological elements may be produced within the body. Such elements, subject to the laws of vitality, may be formative elements (*histogenetic*), whilst others may be retrograde, and give evidence of vital cessation (*histolytic*). Hence the first and last formative element is the molecular. Organic formative fluids deposit molecules, which arrange themselves, subject to vital laws, into nuclei, cell-walls, and higher textures. These, once produced, subsequently decay in an inverse order, breaking down into individual fragments, and ultimately into minute molecules. During the whole life of an individual organism we observe in it a constant series of these formations and disintegrations—of these histogenetic and histolytic actions. The object of these appears to be fitting or elaborating, by chemical and histological processes, organic matter in such a way as to perform its appointed office in assimilation or excretion. A knowledge of the vital and physical changes occurring in these molecules, and of the fluids in which they are formed and dissolved, must evidently not only constitute the basis of physiology as a science, but must ultimately form a groundwork for the arts of horticulture, agriculture, and medicine. It is only by the *conjoined* study of histology and organic chemistry that this great work can ever be accomplished.

CELL TISSUES.

When we examine the structures of living beings under high magnifying powers, numerous tissues, but more especially the fluids, the surfaces of membranes, and the various glands, are seen to contain multitudes of minute vesicles or shut sacs, which have received the name of cells. These have long been recognised with the microscope by observers, particularly in plants; but their importance has only been understood since the labours of Schleiden and Schwann (1841) pointed them out as the elementary form of all organisms. They vary greatly in shape, size, and function, a circumstance which necessitates some arrangement of them. We shall divide them into temporary cells and cells of transition,—understanding by the first, cells which do not proceed further in development than the cell form; and by the last, cells which are transformed into more permanent textures. Referring to the article BOTANY for a description of vegetable cells, we shall here confine ourselves to those found in animals, especially such as are highest in the scale.

1. *Chyle and Lymph Cells.*—These are blood-cells in an early stage of development.

2. *Blood Cells.*—These are of two kinds, coloured and colourless. The coloured cells in fishes, reptiles, and birds are for the most part oval, being largest in reptiles, and smallest in birds. They contain an oval vesicle or nucleus, occupying about a third of their area, which resists the action of acetic acid, while that agent partially dissolves the cell-wall, and destroys the colour. Between the nucleus and cell-wall is a fluid of a yellowish tint. In mammals, with the exception of the order Camelidæ, in which they are oval, the blood corpuscles present the form of bi-concave circular discs, smallest in the Napu musk-deer, and largest in the elephant. They have no included body or nucleus, and consist of a vesicle containing a coloured fluid. On the addition of water, they swell out so as to become globular, and lose their colour; acetic acid rendering them transparent and almost invisible. In consequence of their shape, they readily become piled upon one another in the form of rouleaux. The colourless cells are globular, having a finely molecular aspect externally, and a distinct nucleus, which, on the addition of acetic acid, usually presents two or three granules. In mammals they are somewhat larger, and in the other vertebrate tribes, smaller than the coloured corpuscles.

The different corpuscles of the blood originate in the chyliferous and lacteal system, and are elaborated as the result of the primary or secondary digestion in the various lymphatic glands. In the lymphatic vessels and thoracic duct they are colourless, but the different stages of their development may readily be observed in chyle, which, in addition to the two kinds of corpuscles previously described, contains a multitude of minute molecules, or what is called a molecular basis of fine fatty particles, communicating to it a milky appearance. The bi-concave disc is fully formed in the chyle, and on joining the venous blood of the jugular vein, is rapidly conveyed through the heart to the lungs, where, coming in contact with the oxygen of the air, its contents become coloured, and communicate its characteristic tinge to the blood. In the fœtus the blood corpuscles are formed in the interior of the cells, which are ultimately changed into vessels, and they are rapidly multiplied by a process of fissiparous development.

The functions of the blood-cells are intimately connected with the exchange of oxygen and carbonic acid continually going on between the blood and atmospheric air in the lungs and in the tissues; but their especial function is the further elaboration and preparation of the *liquor sanguinis*, or fluid part of the blood, in which they swim and are ultimately dissolved. This contains all the elements of nutrition necessary for every part of the organism, as well as the effete matters derived from the wearing away of the tissues. The blood corpuscles, therefore, as the formative cells of the nutritive fluid of the body, must be regarded as the most essential of the constituents of the animal frame.

3. *Nerve or Ganglionic Cells.*—These cells, of various sizes and shapes,—simple, bi-polar, or multi-polar,—are composed of a delicate wall and distinct nucleus, with more or less granular contents. Their function is to form a means of communication between the different nerve tubes, and to evolve that peculiar force which is so essential for carrying on the motor, sensitive, and mental processes of the nervous system.

4. *Adipose Cells* constitute the substance of fats, and secrete in their interior the oily and oleaginous matters so necessary, as we shall subsequently see, for various processes in the economy of all living beings.

5. *Pigment Cells* present remarkable variations in size and shape, and are so called from their property of forming in their interior, in a fluid or granular form, the various coloured substances which tint the different textures of plants and animals. This appears to be effected by a species of vital chemistry, which will be subsequently described.

6. *Glandular or Secreting Cells.*—Under this head may be grouped together all those cells, various in form, size, and composition, which have the common function of attracting and selecting from the blood the secretions formed in different glands. Though allied in the performance of this common function, they differ with regard to the nature and amount of the secretion produced, which, so far as can be determined, is not dependent on the structure, chemical composition, or connection with other anatomical elements of the cells themselves. Why some of these cells should secrete bile, others urea, a third class saliva, a fourth milk, and so on, is only explicable by attributing to these minute corpuscles the possession of vital properties, whereby one attracts and selects from the neighbouring blood-vessels the materials which it forms into bile, a second such as it fashions into urea, and so on. No other explanation can be given of a phenomenon which is an ultimate fact in physiology.

7. *The Cells of Transition* are those which, according to the known laws of development, are destined to be transformed into more permanent tissues, in the manner to be hereafter spoken of, and comprehend,—*1st*, Numerous embryonic cells observable in the ovum of plants and animals. *2d*, Fibre cells; *3d*, Epithelial cells; *4th*, Cartilage cells. The great end of these cells is to be transformed into the tissues formed in various organs, such as blood-vessels, nerve tubes, fibres, membranes, bone, &c.

8. *Pathological Cells.*—In the various morbid growths which so frequently occur, forming hypertrophies, strictures, tumours, &c., we constantly find an increased number of the same cells we discover in the healthy textures. At other times we find cells which are peculiar to different structural diseases and such as do not occur in health. These may be denominated pathological cells. Among these may be enumerated:—*1st*, *Pus cells*, the formation of which in a fluid constitutes the morbid substances so long known as pus, or purulent matter. *2d*, *Granule cells*, so called from their containing a number of fatty granules. These may be formed in every kind of normal cell, but occasionally in new cells, as in certain softenings of the cerebral hemispheres. *3d*, *Cancer cells*, so called from their frequency in cancerous growths. *4th*, A variety of indefinite corpuscles, the title of which to the denomination of cells is disputed, such as peculiar diaphanous bodies found in various morbid products—tubercle corpuscles, &c.

The Cell Theory of Organization.

A study of the minute bodies to which we have just alluded in plants and animals has led to a generalization or theory, which, although slightly modified since it was originally put forth by Schleiden and Schwann, still remains one of the most important doctrines in biological science. This theory we shall now give as shortly as possible.

All cells originate in a fluid substance, a so-called *blastema* (βλαστος, *germ*), or germ-substance, which, at one time clear, becomes opaque, from the formation or deposition of numerous molecules and granules. Several of these melt together to form a larger body, upon which there is gradually produced a delicate membrane that gradually separates from it, in consequence of the interposition of fluid. After a time, such a corpuscle, or cell, as it is now called, consists of an external envelope or vesicle (*the cell-wall*), the included body upon which it was formed (*the nucleus*), and a fluid between the two (*the cell fluid*). In the nucleus may frequently be observed one or more included granules (*nucleoli*). The changes which subsequently take place in cells thus formed are as follows:—*1st*, Having reached their full development as cells, they gradually dissolve and perish, or the cell-wall bursts, liberating the fluid contents, which constitute a secretion. *2d*, Various matters may be deposited on the interior of the cell-wall, or in the cell fluid. Thus, albuminous or mineral matter may be deposited which give to certain tissues unusual firmness, as in the fleshy leaves of plants, in the stones of fruit, and in bone; or the fluid may become loaded with albuminous, fatty, pigmentary, or mineral matter, communicating important properties and striking appearances to various tissues. *3d*, The cell-walls undergo remarkable changes, and by their union with neighbouring cells form complex tissues. Thus, by becoming elongated, and subsequently splitting up, fibres are produced; by becoming elongated and uniting endways to similarly changed cells while the partitions between them disappear, tubes are formed; by throwing out radiating branches, which in like manner unite with others proceeding from neighbouring cells, a net-work or plexus of tubes is produced; and by becoming flattened while their edges adhere together, membranes are developed. In this manner all the elementary textures of a living being may be derived from cells. *4th*, Many cells have the power of reproduction, or of forming other cells, and this may be accomplished in four different ways,—(1.) By the cell-wall bursting and liberating included germs, each of which gives rise to a cell. (2.) By the nucleus enlarging and dividing into two, each of these into other two, and so multiplying to a certain extent within the original cell-wall; (3.) By the cells themselves dividing into two or more divisions; and (4.) By processes or buds which are thrown out from one part of the cell, and subsequently separate. These four kinds of reproduction from cells may be called the exogenous, the endogenous, the fissiparous, and the gemmiparous modes of re-development.

A careful study of the transformations which occur in different cells must convince us that they possess a life peculiar to themselves, and perform special functions. They are born and nourished, and they grow, reach maturity, decline, and die. They are the organs of secretion, as it is in their interior that all the different fluid and solid secretions are elaborated. They are the organs of growth, as they constitute the germs out of which all the tissues are produced. They are the organs of reproduction, not only in causing new growth of tissues, but in multiplying the countless species of plants and animals that we find on the surface of the globe.

In order that cells may carry out these different purposes, they must possess different endowments; whilst some possess the property of storing up in their interior and elaborating various substances to form the secretions, others absorb matters which enable them to build up the different tissues of the organism itself, so as to give it support, ductility, and firmness. A third kind store up pigment, which gives colour to the tissues, or accumulate fat for the purposes of evolution, disintegration, or chemical combustion; and a fourth kind, by a modification of nutritive power, are especially charged with the important office of perpetuating and multiplying new living beings to take the place of those which are worn out and die. So long as all these processes go on harmoniously together, health is preserved. But the excess or diminution of these cells in particular parts of the economy occasion various kinds of disorders in secretion, nutrition, and reproduction. Lastly, the fluid part of the blood is not unfrequently drawn out of the vessels, and then a new set of cells spring up in it, which, like pus cells, may serve the purpose of getting rid of the morbid products, or, like cancer cells, propagate it in various directions to the destruction of the economy.

The conditions or laws which regulate cell life appear, so far as we are acquainted with them, to be as follows:—*1st*, They must be in a certain relation to a nutritive fluid or *blastema*, from which they can attract and select the various substances necessary to enable them to carry on their respective functions. The most active growing cells are those that swim in such a fluid. In the higher plants and animals the nutritive fluid (sap or blood) is distributed throughout the economy by a series of canals. *2d*, A certain temperature is necessary to cell life, as it will not proceed below zero or above 145° Fahr. As a general rule, a low temperature checks, whilst an elevated one is favourable to cell growth. *3d*, Room for expansion is necessary to perfect cell formation. Hence they grow most rapidly and perfectly in fluids or very moist substances; and when they begin to press upon one another, or upon unyielding tissues, their development is checked or destroyed. *4th*, An appropriate locality has evidently a great influence over cell formation, and this independent of mere temperature and the other circumstances referred to. This is well observed in the reproduction of tissues, the new matter thrown out originating cells, which, as to their ultimate development, are more or less governed by the neighbouring structures. *5th*, Besides these conditions of a general nature, there is another important one connected with the structure of the cell itself. Thus, if the cell-wall becomes so impregnated with mineral matter that liquids cannot pass through it,—if the cell fluid becomes loaded with albuminous, fatty, or mineral substances, or if the nucleus disappear,—the growth and function of the cell is at once destroyed. Hence the conjoined integrity of the three essential parts of the cell,—viz., cell-wall, cell-fluid, and nucleus, each of which may operate on one another, and on the surrounding blastema, by endosmose and exosmose,—is essential to its activity.

A knowledge of the cell theory as now explained must convince us that the most important vital processes in the economy are essentially connected with the development of the minute corpuscles, which the microscope now enables us to demonstrate and study with the greatest ease. Modern investigation, by its means, has thus completely revolutionized all our previous notions, and proved to us that the cell structures of which we have been speaking are in truth the real agents by which nutrition, secretion, and reproduction are carried on; and by means of which, indirectly, all the animal functions are supported, including even locomotion, sensation, and mental acts. A plant or an animal is in fact a living creature composed of millions of corpuscles, the sum total of the lives of which make up its own. Fat and bone are living tissues, which, in like manner, are composed of as many lives as

there are fat and bone cells aggregated together. Pus, that fluid which surgeons have considered as a deposit or secretion foreign to the body, and which ought to be let out as soon as possible, is, like the blood, a living fluid, crowded with multitudes of animal existences, which are born, live, and die, as man himself does. Views of this kind must not only materially modify the notions hitherto attached to the idea of life, but must satisfy us that in all attempts to support, restrain, or prolong it, we can only do so scientifically through our acquaintance with the structures, on the integrity of which it depends. Hence a knowledge of the minute cells in the various organs and tissues of the animal body, the transformations they undergo in health and disease, and the conditions necessary for their existence, and the performance of their functions, is of essential importance to the medical practitioner.

THE FIBRE TISSUES.

A fibre is a solid elongated body, like a thread, and in living beings exists of various degrees of thickness, varying from $\frac{1}{16000}$th to the $\frac{1}{1400}$th of an inch. What appear to be fibres to the naked eye are in truth bundles of the true fibres, which can only be made visible by means of the microscope. The different kinds of fibres which enter into the tissues are the following:—

1. *Molecular Fibres.*—These are best seen in the decolorized clot of blood, whence they may frequently be observed to form in the field of the microscope by the deposition of minute molecules, which assume a linear arrangement, and subsequently melt together to produce a solid fibre. They vary in thickness from the $\frac{1}{1200}$th to the $\frac{1}{1600}$th of an inch.

2. *White or Areolar Fibres.*—These constitute the areolar or connective textures of the body. They may run in wavy bundles, leaving spaces or areolæ between them, as in the so-called cellular tissue of descriptive anatomists. They may be closer together, and more or less crossed, as in a fibrous aponeurosis, or greatly condensed and running in parallel lines, as in tendon and ligament. Their course may be various and more or less mingled with cells, as in fibro-cartilage, or fibrous morbid growths. This kind of fibre is formed by the elongation and splitting up of cells. They vary in thickness from the $\frac{1}{3000}$th to the $\frac{1}{1200}$th of an inch

3. *Yellow or Elastic Fibres.*—This kind of fibre is yellow in colour and highly elastic; hence the names it has received. It is best seen in the *ligamentum nuchæ* of quadrupeds, or in the *ligamenta subflava* of man, extending between the laminæ of the vertebræ. They form the principal bulk of the large arteries, and present under the microscope a curled appearance at their extremities. The fibres may often be seen to anastomose; and are apparently formed from elongation of the nuclei of cells. They vary in thickness from the $\frac{1}{8000}$th to $\frac{1}{4000}$th of an inch.

4. *Epidermic Fibres.*—This kind of fibre is formed from the splitting up of epidermic cells in various ways, and constitutes the fibrous structure of hair, nail, hoof, horn, feather, quill, and a variety of epidermic appendages. They vary greatly in thickness.

5. *Non-voluntary Contractile Fibres.*—These constitute the so-called muscular coat of hollow viscera, and exist in considerable quantity in the blood-vessels, skin, and iris. Their form is that of ribbon-shaped flattened bands, which are made up of an aggregation of spindle-shaped nucleated cells. They vary greatly in thickness in different textures.

6. *Voluntary Contractile Fibres.*—These constitute the substance of muscle or flesh, the fibrous matter of which may be first divided into solid bundles of fibres, surrounded by a delicate membrane (*sarcolemma*) called the *fasciculus*. The fasiculi are polygonal, and characterized by transverse lines or striæ, which run across them, consisting of alternate dark and light spaces. Each fasciculus, on being broken up, may be shown to consist of numerous minute fibres or fibrillæ, on each of which the same dark and light markings may be seen. The greatest pains have been taken by microscopic observers to determine the ultimate structure of voluntary muscle; but beyond arriving at the fact, that the transverse striæ of the fasciculus are owing to the aggregation of the dark and light markings visible on the minutest fibrillæ, they have not been able to go.

The function of the fibrous tissues is manifold. The white fibrous or connective tissue unites together various structures, especially in the form of tendon, ligament, and aponeurosis. It also offers an elastic medium and support to the frame generally, protecting the blood-vessels and nerves. The yellow elastic tissue performs similar functions; and in addition, in consequence of its great elasticity, serves to restore parts after they have been moved by muscular action; and hence in various places it supplies an antagonist force to muscles. The epidermic fibres are useful as a covering and protection externally, besides forming resisting parts to pressure, and means of offence and defence in numerous animals. The most important property of the fibrous tissues, however, is that of contractility. This exists in different textures, which possess various degrees of power in having it called into activity. Thus, it may be stimulated by cold in the fibres of the bulbs of the hair, but cannot be excited by mechanical irritation or galvanism. In the veins and arteries, on the other hand, cold and mechanical irritation operate, but not galvanism; whereas this agent, with the others, excites contractility in the iris. Lastly, the capillary vessels, in addition to the other stimuli, are influenced by mental emotions, whilst the fibres of flesh are also brought into contraction by the mental act of volition.

Theory of Contractility.

The property of contractility in the fibres of a living being, on the application of a stimulus, is one peculiarly vital, and unlike anything known in physics. It was supposed that the shortening of the fibre was owing to its being thrown into a zig-zag, but it is now known to depend upon its swelling out laterally, and being shortened longitudinally. The property of contractility, however, is not only exerted in such a manner that, by shortening fibres as in muscles, and acting upon the bones and joints, it may induce locomotion. Certain molecular fibres may assume independent motion, as in vibriones, or in the disintegrated molecules of putrid animal or vegetable substances. These bodies, consisting of a fibre more or less long, possess spontaneous movement of a trembling or serpentine character, by which they are propelled through a fluid. Another remarkable movement is seen in the lashing of hair-like processes, shaped like a sabre, which are called cilia, and which cover the mucous surfaces in many parts of the animal body. The peculiar movements of a spermatozoid, in the spermatic fluid, is another example of contractile fibrous motions. In the attached stalk of the vorticellæ, the filament may be seen to assume a spiral form when called into action. Many cells, also, may be seen to enlarge and contract suddenly or slowly, while others contract irregularly, throwing out processes, and thereby continually changing their form, as in the *Amœba*.

The view originally put forth by Haller as to the explanation of contractility was, that it was a vital power inherent in the tissues which possess it; in short, an ultimate fact in physiology; a view which is supported by all that is now known of the subject. It has been maintained, however, by others, that muscular contractility is not so

much inherent in muscle as it is dependent on the nervous system. But this opinion is negatived—1*st*, By many ingenious experiments, and especially some by Dr John Reid, who, having removed a portion of the sciatic nerve in a frog, and then exhausted the contractility of the muscles of the limb by powerful repeated galvanic shocks, found that contractility returned after a period of repose; 2*d*, By the observations of isolated fasciculi of muscle under a microscope, which have been seen to contract when entirely separated from nerve; and, 3*d*, By the fact, that individual cells, and even some parts of plants, contract, which have no nerves. The true agency of nerves in muscular parts is not to give them the property of contractility, but to subject it in various ways to the dominion of the acts and feelings of the mind.

THE TUBE TISSUES.

The tubular tissues are distinguished from hollow viscera by their simple structure, and from fibres by their being composed of distinct walls with contents. The principle forms are as follows:—

1. *Air Tubes.*—In plants, and many of the inferior tribes of animals, their structure contains tubes for the transmission of air which are characterized by a deposition in their interior that assumes the form of a spiral; of bars like a ladder (*scalariform*); or of a reticulated or dotted structure. They are formed by the apposition of cells end to end, the partitions disappearing after the deposition of the spiral or reticulated substance on the inner wall of the cell has been produced. In the higher animals the air tubes are larger and more complex, terminating in blind expansions or air vesicles.

2. *Blood Tubes.*—In this system we may comprehend the chyle and lymphatic as well as the capillary vessels, which, with the more complex substance of the arteries and veins, constitute the circulatory apparatus in animals. Simple ducts and tubes perform a similar office in plants. The arterial, venous, and lymphatic vessels resemble hollow viscera in having several coats, composed of areolar, elastic, and non-voluntary contractile tissues. The two former are most abundant in the larger vessels, the latter in the smaller arteries. The capillary or minutest blood-vessels are just large enough to enable the blood globules to pass through them in single file. They are composed of a delicate membrane, with nuclei scattered here and there through them, and are formed originally from cells which coalesce with one another by processes or branching prolongations. The smaller arteries and veins are highly contractile; and though it has been much disputed whether the capillaries are so, we have little doubt, from careful observations and measurements, that such is the case.

3. *Dental Tubes.*—These are found in the ivory or dentine, such as occur at an early period in the enamel being filled up by mineral matter to communicate increased density and hardness to that tissue.

4. *Nerve Tubes.*—Nervous matter is principally composed of tubes, which are largest and most symmetrical in the cerebro-spinal nerves, smaller but ampullated in the spinal cord, and smallest of all in the brain, where they gradually diminish in calibre towards the convolutions of the cerebral hemispheres. The tube itself consists of an extremely delicate membrane externally, inside which is an albuminous layer, constituting the wall of the tube, called the white substance of Schwann, and this contains an oleo-albuminous fluid; in this there may sometimes be seen a slightly fibrous structure, called the band of Remak, or the axis-cylinder of Purkinje. The wall of the tube is characterized optically by possessing a double line, with a clear space in the centre; and on breaking it up, it unites so as to form globules of various sizes, also distinguished by the double outline. The cause of the swellings or ampullæ in the spinal and cerebral tubes has been ascribed to the greater weakness of the investing membrane, and has been supposed to be a *post-mortem* phenomenon. Towards the circumference of the body these tubes terminate in loops. Throughout the body they form numerous connections, through the medium of the nerve cells, with one another, or with various parts of the nervous system. Their mode of termination in the gray matter of the brain has not yet been traced.

The general function of all the tubular tissues may be said to be that of conduction: the air tubes convey air, the blood tubes distribute the nutritive fluid to all parts of the economy, the dental tubes serve also as nutritive channels, and the nerve tubes conduct the nervous influence.

Theory of Nervous Conduction.

The nerve tubes possess a vital property, named sensibility or excitability, by virtue of which, when irritated, an influence is generated in the irritated or excited part of the nerve tube, and transmitted in certain directions with electric-like velocity. The rapidity with which this is effected negatives the idea that nervous influence travels in the interior of the tube with the contained fluid. It has been supposed that some vibration may be communicated to such fluid; but in fact we are as ignorant of the mode in which the nervous influence travels along a nerve tube as we are of the manner in which galvanism is conducted by a metallic wire. Some nerve tubes only conduct the influence of impressions from the circumference to the nervous centres; others only from the centres towards the circumference. From the circumstance, that some nerves only consist of the former, which, by communicating with the brain, give rise to sensations, they have been called nerves of sensation; whilst such nerves as only consist of the latter, and terminate externally in the muscular system, have been called nerves of motion. Most of the cerebro-spinal nerves, however, are composed of both sets. On tracing a nerve into a ganglion, or a mass of nerve cells, its component tubes separate and pass through it in different directions, in consequence of which an interlacement of them takes place in different directions, and the nerves which emerge from it result from a new combination of tubes, different from those which enter it. The result of this arrangement is, that the impression may be conducted in various ways from one centre or more to another, producing those endless combinations of mental, emotional, sensitive, and motor effects which are produced in the animal frame. These we shall describe more particularly hereafter. In the meantime we may say, that a nerve tube may be excited by psychical or physical causes, the former originating probably in the nerve cells of the brain, the latter from direct pressure or other mechanical causes. As a result of this excitation, a something is generated which, for want of a better term, we call an influence. This influence is then transmitted in various directions, according to the peculiar endowment and anatomical distribution of the tubes excited, occasioning, if they reach the brain, sensation; if the muscles, motion; if the various glands, an increase or diminution of their secretions; and if the blood-vessels, contraction or enlargement of their calibres.

Such are the four great elementary textures of living beings, on the integrity of which are dependent the important vital endowments of growth, contractility, and sensibility. If among these we search for a primary element out of which all the others are evolved, we may place it in some primitive cell, although this, so far as we can determine histologically, is derived from molecular matter, and this in its turn from an organic fluid. An extensive knowledge of the tissues must convince us that the molecule is the primary, as it is the most simple form, and that an aggregation of molecules may even form fibres and membranes

without the agency of cells at all. Again, they may combine so as to form nuclei; that is, simple closed vesicles containing a fluid, as in the bi-concave blood-disks of the mammal, which never proceed further in development. Upon nuclei so produced, however, cell-walls may be formed; and as a result of these, the various secretions and textures, as previously explained. Still, the molecule, and not the cell, seems to us to be the primary form; and it would appear, as we shall afterwards see in speaking of reproduction, that the successive elaborations which matter undergoes takes places by successive formations (*histogenetic*) and disintegrations (*histolytic*) of elementary molecules.

But before we can rightly comprehend the philosophy of the formative process, we must attend not only to the form, but to the chemical changes which organic matter undergoes during the successive transformations that take place during the growth and decay of living beings. This leads us to a short discussion of what is known with regard to organic chemistry.

PHYSIOLOGICAL CHEMISTRY.

Of the sixty-two elementary substances known in nature, only twenty are found in organized beings, of which eleven are non-metallic, and nine metallic. The non-metallic elements are oxygen, hydrogen, carbon, nitrogen, phosphorus, sulphur, chlorine, fluorine, iodine, bromine, and silicon. The metallic elements are potassium, sodium, calcium, magnesium, aluminum, iron, manganese, copper, and lead. Of all these, oxygen, hydrogen, carbon, and nitrogen may be regarded as the most essential, and as the basis of all organic matter. Phosphorus enters into the composition of albumen and fibrine, is solidified in the bones in the form of phosphate, and is also found in cerebral substance. Sulphur is necessary to the constitution of albumen, fibrine, and of caseine, and has been found largely in bile. Iron enters into the constitution of the blood. Calcium, in the form of lime, is united with phosphoric and carbonic acids in the skeleton, and in the covering of cretaceous animals. Sodium, in the condition of soda or of common salt, gives alkalinity to the humours and fluidity to the blood. Potassium has similar properties. Chlorine, existing in hydrochloric acid, forms part of the gastric juice; and fluorine has been found in milk and blood. The other substances are only occasional or accidental, and appear to depend upon peculiarities in the kind of food in animals, or soil in vegetables.

According to a beautiful generalization of M. Dumas, an animal should be regarded, in a chemical point of view, as an apparatus of combustion, which incessantly returns to the atmosphere carbonaceous matters in the shape of carbonic acid, hydrogen as a constituent of water, and free azote in the form of oxide of ammonium. In short, from the animal kingdom as a whole there is continually given off carbonic acid, watery vapour, and azote. Vegetables, on the other hand, absorb and fix these substances, retaining the carbon and hydrogen, and setting free the oxygen. They also abstract azote directly from the air, or indirectly from oxide of ammonium or nitric acid. Vegetables for the most part form organic matter under the influence of solar light. They pass ready formed as food into the bodies of animals, which, during their life or after their death, restore them to the atmosphere from which they were originally derived. Thus the animal kingdom is an apparatus of combustion, the vegetable kingdom an apparatus of reduction; the one produces the elements which the other consumes; so that, in the language of Dumas, they are the "offspring of the air." They come from the atmosphere, and return to it again.

The various mineral matters which enter into the constitution of living beings exhibit the same dependence which animals have upon vegetables, and these, again, upon inorganic matter. They simply pass through living beings, as it were, to serve certain important purposes in the scheme of life. Let us take lime and sulphur as examples. Rain water, loaded with the carbonic acid of the air, falls upon calcareous hills, and carbonate of lime, in a state of solution, enters rivers, and is by them carried to the ocean, where it is seized upon by millions of animals, and converted into their external skeletons or shells. The water of rivers and springs also is absorbed by plants and drank by animals; and so lime enters into their substance, and is converted into various salts of that basis, such as oxalates, tartrates, phosphates, &c. Phosphate of lime is the principal element of the bones, besides entering more or less into the constitution of the other tissues of the superior animals, which are continually excreting as well as assimilating it. Lastly, on their death, the lime is dispersed in various ways; even the bones crumble to pieces; and so the mineral returns to the soil from whence it came. Sulphur passes from one region to another in a similar manner, from the sea, which contains sulphur in large quantities, to the atmosphere, thence to the soil, and thence to plants and animals, from whence it again returns to the bosom of the ocean.

These incessant exchanges between the soil or atmosphere, plants and animals, have been laboriously worked out by M. Dumas, and constitute the theory now known as "the chemical balance of organic nature." Liebig, however, has shown that an animal is not the mere consumer of the organic principles elaborated by vegetables. There can be little doubt that, whilst this is done to a great extent, an animal may also produce them; for instance, it can transform, by a vital chemistry of its own, one principle into another, such as albumen into fat, sugar into oil or dextrine, and so on. It is only by a knowledge of this fact we could understand those remarkable degenerations which recent researches have shown us constitute so large a proportion of the organic diseases of man and animals.

The chemical proximate principles which are of such paramount importance in constituting the substance of living beings may be divided into four groups,—namely, 1*st*, The albuminous; 2*d*, The fatty; 3*d*, The pigmentary; and 4*th*, The mineral principles. All these are more or less associated together in every texture and fluid, but some abound in one, and others in another, giving to each peculiar characters.

Albuminous Principles.—These consist of albumen, fibrine, and caseine. Gelatine and chondrine are also allied to this group, although chemically they exhibit some marked differences from the others. Albumen, fibrine, and caseine also contain sulphur, and the two former a minute quantity of phosphorus; otherwise, their relative proportions of carbon, hydrogen, nitrogen, and oxygen are the same. *Albumen* forms the white of eggs, and occurs in large quantity in all the animal fluids that contribute to the nutrition of the organism. It is also found in most of the animal solids, and in nearly every morbid product. *Fibrine* forms nearly the whole substance of the muscles, but exists in small quantity in the blood. *Caseine* constitutes the chief ingredient in the milk of Mammalia. *Gelatine* is obtained by boiling animal membranes, skin, tendon, and bones, which yield a substance that on cooling becomes semi-solid, and if dried, hard and brittle. Common glue and isinglass represent this substance in different degrees of purity. It is apparently formed from the albuminous tissues by the action of boiling. The various albuminous principles now spoken of constitute the basis of the animal frame. They form, when coagulated, the walls of cells and the substance of fibres, tubes, and membranes. In solution, they are for the most part precipitated by acids and by oil, especially albumen; and when recently solidified, are again

partially dissolved by acids. The partial solubility of albuminous cell-walls and fibres enables the histologist to detect them with great ease under the microscope.

Fatty Principles.—Fatty matter may exist in living bodies under four conditions,—namely, free, saponified, non-saponifiable, and as a fatty acid. Chemically these consist of carbon, hydrogen, and oxygen, in various proportions; and hence have been called non-nitrogenous substances. In this respect they are analogous to starch, gum, and sugar, from which, apparently, they may be readily formed by a process of deoxidation. There can be no doubt, also, that fat may be produced from albuminous substances by a chemical process of a like nature; for muscles, if rendered inactive in the living body, become fatty, and if after death they be exposed to a stream of running water under certain conditions, they are converted into adipocere.

The healthy growth of the living tissues depends essentially on the union of the albuminous and fatty principles, and the constant chemical exchanges which are apparently taking place between them. The development of a young animal from an egg is a good illustration of this fact. It contains only albumen and a yellow fat with some traces of iron. Yet we see in the process of incubation, during which no foreign matter except atmospheric air can be introduced, that feathers, claws, blood-corpuscles, fibrine, cellular tissue, and vessels are produced. Moreover, the mere union of albumen and oil, under certain conditions, is apparently sufficient to produce those elementary molecules out of which all cells, as well as the molecular constitution of the chyle, are formed. The importance of this fact in nutrition and alimentation will be pointed out hereafter.

Pigmentary Principles.—The various tints communicated to the textures of plants and animals are dependent on two causes. First, the formation of a coloured secretion in the interior of cells, which may present a fluid or granular form, and the exact chemical constitution of which has hitherto been little studied. Secondly, refraction of the rays of light, in consequence of a grooved structure more or less covered with fatty particles, as in the brilliant refracting wing-cases of insects, feathers of birds, and in the tapetum of the choroid membrane. The pigment secretions are evidently allied to the oily constituents in living beings, are more or less dependent on light, heat, and exposure to the atmosphere, and are also influenced by the nature of the soil in vegetables and of food in animals.

Mineral Principles.—These are carried into the body of men and animals, combined with acids, partly in their food and partly in their drink. There they are acted upon in various ways, either by chemical changes induced in them by contact with other salts, but more especially by the oxygen of the atmosphere, which, entering the blood and coming in contact with all the tissues and fluids, is continually forming new affinities and combinations. The most important salts which enter the body are those of lime. Phosphate of lime forms the bulk of the bones and of teeth. Carbonate of lime is more abundant in the fluids and bones of graminivorous than of carnivorous animals. It also constitutes the principal part of the skeleton in the Invertebrata. Both salts enter the economy in the way referred to, become dissolved, and find their way into the blood, and from it are deposited in the organic matrix of bone or cartilage to give it firmness. Indeed, bones may be regarded as cartilage loaded with phosphate and carbonate of lime. In plants, and some of the lower forms of animals, silicious salts are deposited in like manner, to form skeleton of the texture. In every case the mineral solution infiltrates in the first place a cell structure; so that, on afterwards becoming solid in consequence of the disappearance of the water, an organized form is communicated to mineral matter, as in the silicious epidermis of the grasses, the shells of the Mollusca and Crustacea, and the bones of mammals. During life, the mineral, like the animal constituents, are continually undergoing changes, new particles being deposited from the blood, while the old ones are absorbed and excreted. Hence the mineral substances necessary for the textures must not only exist in aliment, but are constantly found more or less changed in all the secretions and excretions.

GENERAL PROPERTIES OF LIVING BEINGS.

Having now described the elementary forms and chemical constitution of the textures of living beings, and seen that they possess peculiar endowments, we may next inquire into the general properties which they present. On considering the nature of these, we may at once divide them into two classes,—viz., 1*st*, Those which are reducible to the laws of physics; and 2*d*, Those which, in the actual state of science, cannot be so reduced, and which *therefore* we call vital. The history of physiology exhibits a long series of struggles between the physicists and the vitalists, and we must confess that, in proportion as the vital functions have been encroached upon, so science has advanced. Thus the production of animal heat, and the processes of digestion and respiration, though formerly considered to be vital phenomena, are now known for the most part to be chemical. It is of the utmost importance, therefore, to ascertain what are physical and what are vital phenomena in a living body, not only that we may avoid confounding one with the other, but in order that we may know in what manner the vital functions may be best investigated.

Physical Phenomena of Living Beings.—We observe in the various kinds of living beings phenomena altogether physical, but which are essential to its existence: among these may be mentioned elasticity; gravity; hydraulic, optical, acoustic, and chemical phenomena; imbibition; and endosmose. The importance of this last, in a structure composed of membranes through which fluids are continually passing, must be evident. The cells out of which, as we have seen, most of the tissues are formed, present a membrane admirably adapted for the phenomenon of endosmose, and there can be little doubt that it is constantly operating in these bodies. Again, the absorption of fluid from the stomach and intestinal canal through the mucous membrane, and the processes of absorption and exhalation generally, must be connected with endosmose. Living beings are also subjected to the physical influences of caloric, electricity, and light from without, which operate upon them much in the same manner as they act upon matter in general.

Vital Phenomena of Living Beings.—Although many functions in vegetables and animals could not be explained without physics, there are scarcely any which can wholly be accounted for by mechanical or chemical principles, and thus to the most physical act there are peculiarities superadded in living beings which our present knowledge does not enable us to fathom. The properties of growth, of reproduction, of contractility, and of sensibility are so broadly distinct from anything as yet known to be mechanical, electrical, or hydraulic, as at once to evince the existence of something in connection with living beings alone, which we call vital. When, therefore, we employ this term we only mean that it characterizes certain phenomena which in the present state of our knowledge cannot be accounted for by physical science, and which, being found only in living beings, are consequently vital.

In studying the different phenomena, whether physical or vital, physiologists are in the habit of using the term force much in the same manner that it is used by the general cultivators of science: mechanics has its forces, such as that of the lever; chemistry has its forces, like that of affinity; and physical science has its forces, like

that of attraction. Physiology has also its forces. It has been supposed that in the same manner as we have physical attractions and repulsions, so we have vital attractions and repulsions. Then we have contractile, nervous, and germinative forces. The idea of force, whether in physics or physiology, as explanatory of phenomena, must be regarded only as theory, as a mental creation, which we employ as a convenient term to satisfy that intense desire of arriving at definite causes which is instinctive in man. On the other hand, it is often employed to express action, which may be demonstrated and often measured. In this sense it is as applicable to the action of a stomach or of a liver as it is to that of an electric telegraph or a steam-engine.

According to Mr Grove, the physical forces are "correlative," or have a relation of mutual dependence, each being capable of producing any one of the rest, either directly or through the medium of some other. Thus, the motion of a body retarded by friction gives rise to heat; and, conversely, heat applied to any form of matter produces its expansion,—that is, motion. The friction of two dissimilar bodies produces not merely heat, but electricity; and heat itself, when made to act on certain combinations of metals, also produces electricity; whilst on the other hand, the electric current may produce heat, light, magnetism, or motion, according to the nature of the substances through which it is transmitted. Light, heat, and electricity, again, are closely related to chemical affinity, which is often specially excited by them, and which can in its turn generate these forces; a material *substratum* being required in both cases. In the same way, as pointed out by Dr Carpenter, there may be a correlation of the vital forces. Thus, as we have seen, the most universal agents of growth are cells. But some of these produce one tissue, and some another, having different vital endowments. Thus, cells converted into muscular tissue, exhibit contractility; those converted into nerve, excitability. Here also a certain substratum or material substance is requisite for the conversion of one force into another. Then, as we have seen, there is a certain relation between the nervous and muscular force: one can call the other into action in a degree proportional to its own excitement; and, again, nervous agency is capable of influencing cell-formation in such a manner as to give rise to the idea that it may be re-converted into the forms of vital force necessary to evolve cells. Again, heat, light, and electricity have long been recognised as exciters or stimuli of the vital forces, and these, operating through a peculiar organized structure, may in fact become vital forces themselves, just as heat becomes electricity when it passes through a certain combination of metals. Thus, vital force may be converted into physical force, and *vice versa*, as when we see one set of cells directed to chemical action, another to mechanical movement, and a third to produce electricity, as in the case of the torpedo, or *Gymnotus electricus*.

It results that the physical and vital forces and properties are intimately united in a living body, and that the activity or life which it exhibits is the sum of those phenomena which we observe in it. When therefore we use the term life, we simply mean that an organized substance is possessed of certain properties partly peculiar or vital, and partly physical, which, when acted upon by appropriate stimuli, are competent to give rise to that series of actions in which life consists. We are as ignorant of the true nature of physical as we are of vital properties. It is from the effects alone that we infer their existence. Hence, if one substance exhibits the property of combustibility, it burns; if another, on being stretched, returns to its original size, it is elastic; and if a third presents growth, involving assimilation and excretion, it lives.

PART II.—NORMAL OR HEALTHY PHYSIOLOGY.

Having now ascertained the vital properties and chemical constitution of the elementary textures of the animal body, we have next to describe what is known of the functions of its more complex organs. These have been variously divided by physiologists; but I shall speak of them under three heads,—viz., 1*st*, Function of Nutrition; 2*d*, Function of Innervation; and, 3*d*, Function of Reproduction. The first of these comprehends all those processes called digestion, assimilation, circulation, respiration, absorption, secretion, excretion, &c., which are directed to building up, supporting, and removing the various textures of the body. The function of innervation comprehends those processes connected with locomotion, sensation, and thought or intellect; the third-named function, such as are necessary to the reproduction and development of the animal. The three functions are in the higher animals so intimately mingled together that they are with difficulty separated from one another. But in the lower we find that innervation gradually disappears as we descend in the scale. At first, mind, then voluntary motion, and then sensibility, is not present, until at length, when we arrive at the simplest condition of animal life, as in the infusorial animalcules, we find only an absorbing membrane with the power of reproduction. Although, therefore, the three functions may be intimately united and dependent on one another, we must study in the first place the laws by which each seems to be governed.

FUNCTION OF NUTRITION.

Instead of treating of nutrition as one of many functions, and especially as only comprehending what refers to the reception and assimilation of alimentary matter, we prefer regarding it as a great compound process, for which many acts are necessary, and all of which combine to keep up the nutrition of the economy. We may consider it as consisting of five stages,—viz., 1*st*, The introduction into the stomach and intestinal canal of appropriate alimentary matters; 2*d*, The formation from these of a nutritive fluid, the blood; and the changes it undergoes in the lungs; 3*d*, Passage of fluid from the blood to be transformed into the tissues; 4*th*, The disappearance of the transformed tissues, and their re-absorption into the blood; 5*th*, The excretion of these effete matters from the body in various forms and by different channels. We believe that it is only by understanding nutrition in this enlarged sense that we can obtain a correct explanation of the dependence of one process upon another, as well as of those important affections which may appropriately be called diseases of nutrition. We shall therefore treat of these stages separately, the whole of which will be more readily comprehended by a study of the diagram (p. 657), representing the different parts concerned in the nutritive function of a dog.

STAGE I.—*Introduction into the Stomach and Intestinal Canal of Appropriate Alimentary Matters.*

Aliment.—Food of every variety, when analysed, is resolvable into four elements,—viz., carbon, hydrogen, oxygen, and nitrogen, combined with certain minerals; and we have previously seen that in the great balance of organic nature, whether in the atmosphere, in water, in plants, or in animals, they play the chief part. The chemical constitution of plants and animals is exactly the same; and hence the

Physiology necessity which modern science has elicited for the food derived from one kingdom of nature being composed of

View of the Nutritive System of a Dog.

those elementary substances of which the bodies to be nourished in the other kingdom are themselves made up. The proximate principles, however, which contain these may vary under different circumstances, such as a hot or cold climate, or a peculiar constitution of body,—carnivorous or herbivorous, for example. In all cases, however, the demand for food is regulated by the waste of the tissues; hence the processes of growth require constant supply, and this is increased or diminished by the state of the respiration and the amount of bodily or mental exertion,—circumstances which induce loss of force and of texture.

In endeavouring to ascertain what are the best kinds of Physiology food requisite for meeting the demands of supply, attention must be paid to the following circumstances:—1*st*, The chemical principles which enter into the constitution of the living being to be nourished; 2*d*, The mode in which these are combined to form tissues and organs; 3*d*, The atmosphere which surrounds it; and, 4*th*, The amount of waste produced, as, for instance, amongst men variously employed.

1. With regard to the first point, we have seen that the chemical principles which enter into the constitution of a living being are the albuminous, the fatty, the pigmentary, and the mineral. The pigmentary may here be excluded from consideration, or regarded as a modification of the fatty; so that we may consider, in reference to dietetics, that the essential constituents of the animal frame are the albuminous, the fatty, and the mineral principles. No one of these groups alone will serve to keep up nutrition in an animal body. They must be all united; a fact which has been clearly demonstrated by numerous experiments of Magendie. He fed dogs upon sugar, oil, gum, or butter alone, and found that for one or two weeks they did very well, but after that, became weak, and died on the thirty-second or thirty-sixth day. When they were fed on white bread and water, they lived fifty days; when on cheese and white of egg, they lived longer, but became feeble, emaciated, and lost their hair. More recent experiments by Edwards and Balzac have shown that a diet of bread and gelatine is insufficient, producing death after emaciation, without appreciable lesion. A little addition of brown soup, however, renders bread and gelatine highly nutritious. Hence it is always necessary to associate a proper mixture of albuminous and fatty principles, in which the mineral enters as a constituent part. Of all the articles of food, human milk appears to be that which contains the three essential substances in the best proportions. A like result may be obtained by mixing other articles together, such as fat pork with veal, potatoes with beef, and rice with mutton or fowl. Again, stuffing is generally added to ham and veal, bacon to beans, ham to fowls, and so on. The addition of butter to bread is the almost universal food of the nursery. Mankind have for the most part adopted these rules instinctively. Persons who feed principally on flesh prefer it fat; and those who live largely on vegetables, as potatoes and rice, take considerable quantities of milk. The same result is obtained by the use of fermented liquors. Hence bread and wine constitute a diet resembling milk in chemical constitution. It is not mere nitrogenous or non-nitrogenous kinds of food, however, that will serve for nourishment, as is theoretically supposed by chemists. To form tissue, these chemical constituents must be converted into albumen and oil, so as to produce those elementary molecules found in the chyle, and which constitute the formative substance out of which nuclei and cells are developed. An unacquaintance with this histological truth has been the cause of much error in dietetics. The mineral elements necessary for nutrition, especially the salts of lime, potash, soda, and iron, constitute the ashes obtained by incineration from all articles of food, and are, as we have previously explained, as essential to the animal frame as the fatty and albuminous constituents.

2. With regard to the manner in which the essential constituents of food are combined to form tissues and organs, we have seen that the three groups of principles are necessary to every texture. There are some, however, which abound in one, and some in another. Thus the fibrous tissues abound in albumen, the glandular organs in fat, and the bones in mineral matter. Whenever fluid albumen and fat are brought in contact with one another, the former is precipitated in a membranous form, and if the two are mingled together by trituration, they assume to the naked eye the

appearance of milk or of an emulsion. This is owing to the formation of multitudes of particles such as are found in milk, composed of a delicate vesicle of albumen, containing a minute portion of oil. Such, also, is the invariable structure of all blastemata, or nutritious fluids; and hence the necessity of bringing fluid albumen and oil in contact,—a function performed by the stomach,—so as by their mixture together a properly constituted molecular basis be produced, out of which texture may be formed.

3. The atmosphere which an individual breathes evidently exercises an important influence on the nature and quantity of the diet. If cold and condensed, there is more oxygen, which will unite with the tissues during respiration, and produce more waste, while greater evaporation will take place from the surface; a larger supply is therefore necessary, and principally of matter which will rapidly give rise to carbonic acid. Hence the amount of animal and fatty food used by northern nations. In them, also, it will be found that alcohol in all its various forms is used with the greatest freedom; that is, a non-nitrogenized drink, useful, according to Liebig, as fuel for combustion. In warm countries, on the other hand, where the air is more rarified, a vegetable diet, abounding in sugar and starch, is employed; also non-nitrogenized substances, which, however, being more slow of digestion, are not so readily converted into matter for combustion. Thus, the non-nitrogenous kinds of food, as fat, starch, and sugar, by combination with oxygen, protect the tissues, and produce animal heat. The amount of oxygen in the atmosphere also explains how, with an equal expenditure of force in work, a man requires in summer a less supply of non-nitrogenous food than in winter.

4. The degree of bodily or mental exercise influencing the muscular and nervous textures influences the kind and amount of food. Those who spend their time in either kind of labour require more food than those who pass idle lives. This has been proved experimentally in a variety of ways, and is observable by paying attention to the dietaries of able-bodied men, such as sailors, as compared with those of prisoners and of the sick in hospitals. An able-bodied man requires from 31 to 36 oz. of dry nutritious food daily, of which 26 oz. may be vegetable. In prisons, somewhat less is required, although even there it is not safe to reduce the quantity below 30 oz. daily, as it occasions scurvy.

We can now comprehend some of the more striking phenomena of the modes of life and of respiration in man and animals. Nations of hunters, as well as the carnivorous animals, require a large quantity of fleshy nourishment. In violent corporeal activity they decompose their nitrogenous food into the constituents which serve to be transformed into the tissues on the one hand, and into carbon and hydrogen, to supply respiration, on the other. Hence the unquiet and restlessly active habits of the hunter and of rapacious animals, as well as the extended area for their existence; circumstances which require a scanty population. We meet with the other extreme among the nations which—as in the East Indian races, the Negroes—live wholly on rice, bananas, or similar vegetable substances, in which little nitrogenous matter exists. Hence the enormous quantity which these nations are forced to take in order to extract the necessary amount of actual nourishment for the tissues and for respiration. In this respect they resemble the herbivorous animals who pass most of their lives in a state of nature in feeding and sleeping. In the polar regions, again, we find an immoderate consumption of fat. Here man must produce a greater quantity of heat in order to live, and requires thereto a larger amount of combustible matter or fuel. For this purpose there could be scarcely any substance so applicable as the fat of animals, which principally consists of carbon and hydrogen. Finally, where the breeding of cattle is carried on, we have a transitional state, since man here makes use of the domestic animals to provide himself, in addition to meat, with the substances devoid of nitrogen, in the constituents of milk and the rich fat of the domestic animals, which is almost wholly absent in the wild ones. In this manner a skilful agricultural people leads the most judicious life, mingling nutritious substances in the same proportion as nature has mixed it for the suckling in milk, and deriving them from both the vegetable and animal kingdoms. For these generalizations we are indebted to Liebig.

Want of solid aliment produces a peculiar sensation called *hunger*, while want of liquid causes another called *thirst*. These are not so much dependent on a peculiar condition of the stomach or œsophagus as they are upon the general wants of the system. Voyagers in the arctic regions have related numerous instances among the Esquimaux of men who could devour enormous quantities of animal food with impunity; and other cases are known where, from habit, other persons have survived on surprisingly small quantities of nourishment. Certain animals, when they are large and fat, fall into a torpid state on the approach of winter, and continue so until the warmth of spring returns. During this period they take no food; their respiration is exceedingly slow; the blood has rather a gentle undulation than a circulation, and the trivial losses which take place are repaired by the gradual absorption of fat. Hence, at the end of the hybernating season, the emaciation of animals subject to its influence is very considerable. Some authentic cases are known of Indian fakirs who have sustained a complete fast, when in a state of trance, for from four to six weeks. Under ordinary circumstances, however, abstinence from food cannot be supported beyond the fourth or fifth day without danger. Young animals generally sink more rapidly than old ones. Of the 150 individuals wrecked in the Medusa, only 15 survived after 13 days of starvation; and some of these had assisted in eating parts of the dead bodies of their companions. One of the most important effects of starvation to attend to is, that after some days it destroys the power of digestion itself to a great extent. Hence the extreme caution necessary in treating such a case. At first only fluids should be given containing little nutriment, the amount of which must be gradually increased.

Mastication.—The food must be properly prepared for the changes it is destined to undergo in the stomach, and to this end it must be broken down by the action of the teeth, jaws, and tongue.

For a description of the teeth, the article ODONTOLOGY may be referred to. All that need be said here is, that they are organs admirably adapted, in man and the inferior animals, for seizing, lacerating, and grinding various kinds of food. They are fixed in the jaws, which move about in various directions by the action of the muscles. Man having a variety of movements, possesses a very complicated apparatus for this purpose. The tongue continually gathers together the aliment from below the dental arches, and when it is of soft material, assists in crushing it against the palate. To fulfil this function, it not only possesses great mobility, but is endowed with tactile sensibility, whereby we are enabled to judge of the physical qualities and situation of aliment in the mouth, as well as to push it about continually, and appreciate the degree of trituration it undergoes. The lips also being closed, they, with the muscular walls of the cheeks, assist mastication, in keeping the food into the cavity of the mouth, and preventing its accumulation outside the dental arches. As the result of these combined actions, the food is broken down, the utility of which must be obvious. All chemical processes, and the action of solvents, is favoured by division of the matter to be operated on. Too rapid eating is a common cause of indigestion; and considerable masses of food, if not broken

by the teeth, pass through the digestive canal unaltered, and deficient nourishment is the result, and this especially if they be principally vegetable, or contain the skins of fruits and husks of grain.

Insalivation.—The next process the food is subjected to is a mixture with a peculiar fluid, the saliva. This is a slightly viscid, transparent liquid, which, on standing, deposits a little flocculent sediment, composed principally of the scaly epithelium of the mouth and of the nucleated cells of the salivary glands. (See diagram, 1, 2, and 3.) It contains an organic chemical substance called ptyaline or salivine, on which its peculiar properties are supposed to depend. The food in the mouth constitutes the stimulus for the flow of saliva; and the common expression of the idea of a feast making a man's mouth water shows that the secretion may be excited by mental emotions. Its uses are,—1*st*, By keeping the mouth moist, to favour articulation; 2*d*, To assist in mastication, it being much more difficult to break down dry than moist substances; 3*d*, To facilitate deglutition, as it is impossible to swallow dry matters; 4*th*, To operate upon certain constituents of the food chemically, and although there is great difference of opinion as to how this is accomplished, it is supposed to affect more especially the starchy constituents, readily converting them into glucose or grape sugar; 5*th*, Liebig supposes that, owing to the viscidity of the saliva, air, in the form of froth, is carried to the stomach, and then yields up its oxygen to unite with the tissues.

Deglutition.—The food, reduced to a minute pulp by means of mastication and insalivation, is now carried from the mouth, through the œsophagus or gullet to the stomach (diagram, A). This is accomplished by a rapid contraction of numerous muscular parts, which unite together to produce the desired effect by the agency of a certain series of nerves acting through the spinal cord; hence called *diastaltic* (δια, *through*, στελλω, *to contract*). So long as the bolus of food is contained in the anterior part of the mouth it is under the control of the will, but once pushed back by the pressure of the tongue against the hard palate, to the posterior third of the tongue, it is involuntarily conveyed into the stomach. For this purpose, the lips are closed, to prevent escape of the morsel anteriorly; the soft palate is elevated to prevent its passage into the nasal cavities above; the contraction and backward action of the tongue presses the epiglottis over the larynx, which prevents its going into the windpipe inferiorly; and thus, no other mode of escape being left open, the pressure of the various muscles of the mouth, pharynx, and œsophagus, carry it by a continuous wave-like motion from above downwards towards the stomach. The cardiac orifice of the stomach then opens, and it slips through into that viscus.

Digestion in the Stomach.—The stomach is a bag (diagram, E) in which further mechanical and chemical processes are made to operate upon the food, in order to fit it for assimilation or conversion into blood and tissues. The substance of this bag is composed of a serous membrane externally, a muscular coat in its centre, and a mucous layer internally. The muscular coat is composed of three layers of contractile non-voluntary fibre, which closes upon the food, and subjects it to trituration or kneading, whereby the whole of it is intimately mingled together, and mixed with the gastric juice. It is also pushed about in a certain direction, moving along the great curvature from left to right, and then along the lesser curvature from right to left. These motions continue until the entire mass of food is broken down into a fine pulp, called chyme, and passes out of the stomach through the pyloric orifice. The stomach seems to be more irritable during the period of digestion, and its contractility more energetic; so that a stimulus will operate then which will produce no effect in the interval, or when fasting. Hence is explained why, during digestion, the outward orifice is so firmly closed that nothing but the finest pulp passes through it; but this process once over, undigested masses, and even large bodies, such as coins, have been known to go through.

The different motions of the stomach now spoken of have actually been seen to take place in the living human body, in a remarkable case, the study of which has so improved our knowledge of this function, that it deserves especial notice. It was that of a young man named St Martin, a Canadian, eighteen years of age, who, when in perfectly good health, was accidentally wounded by the discharge of a musket, on the 6th of June 1822. "The charge," says Dr Beaumont, who describes the case, "consisting of powder and duck-shot, was received in the left side, at the distance of one yard from the muzzle of the gun. The contents entered posteriorly, and in an oblique direction, forward and inward, literally blowing off the integuments and muscles to the size of a man's hand, fracturing and carrying away the anterior half of the sixth rib, fracturing the fifth, lacerating the lower portion of the left lobe of the lung, the diaphragm, and perforating the stomach." From this injury he gradually recovered, but the orifice never closed. When healed, twelve months after the accident, the perforation was two-and-a-half inches in diameter. Subsequently a small fold of the mucous coat of the stomach appeared, which gradually increased till it filled the aperture, and acted as a valve, so as completely to prevent any efflux from within, but to admit of being pushed back by the finger from without. Dr Beaumont, who had carried this difficult case to a successful termination, took the man into his service, and commenced a series of careful observations, which he has embodied in one of the most instructive works extant on the subject of digestion. On placing a solid substance through the opening into the stomach of St Martin, it was seen by Dr Beaumont to be subjected to the movements described.

These movements, however, though useful in perfecting and facilitating digestion, do not constitute the essential part of the process, as was shown by the experiments of Spallanzani, who caused metallic balls to be swallowed, filled with food, which, notwithstanding, was perfectly digested in the stomach. The mucous coat of the organ contains a multitude of follicular glands, that secrete an acid fluid, the gastric juice, which acts as a chemical solvent on the food subjected to it. This is not merely owing to acidity, but to the presence of a peculiar organic substance called pepsine, which is so powerful that one part dissolved in sixty thousand parts of water will digest meat and other alimentary substances. It is poured forth when food reaches the stomach, and is secreted in the tubular glands in the intervals of repose.

The conditions favourable for good digestion in the stomach are,—1*st*, A temperature of about 100° Fahrenheit; 2*d*, Constant movement of the walls of the stomach, which brings in succession every part of the food in contact with the mucous membrane and gastric juice; 3*d*, The removal of such portions as have been fully digested, so that what remains undigested may be brought more completely into contact with the solvent fluid; and 4*th*, A state of softness and minute division of the aliment. Numerous experiments have shown that digestion will go on in gastric juice out of the stomach, but takes a three or four times longer period than when performed by the stomach itself.

According to the experiments of Dr Beaumont upon St Martin's stomach, the rapidity of digestion varies according as the food is more minutely divided, whereby the extent of surface with which the gastric fluid can come in contact with it is proportionally increased. Liquid substances are for the most part absorbed by the vessels of the stomach at once, and any solid matter suspended in them, as in soup, are concentrated into a thicker material before the gastric

juice operates upon them. Solid matters are affected so rapidly during health that a full meal, consisting of animal and vegetable substances, may be converted into chyme in about an hour, and the stomach left empty in two hours and a half. Dr Beaumont found that among the substances most quickly digested were rice and tripe, both of which were digested in one hour. Eggs, salmon, trout, apples, and venison were digested in one hour and a half. Tapioca, barley, milk, liver, and fish, in two hours. Turkey, lamb, and pork, in two hours and a half. Beef, mutton, and fowls required from three to three and a half hours, and these were more digestible than veal. These facts were different from what was anticipated, and show that prevailing notions as to the digestibility of different kinds of food are very erroneous. It must be remembered, however, that easy digestibility does not imply high nutritive power. A substance may be nutritious, though so hard as not to be readily broken down; and many soft, easily digested materials may contain a comparatively small amount of nutriment.

Other circumstances besides those referred to affect digestion in the stomach. Among these are,—1*st*, The quantity of food taken: the stomach should be moderately filled, but not distended; 2*d*, The time which has elapsed since the last meal, which should always be long enough for the food of one meal to have completely left the stomach before more is introduced; 3*d*, The amount of exercise previous to and subsequent to a meal; gentle exercise being favourable, and over-exertion injurious to digestion; 4*th*, The state of mind; tranquillity of temper being apparently essential to a quick and due digestion; 5*th*, The bodily health; 6*th*, The state of the weather; 7*th*, Period of life; digestion being more active in the young than in the old.

Digestion in the Intestines.—The intestines have been divided into small and large, and each of these subdivided into three portions. Thus the small intestine is divided into duodenum (see diagram, I), jejunum (K), and ileum (L); and the larger intestine into cæcum (M), colon (N), and rectum (O). The whole constitutes a hollow tube with serous, contractile, and mucous coats, similar, but not identical with those of the stomach. The food operated on in the manner described enters the upper part of this tube, the duodenum, in the form of a thick, grumous fluid called chyme, of a strong, disagreeable acid odour and taste, and containing undigested portions of the food. This is now propelled from above downwards by the action of the contractile fibres of the intestine. As it descends, it is subjected to two kinds of operations,—1*st*, The influence of various fluids with which it is mixed; and 2*d*, The gradual absorption of its nutritive substance through the intestinal walls into the system.

Shortly after the chyme has passed out of the stomach it becomes mixed with the bile and the pancreatic juice,—two fluids secreted by the liver and the pancreas, which in man enter the duodenum by a common opening. The exact influence exerted by the bile on the chyme is not known, but it is supposed so to operate as to render the nutritive and excrementitious matter more easily separable. The bile serves other purposes, which will be dwelt on subsequently. The pancreatic juice is a clear alkaline fluid, which has the property, when mingled with a drop of oil, of emulsionizing it with the greatest readiness. Numerous observations and experiments by M. Bernard have shown that it operates with the greatest readiness on the fatty constituents of the food; and that in such animals as have the pancreatic separated from the biliary duct for some distance, as in the rabbit, milky chyle is only formed in the lymphatics after the food has passed the former. Hence there can be little doubt it does emulsionize the fluid fat of the food, and fit it for assimilation. At the same time, recent observations show that this is not its exclusive action, but that it also assists in digesting the other constituents which have escaped the operations of the mouth and stomach. The chyme is also mingled with the fluid of the Brunonian glands of the duodenum, and of the glands of Peyer and Lieberkuhn, scattered over the small intestine generally, but the particular changes these induce in it are not known.

As the chyme passes along the intestinal canal from above downwards, it is squeezed by successive contractions of the tube forcibly against the mucous coat of the intestine. This is covered over with prominences of various forms and lengths, denominated *villi*, which are pendulous folds or projections of the mucous coat itself, so as to afford a great extent of surface, over which the chyme passes. The more fluid parts, containing such portions of the food as have been reduced to excessive fineness, now pass through the membrane, and enter a series of ducts provided for that purpose. As the chyme, therefore, descends the alimentary tube, it is constantly losing its more fluid and nutritive portions, while other portions of it are being still farther digested and prepared for a like absorption. On reaching the cæcum, or commencement of the large intestine, it assumes a fœcal odour, and has now lost nearly the whole of its nutritive matters. Such as remain, however, are absorbed by the large intestine, whilst the useless matter becomes more and more solid, until it is expelled through the rectum. Supposing that thirty ounces of solid nutriment have been taken in the course of twenty-four hours by a healthy individual, only five of these are expelled as fœces. So that twenty-five ounces have been prepared, elaborated, and finally passed into the body to form blood, and through it into the various tissues and secretions, to supply the wants of the economy.

Stage II.—*The Formation from the Alimentary Matters of a Nutritive Fluid, the Blood; and the Changes it undergoes in the Lungs.*

Chylification.—The nutritive matters of the food, in a state of the minutest division, pass through the cell-walls of the epithelium covering the intestinal villi, probably by endosmose, although it has been supposed that there are minute pores which permit their entrance. From the interior of these cells they pass into the extremities of ducts, called lacteals, in a way that has hitherto eluded all research. What, however, *has* been seen is, that, when digestion in the intestines is active, the epithelial cells of the villi are filled with the fatty molecules and granules of an emulsion, the extremities of the villi themselves appear turgid, and the lacteals within them, where they are visible, are filled with a milky fluid. The continuation of these lacteals on the peritoneal coat of the intestines are also filled with this milky fluid or chyle, which flows in a continuous stream through the numerous lymphatic glands towards the thoracic duct. The chyle, when it is first examined on leaving the intestine, presents a milky appearance, and consists of a multitude of minute molecules, or a molecular basis when examined microscopically. After passing through the lymphatic glands, however, these molecules may be seen to be mingled with larger corpuscles, which are the lymph and chyle corpuscles previously described, and which are subsequently transformed into those of the blood.

Function of the Blood-Glands.—There are a series of glands, widely disseminated through the body, characterized by being very vascular, forming in their interior a multitude of colourless nuclei and cells, having no ducts, but richly furnished with lymphatics. To this group of organs not only belong the lymphatic glands, but the spleen the supra-renal capsules, the thymus, and thyroid glands. In infancy and early childhood the thymus and supra-renal capsules are large and active; they then decline and almost

disappear in man. The others are permanently active throughout life. The lymphatic glands evidently exercise a great influence over the fluid which passes through them, the exact nature of which is unknown, but which serves to elaborate or fit it more perfectly for the function it is to undergo. The fluid derived from the intestines in the manner described, passes through the mesenteric lymphatic glands, is of a milky appearance, and called chyle; that which goes through the other lymphatic glands is limpid, and denominated lymph. They also pour their contents into the thoracic duct, which in man enters the angle formed by the left jugular and axillary veins (diagram, 6); so that the whole joins the blood at that point. The thoracic duct further receives the lymphatics coming from the other blood glands, each of which contributes numerous corpuscles, in various stages of development, destined to become blood corpuscles.

Sanguification.—The blood, therefore, is formed and kept up not only by the nutritive matter derived directly from alimentary matters digested in the intestines, but by the constant secretion of fluids abounding in corpuscles derived from the blood-glands on the one hand, and lymph and matters absorbed into the circulation from the tissues of the economy on the other. Of this latter process, however, we shall speak subsequently. The formation of blood is undoubtedly connected with the reception of chyle and the function of the blood-glands. The former furnishes the proximate nutritive principles—albuminous, fatty, and mineral—reduced to a fine emulsion. In the blood-glands are produced the corpuscles according to the laws of cell growth, which, floating in the fluid, become more and more developed as they flow along the lacteals, and through the lymphatic glands towards the blood, on reaching which they are immediately transmitted through the right side of the heart to the lungs, and become blood corpuscles. Whether all the corpuscles formed in the blood-glands, and more especially in the spleen, reach the circulation through the thoracic duct, is doubtful. It is probable that the Malpighian glands of the latter organ may have some direct connection with the veins, although this has not been clearly demonstrated anatomically. The blood of the splenic vein, however, is always more rich in colourless cells than any other kind of blood; and in certain morbid conditions, where the spleen and other blood-glands are enlarged, that fluid is crowded throughout with colourless cells, constituting a morbid condition Dr Bennett first discovered and described, denominated Leucocythemia, or white cell-blood. That the corpuscles formed in these glands, therefore, do get into the blood is certain, although the channel by which they do so has not yet been clearly demonstrated. In the lungs most of the corpuscles in a state of health become coloured, and the blood itself undergoes important alterations.

Circulation of the Blood.—Having seen how the nutritive elements of the food are converted into blood, the method by which it is distributed or circulated throughout the organism should next be described. This circulation is carried on through the heart, the arteries, the capillaries or intermediary vessels and veins, back to the heart again. In the higher animals, there may be said to be two circulations, one connected with the body generally—the systemic or greater circulation—the other with the lungs—the pulmonary or lesser circulation. Let us suppose that it commences with the left ventricle of the heart (see diagram, 9). The blood passes from thence by the aorta through the systemic arteries into the capillaries, and back by the veins to the right auricle of the heart. From thence it goes into the right ventricle of the same organ through the pulmonary artery to the capillaries of the lung, in which it is exposed to the atmosphere, and then back through the pulmonary veins to the left auricle and left ventricle, where we saw that it commenced. In this constant round it is subject,—1*st*, To various forces which serve to propel it; and 2*d*, To different changes, the result of the respiratory and nutritive processes.

1. The most important force which propels the blood is induced by the contractions of the muscular walls of the heart, an organ so constructed that, by the union of contractile cavities and valves, the fluid is constantly sent through it only in certain directions. (For a description of the heart, see ANATOMY.) The action of this apparatus is accompanied by certain noises, caused by the combined contraction of the muscular walls, the rushing of the fluid, and the flapping together of the valves, an exact appreciation of which is the method by which the modern physician is enabled, with wonderful accuracy, to determine the diseases or derangements of the organ. The apex of the heart also is at each ventricular contraction tilted upwards and forwards, so as to strike the chest anteriorly between the fifth and sixth ribs, a little below and to the inside of the left nipple. This is caused by the peculiar spiral arrangement of its contractile fibres. The inner surface of the heart is considerably more irritable than the outer, and the right auricle retains the power of contractility longer than any other part of the body, and has consequently been called *ultimum moriens*. The blood is the natural stimulus to this contractility, and hence why, the more blood is forced into it as the result of exercise and increased respiration, the more rapid its actions become. The heart, however, will continue to contract regularly when cut out of the body of an animal recently killed, and when deprived of blood, but then the stimulus is supplied by the air, or by the table on which it lies. Under any circumstances, the rhythmical action of its various parts is owing to the distribution of ganglionic nerves in its substance, constituting one of the excito-motory actions which will be subsequently described. The heart is also readily excited by various emotions of the mind, though not by volition; hence in ancient times it was considered the peculiar seat of the affections and passions, an opinion which may be still traced in numerous expressions common to the phraseology of all languages even in the present day.

The force with which the left ventricle of the heart contracts is about double that exerted by the contraction of the right, which results from the greater thickness of its walls, and the greater resistance it has to overcome. It has been calculated that the static force with which the blood is impelled in the human aorta from the ventricle is equal to that of 4 lb. 4 oz., and in that of a mare is equal to 11 lb. 9 oz. The frequency of the heart's action is modified by a variety of circumstances, which we shall allude to immediately when speaking of the pulse. The arteries are tubes composed of elastic and contractile fibrous tissues, the former being most abundant in the largest vessels, where the pressure is greatest, while the latter exists almost alone, where the impulse of the heart is scarcely felt. Their functions are,—1*st*, The conveyance and distribution of blood to several parts of the body; 2*d*, The gradual conversion of the pulsatile or wave-like movements into a uniform flow.

The blood nowhere passes through an artery so rapidly as it is forced into it by the left ventricle of the heart, on account of the resistance offered by all the tubes against which it is forced. The consequence is, that when it receives the wave of blood, both the diameter and length of the vessel is increased, and this is followed by a recoil and recovery of its previous position, owing to the elasticity of the tube. These operations constitute the pulse, which is felt when the finger slightly compresses an artery. The pulse differs after violent exercise, according to the time of the day and position of the body. Exercise raises the pulse. It is quicker in the morning than in the evening; and hence, it has been

supposed, why a glass of wine is more stimulating early in the day than at night. In health, the pulse reaches its maximum about noon, and its minimum towards midnight. It is more frequent in the erect than in the sitting position, and quicker then than in the recumbent posture. The difference between standing and sitting is about 10 pulsations; between sitting and lying, 5; and between standing and lying, 15 pulsations; much, however, depends on the muscular effort employed. The natural pulse in the adult male may be stated as varying between 60 and 70 pulsations in the minute; that of the female being, on an average, about 10 beats more. In a newly-born infant, it is from 130 to 140; in old age, from 50 to 60. In diseases, the deviation from the healthy standard as to frequency is very remarkable. It has been known in profound coma to be only 17, and in cases of water in the brain in children it has been counted 200 in the minute. The volume or force of the pulse may also vary; hence the terms strong or weak, full or small, hard or soft, rigid, tense, wiry, thready, &c. As regards rhythm, it may be regular, irregular, unequal, intermittent, jerking, &c.

The capillaries, as was previously remarked, consist of delicate membranous contractile tubes, and their functions seem to be,—1*st*, To subdivide the blood, so that it may be brought within the attractive influence of the tissues; and, 2*d*, To act as fine filters, permitting an exchange of matter to be constantly carried on between the blood and the textures. In the transparent webs of certain animals, the blood may be seen passing through these tubes in a state of health with a uniform flow. There is no evidence that they exercise any influence in propelling the blood by contracting their walls, but there is every reason to suppose that the constant attraction exerted by the tissues in drawing nutritive matter from the blood must exercise a considerable power in drawing the blood onwards. We observe this in plants and animals which have no hearts or contractile vessels to propel the nutritive fluid, and we see it strongly manifested where, in consequence of increased local growth, the blood increases in a part, as in the scalp during the annual growth of the stag's horns, in the breast during lactation, in the gums during dentition, and so on. In all such cases the vessels of the part are enlarged and turgid with blood, a phenomenon formerly ascribed vaguely to a "determination of blood to the part," but now known to result from the increased attractive force exercised by the tissues on the blood in places which are the seat of excessive local growth. The same theory serves to explain, as we shall subsequently see, the phenomenon of the morbid process known as inflammation.

The veins arise from the capillaries, and are similar in structure to the arteries, with the exception that the elastic tissue is not so thick. It has been supposed that the forces propelling the blood through the arteries and capillaries are sufficient to cause its return to the heart through the veins, but this is assisted by internal valves and by the respiratory movements of the chest. The former are numerous, and so arranged that the blood can never return towards the capillaries. Every motion of the body and contraction of the muscles through which veins pass must, by compressing them, and thereby squeezing the blood towards the heart, assist its transit. Expiration favours the flow of blood in the arteries, and inspiration favours it in the veins, but does not operate in vessels distant from the thorax, and even in them to no great extent.

It is very difficult to determine the rapidity of the blood in different parts of the circulation. The most satisfactory results have been arrived at from watching the period occupied by poisons in passing from one part of the body to another, as in the experiments of Blake. From them it would appear that a portion of blood can traverse the entire circulation in the horse in half a minute.

The circulation presents peculiarities—1*st*, In different parts of the body; 2*d*, In the fœtus; 3*d*, In various animals, to particularize which here would lead us too far. One of the most important of these peculiarities occurs in the cranium, which being an unyielding osseous case, its contents are pressed upon by the atmosphere from below, like an inverted jar in a pneumatic trough. The result is, that so long as the cranial walls are uninjured, it must always hold the same amount of fluid. Hence the notion, that by general or local bleeding you can draw blood from the brain, is erroneous, although, by weakening the action of the heart, it is of course possible to diminish the pressure it exercises on the cerebral vessels.

2. The changes which the circulating fluid undergoes during its transit through the body are, the conversion of arterial into venous blood in the systemic capillaries, and its re-conversion into arterial blood in the pulmonary capillaries. This leads us to discuss in the next place the function of

Respiration.—This is carried on by means of lungs, the structure of which organs is so arranged as to expose a large surface, covered with capillary blood-vessels, to the action of the atmosphere. The dilation of the chest during ordinary inspiration is principally owing to the contraction and descent of the diaphragm muscle. But when a deep breath is taken, the cavity of the chest is further dilated by the intercostal, scaleni, serrati, and other muscles. Expiration ordinarily is owing to the elasticity of the lungs and walls of the chest, aided by the contractions of the abdominal muscles. During forced expiration the *longissimus Dorsi, Sacro lumbales,* and other muscles, cooperate.

The number of respirations which occur in the minute during health are from fourteen to eighteen, but in disease they have been known to be so low as seven, and so high as a hundred. The amount of air inspired also varies; in health ranging from 20 to 25 cubic inches (Coathupe). A man's average breathing capacity is best tested by a forcible expiration, which yields, according to Hutchinson, 225 cubic inches, as measured by the spirometer.

The great change which the atmospheric air undergoes in going into and coming out of the lungs is the removal of a portion of the oxygen and the substitution of a quantity of carbonic acid gas. For a long time it was supposed that the loss of the one was exactly equal to the production of the other, but it is now known that the volume of oxygen which is absorbed is far greater than that of the carbonic acid given off; and hence we must conclude that the former gas serves not only for the oxidation of carbon, but also of hydrogen in the animal organism. If the air be already charged in some degree with carbonic acid gas, the quantity exhaled is much less, a circumstance which strongly points out the necessity of ventilation. It is not sufficient for health that a room should contain the quantity of air requisite for the respiration of its inhabitants during a given time, since long before its exhaustion it will contain a quantity of carbonic acid sufficient to interfere with the necessary excretion from the blood. Hence the headache and other symptoms often experienced in breathing confined air. The manner in which oxygen is absorbed and carbonic acid given off, seems owing to the physical law described by Professor Graham with respect to diffusion of gases; and the quantity of the former which enters will be much greater than that of the latter, which passes out in the proportion of 1174 to 1000. The one-sixth of oxygen which thus enters the body, and is not converted into carbonic acid, is supposed to combine with hydrogen, furnished by the food and by the disintegration of the tissues, to produce water. Part of the water so formed is again exhaled in the form of vapour from the lungs, whilst another part is used in oxidizing the sulphur and phos-

phorus taken in with the food, and excreted chiefly in the condition of sulphuric and phosphoric acids. The absolute quantity of solid carbon given off by the lungs is about 160 grains per hour, or 8 oz. troy in the twenty-four hours. The amount of watery vapour given off varies from 6 to 27 oz., according to the nature of the diet, amount of exercise, temperature, humidity of the atmosphere, &c., &c. As regards the effects of respiration on the blood, the most striking is the change of colour of the claret-like venous into the bright scarlet of arterial blood. The temperature of arterial blood is one or two degrees higher than venous blood. (Davy.) The specific gravity and number of corpuscles also are said to be somewhat greater, and it contains a larger amount of oxygen and less carbonic acid.

Numerous chemical theories have been advanced to explain the manner in which oxygen is removed from the inspired air, and a quantity of carbonic acid gas added to expired air. To describe and criticise them in this article would be impossible with the limits prescribed us. Besides, whether the oxygen, after forming an acid, unites with the alkalies, whether it attaches itself to the corpuscles or to the fibrin, or unites with phosphorus and fatty matter, are points not yet finally determined.

If respiration be embarrassed or difficult, it constitutes *dyspnœa*; if arrested, from exclusion of atmospheric air, *asphyxia* is produced. As a general rule, if the air be cut off from the lungs of a warm-blooded animal by strangulation or immersion in water, all external muscular movements will cease in a period varying from three to five minutes, and the circulation comes to a stop in two minutes. Some individuals, by force of habit, seem to have acquired the power of retaining their consciousness for a considerable time under water, as in the divers of Ceylon, some of whom have been known to remain immersed and actively picking up oysters from three to five minutes. This period, under ordinary circumstances, is sufficient to induce death, for few persons recover who have been under water four minutes. Exceptional instances indeed are on record where persons have revived after a submersion of half an hour. It is supposed, however, that in these a state of syncope was occasioned at the moment of immersion, from fear, mental emotion, or concussion of the brain, so that in them respiration did not exist in its full activity. To restore asphyxiated persons no time should be lost. The individual should be immediately placed on the abdomen, with one of the arms below the forehead, to prevent the possibility of the nose and mouth being compressed by the ground. The body should then be alternately rolled on the side, and again placed on the abdomen, so as to imitate the compression and expansion of the chest in respiration. The extremities should be assiduously rubbed, especially pressing upwards, and warmth applied.

STAGE III.—*Passage of Fluid from the Blood to be transformed into the Tissues.*

We have now seen how nutritive matter enters the body, and the changes it undergoes to be transformed into blood. We have also seen how the blood is carried to all parts of the organism. We have next to trace how that organism is built up and maintained by substances derived from that blood.

We have previously shown that the tissues have a vital property of attraction and selection, whereby the necessary materials are drawn through the delicate membranous walls of the capillaries, and transformed chemically and structurally into the textures. We are forced to adopt this theory, for it can easily be shown that all the tissues depend on one fluid, the blood, for their nourishment; whilst it is also clear that this same fluid in different tissues and organs gives rise to different chemical and structural results. In this manner an animal is maintained for a series of years with the same physical characters, the different proportions between the supply and loss causing the rapid growth of the young, the stationary period of adult life, and the decline of age. Of the ultimate causes of the different variations in growth we know nothing. All that science can accomplish is to obtain a knowledge of the conditions on which it depends. Some of these we have spoken of when describing the cell theory, but there are four others to which we shall allude in this place.

1. *A healthy quality of the blood* is necessary for a healthy formation of texture, and this implies that all the processes of nutrition should be properly performed, including digestion, assimilation, respiration, secretion, excretion, and so on. Any one of these being disturbed, growth of the body, in whole or in part, may be faulty from want of appropriate material. The blood, however, enjoys to a certain extent the power of spontaneously correcting its own deteriorations, and if these be not excessive or too long continued, it rapidly separates, or gets rid of them by means of some apparatus, and its normal characters are restored. We are continually meeting with these occurrences during our observation of disease; and in this way we account for and see the use of occasional diaphoresis, diarrhœa, epistaxis, loaded urine, and so on. It is also possible that the excretion of one substance is more or less connected with the formation of another, as in the instances of what Mr Paget calls *complemental* nutrition, of which the growth of the beard in man, and of the mammæ in females at the period of puberty, are illustrations.

2. *A proper quantity of blood in a part* is also essential for growth, as is proved by the effects of those occurrences which, by destroying or injuring the principal vessel leading to it, causes its wasting or death. It is also observable that whenever parts are actively growing, they attract more blood to them than usual, showing that there is an intimate relation between activity of formation and the quantity of blood in the textures.

3. *A certain influence of the nervous system* is so blended and mingled with nutrition of parts in the higher animals that the improvement of the one materially interferes with the advancement of the other. Thus there is scarcely an organ in the body the functions of which may not be more or less deranged by various conditions of the mind. Hope and confidence are highly favourable to the resolution of numerous diseases; while fear and a foreboding of evil seldom fail to aggravate the most simple maladies, and in dangerous ones often render them fatal. Destruction of a nerve leading to a part, not only may cause wasting of the tissue, but often ulceration and destruction of it. The same occurs when disease attacks the spinal cord.

4. *A healthy state of the part to be nourished* is as necessary for growth as the other conditions mentioned. If the property of attracting and selecting materials from the blood be inherent in the textures themselves, as we have seen is probable, it follows that, if these textures be seriously altered or destroyed, the property will also be altered or destroyed. Now, this is what really takes place, and hence why so many diseases of texture, once occasioned, are kept up in spite of all the interference of art. Such is the reason, also, that blows and other injuries, by exciting or diminishing the vital properties of the textures, give rise to what are called inflammations, tumours, and other forms of so-called morbid growths.

Such are the conditions which serve to regulate growth in the animal economy. The process may be in excess or diminution, constituting what is called *hypertrophy* and *atrophy*. There is one modification of growth, however, which we must refer to especially, and which has long been known under the name of *secretion.*

Secretion.—This process was for a long time considered as one opposed to growth; that is, as a function having for its object to separate matters from, while growth was directed to storing up or adding them to, the organism. We now know that secretion is simply a form of growth, and is carried on under the influence of the same laws which regulate the development, maturation, and decline of nucleated cells in general, and of the conditions just referred to in particular. Under the head of "Cell Tissues" we have alluded to the peculiar properties of secreting cells. They are generally formed on one side of a basement membrane, while on the other side blood-vessels are distributed, from which their contents are derived. The variations in glands simply result from the convolutions and greater or less complexity of these universal gland elements. No relation apparently exists between the structure of the glandular apparatus, or the nerves supplying it, and the secretion it pours forth. Thus the pancreas, the lacrymal and mammary glands, are very much alike in their anatomical elements, although the pancreatic and lacrymal fluids and milk are widely different. This fact is sufficient to convince us that a property of a peculiar kind, essentially vital, must reside in the cells themselves, which occasions these results.

STAGE IV.—*Disappearance of the Transformed Tissues, and their Re-absorption into the Blood.*

While, on the one hand, matters are always passing from the blood to build up the tissues, on the other, matters are continually passing into the blood from those tissues which have fulfilled their appointed functions. The new material takes exactly the place and form of the old; so that the general configuration of the body is preserved, while continually and imperceptibly undergoing a change. Although in adult animals we cannot see the tissues forming, in the embryo we can, and are consequently enabled to infer the steps of the process. But we cannot see the healthy tissues disintegrating and absorbing, even in the embryo; and this source of information is therefore cut off from us. Almost all that we know of this process, from actual observation, is derived from the study of morbid anatomy. From this we learn that new formations, such as pus and cancer cells, break down and are reduced to a fluid state in the inverse order to that in which they were developed. Thus a fluid exudation is poured out from the vessels. It coagulates in the form of molecules and granules. These unite to form nuclei, around which cell-walls are produced. If this be their ultimate point of development, they are again reduced to the fluid state, first by the solution of the cell-wall, and subsequently by that of the nucleus. The whole now again presents a molecular and granular aspect, whilst the more fluid portions again pass through the walls of the blood-vessels, and enter the circulation. We do not see this process in health, but doubtless particle after particle of solid matter is reduced to fluid, and disappears, in order to give place to new particles, which for a time become solid, assume form, fulfil their function and allotted period of life, and then dissolve, are absorbed and excreted as their predecessors were before them.

Function of the Blood.—The blood, therefore, is a wonderfully complex fluid, partly made up of organic materials derived from the alimentary canal and blood-glands (*primary digestion*), partly derived from organic materials derived from the tissues and gaseous fluids received from the atmosphere through the lungs (*secondary digestion*). The constituents thus obtained from such various sources are modelled and changed during the circulation, so that they may readily pass off by other channels, and so escape from the economy. The stream of blood carries them to the various excretory organs, where they are separated; and thus the vast importance of a continued circulation of fluid is made manifest, not only in carrying materials of growth to build up the frame, but in removing the effete or worn-out particles which have fulfilled their office. In this manner the circulation of the blood may be compared to a river flowing through a populous city, which not only supplies the wants of its inhabitants, but conveys from them all the impurities which, through numerous channels, find their way into its stream. The general properties of this fluid now demand attention.

The blood corpuscles of which we have previously spoken float in a straw-coloured transparent fluid, the *liquor sanguinis*, which, when it ceases to circulate in the vessels, has the property of coagulating. This may be seen under the microscope to take place, in consequence of the deposition of the fibrin held in solution, in the form of molecular fibres, whereby a fibrous mesh-work is produced, entangling the corpuscles. The clot of the blood, therefore, is composed of the fibrin and corpuscles, while the serum is set free. When the blood coagulates slowly, or is unusually viscous from an increase of its fibrin, the corpuscles sink to the bottom, leaving a colourless layer on the surface of the clot, which was formerly supposed erroneously to be a distinctive sign of inflammation. In addition to fibrin, the *liquor sanguinis* holds in solution albumen, fat, and salts, and all those substances which are necessary, directly or indirectly, for the formation of the tissues and secretions. It may be regarded as the most elaborated portion of the blood, inasmuch as the corpuscles are dissolved in it; and, as previously stated, it receives the results both of the primary and secondary digestions. So prepared, it is the essential material or nourishing fluid, which, attracted through the capillaries by the tissues, is the foundation for all the formative processes of the economy.

Chemical Composition of the Blood.—The chemical constitution of the blood has been investigated by numerous distinguished chemists. We give the results arrived at, from a large number of data, by Becquerel and Rodier:—

Table, showing the Maxima, Minima, and Average Numbers of the Different Constituents in 1000 *parts of the Blood of Man:—*

	Mean.	Maxima.	Minima.
Density of defibrinated blood	1060 2	1062 0	1058·0
Density of serum	1028·0	1030·0	1027·0
Water	779·0	800·0	760·0
Blood corpuscles	141·1	152·0	131·0
Albumen	69·4	73·0	62·0
Fibrin	2·2	3 5	1·5
Extractive matters and free salts	6·8	8·0	5 0
Fatty matters	1·600	3·255	1·000
Serolin	·020	·080	impond.
Phosphorized fat	·488	1·000	·270
Cholesterin	·088	·175	·030
Saponified fat	1·004	2·000	·700

From 1000 parts of blood, after calcination, they obtained—

Chloride of sodium	3 1	4·2	2·3
Other soluble salts	2·5	3·2	2·0
Phosphates	·334	·7	·225
Iron	·565	·633	·508

We may say that the chemical composition of the blood in a general way is as follows:—1*st*, The great bulk of the blood is made up of water, varying in a healthy state from 760 to 800 parts in 1000; 2*d*, The fibrin is small in quantity, varying from ½ to 3 parts; 3*d*, The amount of albumen ranges between 60 and 70 parts; 4*th*, The blood corpuscles vary from 130 to 150 parts; 5*th*, The extractive matters and fat range from 1 to 4 parts; and 6*th*, The saline matters range from 5 to 10 parts. These are not the exact proportions, but approximative results which are more easily retained by the mind. The mean amount of this fluid in the human adult male is 34½ lb.; in the female, 26 lb. (Valentin.) These various results differ in diseased conditions of the body, con-

cerning which the following conclusions were formed by Becquerel and Rodier:—1*st*, That the simple fact of the development of a disease almost always modifies in a notable manner the composition of that fluid. 2*d*, That venesection exercises a remarkable influence on the composition of the blood; the more marked, the oftener it is repeated. Under these circumstances, the blood is impoverished and rendered more watery; the albumen is slightly diminished; the fibrin, extractive matters, and free salts are not influenced, but there is a decided diminution of the corpuscles. 3*d*, That in a plethoric condition of the system there is no relative increase in the number of the corpuscles, or in fact in any other change in the composition of the blood; it is simply the mass of the blood that is increased. 4*th*, That anæmia is characterized by a diminution in the amount of the corpuscles. 5*th*, That inflammation induces an increase of the fibrin and of the cholesterine; the former varying from 4 to 10, and the latter being almost doubled. The albumen is diminished. 6*th*, That the amount of fibrin is diminished, and possibly its physical conditions altered, under two conditions. The first embraces fevers, exanthematous diseases, and intoxication; the second, starvation and *purpura hæmorrhagica*. 7*th*, That when any of the secretions are checked, their essential principles are contained in the blood in excess. For instance, when secretion of the urine is suppressed, urea is found in the blood; when the bile is not excreted, it abounds in the blood, &c. And, 8*th*, That there are three diseases in which the albumen of the blood is notably diminished,—viz., in Bright's disease, in certain affections of the heart accompanied by dropsy, and in severe cases of puerperal fever.

Animal Heat.—Many of the processes we have described are accompanied by an exchange of chemical elements, which, in the act of forming new combinations, evolve heat. Thus the union of oxygen with the blood in the lungs, and the formation of carbonic acid gas in the capillaries make up together the amount of animal heat found in the body. The average temperature, as estimated by placing a thermometer in those internal parts which are most easily accessible, is from 98° to 100° Fahrenheit. In children it is about 2° higher. In febrile diseases it has been observed to rise to the height of 108°·5 in children, and to 107° in adults. In Asiatic cholera it may sink to 77°, or even lower, and the breath itself feels cool to the naked hand. The natural temperature of the body, though slightly affected by temperature, food, and exercise, is on the whole pretty stationary; a circumstance which for the most part is owing to the power of evaporation possessed by the skin. Hence the danger of suddenly checking perspiration, in exposing the surface to cold. The temperature of the various tribes of animals differs considerably, birds having a higher, and reptiles and fishes a much lower temperature than mammals, according to the medium they live in. They cannot, however, endure severe changes in external heat and cold. Man alone, by his power over food and the supply of artificial clothing and exercise, is enabled to bear without injury extremes of atmospheric temperature that no other animal could endure.

We have seen that more oxygen is taken in by the lungs than escapes from them in the form of carbonic acid gas. This excess, by uniting in the tissues with the carbon and hydrogen received into the system as food, produces heat; and the carbon in its conversion into carbonic acid, and the hydrogen in its change into water, gives off exactly the same amount of heat as if these processes had been carried on out of the body. Hence the quantity of heat generated bears a direct relation to the activity of respiration and the supply of food. Thus the respiratory process is most active in birds, and they possess the highest animal temperature; and in reptiles, in whom respiration is slow, the heat evolved is much less. Even in man all the circumstances which induce rapid breathing, such as exercise, occasion increased heat. As regards the influence of food, we observe that in northern climes, where the oxygen in the air is more abundant, the quantity of food taken is greater than among the inhabitants of tropical countries. The nature of the food, also, in the one, abounding in fatty and oily substances rich in carbon and hydrogen, is better adapted to combine rapidly with the excess of oxygen than the vegetable and starchy compounds used in others. The effects of alcohol, a highly carbonaceous substance, in keeping up animal heat, is in like manner thus explained; a substance which, rapidly entering the blood, combines with the excess of oxygen, and thus supports the temperature of the body when exhaustion from want of food, or from exercise too long continued, has been occasioned. Thus, in the words of Liebig, to whom we are indebted for establishing this theory of animal heat, "The animal body acts as a furnace, which we supply with fuel. It signifies nothing what intermediate forms food may assume, or what changes it may undergo in the body; the last change is uniformly the conversion of its carbon into carbonic acid, and of its hydrogen into water; the unassimilated nitrogen of the food, along with the unburned or unoxidized carbon, is expelled in the urine or in the solid excrements. In order to keep up in the furnace a constant temperature, we must vary the supply of fuel according to the external temperature, that is, according to the supply of oxygen. Hence, in the animal organism two processes of oxidation are going on; one in the lungs, the other in the capillaries. By means of the former, in spite of the degree of cooling, and of the increased evaporation which takes place there, the constant temperature of the lungs is kept up, while the heat of the rest of the body is supplied by the latter."

Stage V.—*Discharge of Effete Matters from the Body in Various Forms and by Different Channels.*

We have already seen that the textures of the body, while they are continually assimilating new particles of matter from the blood, are constantly giving up to that fluid the particles which have lived and are worn out. These in a fluid form, but more or less chemically changed, constitute the fibrin, and a portion of the fat, extractive matters, and salts which circulate in that fluid. They are the results of the disintegration of the tissues,—that is, of the secondary digestion of organic matter which takes place in the body,—and being useless, are now separated from the economy in the following ways, as—

1. *Excretion from the Lungs.*—A large amount of watery vapour and of carbonic acid are, as we have seen, continually passing off from the lungs. The water thus exhaled daily varies from 6 to 27 oz., and the carbon, in the form of carbonic acid, separated in the same space of time, amounts to 8 oz. troy. In addition, then, to considering the lungs as organs which supply oxygen to the blood, and as supporters of animal heat, they must be regarded as an apparatus of excretion, whereby oxygen, hydrogen, and carbon are continually separated from the body in a given form. Under the heads of Respiration and Animal Heat we have sufficiently dwelt on these points.

2. *Excretion from the Liver.*—Bile, as we have previously seen, is a secretion, but as it is one of those secretions which are produced in order to be excreted, and as the principal function of the liver is the separation from the blood of matters which, if retained, would be injurious to it, we must speak of it in this place.

The blood which supplies the liver is, like that which goes to the lungs, venous, and the portal vein which carries it there originates for the most part from the intestines (diagram, 12). Hence it differs from other blood in more

frequently containing principles derived from the primary digestion, more especially fat, dextrine, and sugar; whilst it does not possess so much fibrin, a substance principally formed from the secondary digestion; so that the clot it forms is deficient in firmness. The food, in traversing the alimentary canal, not only parts with substances which enter the systemic circulation to form blood, but also with portions of its material which enter the blood-vessels, and are at once directed through the portal vein to the liver, in order to form bile. We can easily understand, therefore, how rich eating and little exercise favour the production of those symptoms which are denominated bilious.

When the blood arrives by the portal vein at the liver, it breaks up into a multitude of minute capillaries, which, with a mass of secreting cells filling up the interspaces between them, are arranged in small masses or lobules. The vital property of the cells is to attract and select from the blood materials which they fashion into bile in their interior, and this is subsequently discharged into ducts, and accumulated in a gall-bladder until it joins the food in the duodenum, as previously described. The bile thus formed is a viscous yellow or greenish fluid, and of strong bitter taste, the amount of which formed daily has been estimated at 17 or 24 oz., but varies under a great variety of circumstances. It is composed of water holding salts in solution, with about 80 in 1000 parts of mucus, colouring matter, and fat. The salts are those of soda, potash, and ammonia, in combination with acids, one of which contains sulphur as a constituent. The colouring matter is called *biliphin*, and the fatty matter is composed principally of cholesterine, mingled with a small proportion of fatty acids.

Bile is excreted in two ways. A portion of it, including the colouring matter, passes through the whole alimentary canal. The greater portion, however, is absorbed into the blood, and is ultimately carried off by the respiratory process in the form of carbonic acid. The amount of the excretion in these two ways varies greatly, one being to a certain extent increased if the other be diminished. It is absolutely necessary for the bile to be conducted out of the system, and if, through any obstruction in the duct, it be prevented from being discharged, the bile enters the blood, producing jaundice, and acts as a poison. Although, therefore, the bile is useful as a secretion in operating on the chyme, there can be no doubt that its principal function is that of purifying the blood of hydrogen and carbon, and acting as an excretion.

The liver also secretes a large quantity of free fat, which, accumulating in the cells of the organ, often causes its enlargement, or so-called fatty liver. It has further been shown by Bernard constantly to secrete a substance which, when separated, presents all the physical and chemical properties of hydrated starch. The moment this comes in contact with the blood of the hepatic vein, it is converted into sugar, which in its turn is decomposed by the oxygen of the air in the lungs, and there disappears. If the pulmonary action be insufficient to accomplish this, the sugar becomes in excess in the blood generally, and is excreted by the kidneys, forming the disease known as diabetes. Hence also why a section of the pneumo-gastric nerves, injuring the fourth ventricle of the brain, and occasionally blows on the head, may occasion diabetes. The liver, whether giving off bile, fat, or starch, is thus evidently a great excretor of hydro-carbon, which is converted into water and carbonic acid, and given off by the lungs.

That the lungs and liver are to a certain extent associated for the purpose of a common function, is further shown by the circumstance, that in those cases where the lungs imperfectly separate carbonic acid gas, the action of the liver is particularly apt to be disturbed. Thus, if more non-nitrogenized food be taken than can be got rid of by the lungs in the form of carbonic acid, the liver pours a greater quantity of bile into the duodenum, causing those symptoms known as *bilious*. This is what happens frequently to Europeans in tropical climates. The rarity of the atmosphere, and the little exercise which is taken, throws increased work upon the liver. The appetite is stimulated by drugs and spices, which increase the disturbance, rendering a return to Europe necessary. All such persons, therefore, should carefully adapt a certain diet to the amount of exercise they take and the vigour of the respiration, avoiding carbonaceous, especially oily food, and alcoholic drinks, and living according to the simple habits of the natives.

Excretion from the Kidneys.—The two kidneys contain in their cortical substance globular convolutions of capillary vessels, which hang in the blind extremities of the tubular glands. This arrangement permits the ready passage of a large amount of water from the blood, which, as it flows out through the duct, receives the secretion formed by the cells which line them. The whole accumulates in the urinary bladder in the form of urine, and is expelled from time to time voluntarily (diagram, P and R). The daily amount of urine discharged in a healthy person is about 35 fluid ounces, of a wine-yellow colour, and is slightly acid in its re-action on vegetable colours. Its composition, according to Becquerel, is as follows:—

Water	967·
Urea	14·230
Uric acid	·468
Colouring matter; Mucus and animal extractive matter — inseparable	10·167
Salts: Sulphates (Soda, Potash); Bi-phosphates (Lime, Soda, Magnesia, Ammonia); Chlorides (Sodium, Potassium); Hippurate of soda; Fluate of soda	8·135
Silica	traces
	1000·000

The proportion of these constituents varies greatly, even in health, according to the amount and quality of the food and drink, the occupation, period of life, sex, and other circumstances. In disease the variations are still greater. The quantity, as a whole, may be increased or diminished, and the saline constituents may be so augmented as to be deposited on cooling, causing the formation of various salts. The urine may also be loaded with foreign substances, as blood, albumen, pus, sugar, &c. Hence why a careful examination of this fluid is so important to the physician, as indicating a variety of morbid conditions, not only of the urinary organs themselves, but of the constitution generally.

The kidneys, therefore, separate,—1*st*, A large quantity of the water which enters the body as drink; 2*d*, Certain materials derived from the primary digestion; and, 3*d*, Matters the result of the secondary digestion, or disintegration of the tissues. The principal object of the kidney is to separate two substances rich in nitrogen; so that, while the liver may be considered as an organ excreting hydro-carbon, the kidneys must be regarded as organs which separate nitrogenous substances. The forms these assume are two, viz., urea and uric acid. Of the former, 270 grains, or more than half an ounce, are excreted by a healthy man daily, and of the latter, somewhat more than 8 grains. According to Liebig, when the vital force in the albuminous tissues is no longer able to resist the chemical action of the oxygen which is conveyed to them in the arterial blood, it combines with their elements, and forms products, among which uric acid is the most important. But if sufficient oxygen and water be conveyed into the arterial blood, the greater part of the uric acid, or more insoluble salts, is converted into urea and carbonic acid; so

that the effete nitrogenized elements of the tissues reach the emunctories in a soluble form, a condition necessary for their ready secretion. Hence the more oxygen enters a tissue during its disintegration, the more complete will be the conversion of the insoluble uric acid into the soluble urea, and the more easy its elimination from the body.

In this manner is explained how the urine of the boa-constrictor is semi-solid, consisting almost entirely of bi-urate of ammonia, as the animal eats an enormous meal of nitrogenous food; but being a cold-blooded, slowly-respiring animal, it takes in too little oxygen to convert the uric acid into urea. On the other hand, the lion and the tiger, equally carnivorous with the serpent, are rapidly-respiring, warm-blooded animals; and although, from their violent muscular exertions, rapid and great destruction must occur, scarcely a trace of uric acid is found in their urine, as it is all converted into urea at the moment of its formation, in consequence of the abundant supply of oxygen. The non-nitrogenized elements of our food, however, considerably interfere with the conversion of uric acid into urea, because they also combine with oxygen. Hence, according to Liebig, man, being an omnivorous animal, partakes of a sufficient amount of food rich in carbon to prevent the complete conversion of insoluble uric acid into soluble urea; consequently, the former substance appears in the urine, its proportion to urea being as 1 to 32.

In addition to urea and uric acid, which are the excretory products of the nitrogenous compounds, the kidney is continually separating from the blood a large quantity of earthy salts. These are separated daily, to the amount of 138 grains, and they consist of combinations of chlorine, sulphuric, and phosphoric acids, with soda, lime, magnesia, and potass. Of these, the phosphatic salts are by far the most important. It has been calculated that about 6¼ grains of phosphoric acid are thrown off by the kidneys in twenty-four hours, which are united to the four bases,—soda, ammonia, lime, and magnesia,—forming two double and one simple salt,—viz., the ammoniaco-phosphate of soda; the ammoniaco-magnesian, or triple phosphate; and the phosphate of lime.

Both the organic and mineral products may undergo excess or diminution, resulting from derangements in the primary or secondary digestive processes. Excess of uric acid in the blood may arise in two ways, constituting a tendency to gout or rheumatism,—the first from indulgence in eating, the second from hard labour and wasting of the tissues. Or the mineral salts may form in abundance from eating substances they contain; or from disintegration of the textures, the result of severe study; or, as occurs in old age, from their natural decay.

Excretion from the Skin.—The skin not only serves as a most efficient protective covering to the body, but is a most important organ, constantly excreting watery and fatty matters. The epidermis, hair, and various appendages which are constantly growing from the surface, may, in addition to the special purposes they are fitted for, also be regarded as excretory.

The water separated from the blood by tubular glands—the so-called sudoriparous or sweat glands—is for the most part carried off from the surface in the form of vapour as fast as it is separated. When, from increased exertion or other cause, the perspiration is augmented in quantity, or when, from a greater degree of moisture in the atmosphere, it is not readily evaporated, it becomes visible in the form of minute drops, which distil from the surface. The fluid consists principally of water, holding in solution a small quantity of the salts of soda, potash, and lime, with a trace of oxide of iron. The amount given off daily varies greatly—the maximum, according to Séguin, being 5 lb., and the minimum, 1 lb. 11 oz. 4 dr. The average quantity, according to Valentin, is 2¼ lb. There is an intimate relation between the functions of the skin and those of the lungs and kidneys,—the one being more active when the other is depressed. Animals, on being covered with an impermeable varnish die, with all the symptoms of asphyxia, while the temperature of the body rapidly sinks 36 degrees. Again, skin diseases, and especially febrile eruptions, materially affect the kidney, and thereby give rise to secondary dropsies.

An oily fluid is constantly poured out on the skin from another series of follicular or sebaceous glands, preventing it from being dried and cracked by the action of the sun and air. Hence it is more abundant in the races which inhabit warm climates. In these, and many of the lower animals, the sebaceous matter possesses a distinctive odour, whereby they can readily be traced by quick-scented dogs. Generally speaking, the oily matter excreted from the skin is conveyed directly to the hairs or other epidermic appendages in those parts of the surface which are supplied by them.

The hair and nails grow from the base of a follicle or gland, and are developed from the cells formed in the base of such follicle so as to form a fibrous structure. A hair, if allowed to grow, tapers towards a point, and then splits up like a painter's brush, becomes brittle, and breaks off. There can be no doubt that the oily or sebaceous matter which Nature has provided to lubricate such structures keeps them soft, and prevents their breaking off too suddenly. The colour of the hair depends upon the presence of pigment secreted within the cells of the follicle. Well-authenticated instances of hair turning white in a short period, from excessive grief or anxiety, are known. According to Vauquelin, this is owing to the secretion of an acid fluid, which percolates the hair, and chemically destroys the colouring matter. In the various classes of animals the epidermic appendages serve the purposes of warmth, of defence, or as aids to the sense of touch; and the modifications they undergo,—as seen in horn, the quills of the porcupine, the feathers of birds, the scales of fishes, the wing-cases and spines of insects, &c.,—embrace a singular variety of form, constituted of the same structure.

The colour of the skin was formerly supposed to exist in a distinct membrane called the *rete mucosum*, situated between the epidermis and chorion. It is now known to depend on the deposition of pigment in the lower cells of the epidermis, or those nearest the blood-vessels, and to be influenced by the general laws which regulate the formation of pigment in the animal and vegetable worlds.

Excretion from the Intestines.—We have seen that the solid nutritive matter received as food daily ought to amount to 30 oz.; of these, 25 oz. are absorbed, and only 5 oz. rejected daily from the intestines. These consist of certain parts of the food which have escaped the digestive process, and of various secretions which have been poured into the alimentary canal during its passage. Among the latter are numerous crystals of triple phosphate, showing that earthy matters are excreted in large quantities by this channel. In the large intestine, and especially in the cæcum, a further chemical change is effected. In the latter situation the peculiar fœcal odour is first produced, owing, it is supposed, to the secretion of an acrid liquid there, causing another kind of digestion.

Such is a general sketch of the function of nutrition, from which we observe, from an extended point of view, that it is a continuous round, which in the natural world may be said to commence with the reception and terminate with the preparation of aliment, vegetable or animal. This is observable not only in the "chemical balance of organic nature," so beautifully described by Dumas, but in the incessant chemical compositions and decompositions, as well as structural formations and disintegrations, which are

peculiar to all vital entities. If so, it must be apparent that our knowledge of the animal economy, and of the diseases to which it is liable, can only be elucidated by investigating the nature of such chemical and structural changes, together with the necessary relations that each one bears to the others, and that it is on such kind of knowledge alone that medicine as a scientific art can ever repose in security.

We can, for instance, now readily understand how derangement in one stage of the nutritive process more or less affects the others. Thus, if alimentary matters are not furnished in sufficient quantity, and of a proper quality, the blood is rendered abnormal, and it necessarily follows that the matters it gives off will be abnormal also, and its subsequent transformations more or less modified. Again, if secretion be checked, the blood is not drained of its effete matter; and if excretion be prevented, the secretions themselves may enter the blood, and act upon it as a poison.

A diseased or morbid state of the blood, therefore, may arise from either of the stages of nutrition we have described being rendered irregular, or otherwise abnormal. In whatever part of the circle interruption takes place, it will, if long continued, affect the whole. Thus, a bad assimilation of food produces through the blood bad secretions and excretions, whilst an accidental arrest of one of the latter reacts through the blood on the assimilating powers. The forms of disease thus arising may be endless; but as regards nutrition, they may all be traced to the following causes:—

1. An improper quantity or quality of the food.
2. Circumstances preventing assimilation or impeding respiration.
3. Altered quantity or quality of nutritive matters passing out of the blood.
4. The accumulation of effete matters in the blood.
5. Obstacles to the excretion of these from the body.

Examples in which each of these causes, separately or combined, have occasioned disease, are of frequent occurrence. It is true that all general diseases are accompanied by certain changes in the blood, but these changes are to be removed, not by operating on that fluid directly, but by obviating or removing those circumstances which have deranged the stage of nutrition primarily affected. For instance, a very intense form of disease may be produced in infants from improper lactation. The remedy is obvious, and we procure a healthy nurse. Ischuria is followed by coma, from the accumulation of urea. We give diuretics to increase the flow of urine, and the symptoms subside. In the one case we furnish the elementary principles necessary for nutrition; in the other, we remove the residue of the process. In both cases the blood is diseased, but its restoration to health is produced by acting on a knowledge of the causes which led to its derangement.

In the same manner we might illustrate the indications for correct practice in the other classes of causes tending to derange the blood, which we have enumerated. Thus, although there be a proper quantity or quality of the food, there may be circumstances which impede its assimilation; for instance, a too great acidity or irritability of the stomach, the use of alcoholic drinks, inflammation or cancer of the organ. It is the discovery and removal of these that constitute the chief indications of the scientific practitioner. Again, the capillary vessels become over-distended with blood, and the exudation of *liquor sanguinis* to an unusual amount takes place, constituting inflammation. How is this to be treated? In the early stage, topical bleeding, if directly applied to the part, may diminish the congestion, and the application of cold will check the amount of exudation. But the exudation having once coagulated outside the vessels, acts as a foreign body, and the treatment must then be directed to furthering the transformations which take place in it, and facilitating the absorption and excretion of effete matter. This is accomplished by the local application of heat and moisture, the internal use of neutral salts to dissolve the increase of fibrin in the blood, and the employment of diuretics and purgatives to assist its excretion by the kidneys or intestines.

The general principle we are anxious to establish from this general sketch of the nutritive functions is—that diseases of nutrition and of the blood are only to be combated by an endeavour to restore the deranged processes to their healthy state, in the order in which they were impaired; that for this purpose, a knowledge of the process of nutrition is a preliminary step to the proper treatment of these affections; that the theory of acting directly on the blood is incorrect; and that an expectant system is as bad as a purely empirical one.

FUNCTION OF INNERVATION.

The function of innervation, like that of nutrition, consists in the performance of various actions, widely different from each other, although associated together. These actions lead to the manifestation of intelligence, sensation, and combined motion, and are dependent on the vitality of complex organs,—viz., the brain, spinal cord, and nerves. But as the connection between these cannot be shown to exhibit such an order of functional sequence as has been made apparent among the nutritive processes, it will be necessary to describe them in a different manner.

General Arrangement of the Nervous System.

To the eye, the nervous system appears to be composed of two structures—the gray or ganglionic, and the white or fibrous. The ganglionic, when examined under high powers, may be seen to be composed of nucleated cells, varying greatly in size and shape, mingled with a greater or less number of nerve-tubes, also varying in calibre. The fibres, as we have previously seen, consist of minute tubes. There are also bundles of gelatinous or flat fibres, the nature of which is much disputed, very common in the olfactory nerve and sympathetic system of nerves. There can be no doubt that some nerve-tubes run into the ganglionic corpuscles, whilst others originate from them. It is also now rendered certain that the same ganglionic cell may receive and give off nerve-tubes, each having distinct properties, the one of conveying the influence of impressions to, and the other of conveying influences from, the nervous centres.

The general arrangement of the two kinds of structures should be known. By cerebrum, or brain proper, ought to be understood that part of the encephalon constituting the cerebral lobes, situated above and outside the *corpus callosum;* by the spinal cord, all the parts situated below this great commissure, consisting of *corpora striata, optic thalami, corpora quadrigemina, cerebellum, pons Varolii, medulla oblongata,* and *medulla spinalis.* In this way, we have a cranial and a vertebral portion of the spinal cord.

In the cerebrum, or brain proper, the ganglionic or corpuscular structure is external to the fibrous or tubular. It presents on the surface numerous anfractuosities, whereby a large quantity of matter is capable of being contained in a small space. This crumpled-up sheet of gray substance has been appropriately called the hemispherical ganglion. (Solly.) In the cranial portion of the spinal cord, the gray matter exists in masses, constituting a chain of ganglia at the base of the encephalon, more or less connected with each other and with the white matter of the brain proper above, and the vertebral portion of the cord below. In this last part of the nervous system the gray matter is internal to the white, and assumes the form of the letter X, having two posterior and two anterior cornua,—an arrangement which allows the latter to be distributed in the form of nerve-tubes to all parts of the frame.

The white tubular structure of the vertebral portion of the cord is divided by the anterior and posterior horns of gray matter, together with the anterior and posterior sulci, into three divisions or columns on each side. On tracing these upwards into the *medulla oblongata*, the anterior and middle ones may be seen to decussate there with each other, whilst the posterior columns do not decussate. On tracing the columns up into the cerebral lobes, we observe that the anterior or pyramidal tracts send off a bundle of fibres, which passes below the olivary body, and is lost in the cerebellum—(*Arciform band* of Solly). The principal portion of the tract passes through the *corpus striatum*, and anterior portion of the optic thalamus, and is ultimately lost in the white substance of the cerebral hemispheres. The middle column, or olivary tract, may be traced through the substance of the optic thalamus and *corpora quadrigemina*, to be in like manner lost in the cerebral hemispheres. The posterior column, or restiform tract, passes almost entirely to the cerebellum.

In addition to the diverging fibres in the cerebral hemispheres which may be traced from below upwards, connecting the hemispherical ganglion with the structures below, the brain proper also possesses bands of transverse fibres, constituting the commissures connecting the two hemispheres of the brain together, as well as longitudinal fibres connecting the anterior with the posterior lobes. In the spinal cord it results, from the investigations of Lockhart Clarke, that there is a decussation of various bundles of fibres throughout its whole extent. It is now also determined that many of the fibres in the nerves may be traced directly into the gray substance of the cord—a fact originally stated by Grainger, but confirmed by Budge and Kölliker. Further, it has recently been shown that, by means of these fibres, an anastomosis is kept up between the various columns, even those on both sides of the cord, through the medium of nerve-cells in the gray matter; an important fact, principally demonstrated by the labours of Stilling, Remak, Van der Kolk, Schilling, Kupffer, and Owsjannikow.

These later observations, indeed, open up to us the probability that the numerous actions hitherto called reflex are truly direct, and are carried on by a series of nervous filaments running in different directions, which have yet to be described. There can be no doubt that they pass and operate through the cord; and hence the term *diastaltic* proposed by Marshall Hall instead of reflex, is in every

way more appropriate. The importance of this view appears to us so great, that we refer to the accompanying figures from the Thesis of Owsjannikow,[1] showing the connection of the nerves and ganglionic cells in the spinal cord of the salmon, as indicative of probable similar relations yet to be discovered in man.

General Functions of the Nervous System.

The great difference in structure existing between the gray and white matter of the nervous system would, *à priori*, lead to the supposition that they performed separate functions. The theory at present entertained on this point is, that while the gray matter eliminates or evolves nervous power, the white matter simply conducts to and from this ganglionic structure the influences which are sent or originate there.

The brain proper furnishes the conditions necessary for the manifestation of the intellectual faculties properly so called, of the emotions and passions, of volition, and is essential to sensation. That the evolution of the power especially connected with mind is dependent on the hemispherical ganglion, is rendered probable by the following facts:—1. In the animal kingdom generally, a correspondence is observed between the quantity of gray matter, depth of convolutions, and the sagacity of the animal. 2. At birth, the gray matter of the cerebrum is very defective; so much so, indeed, that the convolutions are, as it were, in the first stage of their formation, being only marked out by superficial fissures almost confined to the surface of the brain. As the cineritious substance increases, the intelligence becomes developed. 3. The results of experiments by Flourens, Rolando, Hertwig, and others, have shown that, on slicing away the brain, the animal becomes more

[1] *Disquisitiones Microscopicæ de Medullæ Spinalis Textura*, 1854.

dull and stupid in proportion to the quantity of cortical substance removed. 4. Clinical observation points out, that in those cases in which the disease has been afterwards found to commence at the circumference of the brain, and proceed towards the centre, the mental faculties are affected *first;* whereas in those diseases which commence at the central parts of the organ, and proceed towards the circumference, they are affected *last.*

The white tubular matter of the brain proper serves, by means of the diverging fibres, to conduct the influences originating in the hemispherical ganglion to the nerves of the head and trunk, whilst they also conduct the influence of impressions made on the trunk, in an inverse manner, up to the cerebral convolutions. The other transverse and longitudinal fibres which connect together the two hemispheres, and various parts of the hemispherical ganglion, are probably subservient to that combination of the mental faculties which characterizes thought.

The spinal cord, both in its cranial and vertebral portions, furnishes the conditions necessary for combined movements; and that the nervous power necessary for this purpose depends upon the gray matter, is rendered probable by the following facts:—1*st,* Its universal connection with all motor nerves. 2*d,* Its increased quantity in those portions of the spinal cord from whence issue large nervous trunks. 3*d,* Its collection in masses at the origin of such nerves in the lower animals as furnish peculiar organs requiring a large quantity of nervous power, as in the *Triglia volitans, Raia torpedo, Silurus,* &c. 4*th,* Clinical observation points out that, in cases where the central portion of the cord is affected previous to the external portion, an individual retains the sensibility of, and power of moving, the limbs, but wants the power to stand, walk, or keep himself erect, when the eyes are shut; whereas, when diseases commence in the meninges of the cord or externally, pain, twitchings, spasms, numbness, or paralysis, are the first symptoms present, dependent on lesion of the white conducting matter.

The white matter of the cord acts as a conductor, in the same manner that it does in the brain proper, and there can be no doubt that the influence arising from impressions is carried not only along the fibres, formerly noticed, which connect the brain and two portions of the spinal cord together, but along those more recently discovered, which decussate or anastomose in the cord itself (Brown-Sequard), and are connected with the ganglionic cells of the gray matter.

The various nerves of the body consist for the most part of nerve-tubes running in parallel lines. Yet some contain ganglionic corpuscles, as the olfactory and the ultimate expansion of the optic and auditory nerves; whilst the sympathetic nerve contains in various places not only ganglia, but gelatinous flat fibres. The posterior roots of the spinal nerves possess a ganglion, the function of which is quite unknown. These roots are connected with the posterior horn of gray matter in the cord, while the anterior roots are connected with the anterior horns. As regards function, the nerves may be considered as—1*st,* Nerves of special sensation, such as the olfactory, optic, auditory, part of the glosso-pharyngeal and lingual branch of the fifth. 2*d,* Nerves of common sensation, such as the greater portion of the fifth, and part of the glosso-pharyngeal. 3*d,* Nerves of motion, such as the third, fourth, lesser division of the fifth, sixth, facial, or *portio dura* of the seventh, and the hypo-glossal. 4*th,* Senso-motory or mixed nerves, such as the pneumo-gastric, third division of the fifth, and the spinal nerves. 5*th,* Sympathetic nerves, including the numerous ganglionic nerves of the head, thorax, and abdomen,—the exact function of which has not yet been fully investigated, although they seem to influence the excito-motory and excito-nutrient acts of the internal viscera and organs of sense.

All nerves are endowed with a peculiar vital property called *sensibility,* inherent in their structure, by virtue of which they may be excited on the application of appropriate stimuli, so as to transmit the influence of the impressions they receive to or from the brain, spinal cord, or certain ganglia, that may be considered as nervous centres. The nerves of special sensation convey *to* their nervous centres the influence of impressions caused by odoriferous bodies, by light, sound, and by sapid substances. The nerves of common sensation convey the influence of impressions *to* their nervous centres, caused by mechanical or chemical substances. The nerves of motion carry *from* the nervous centres the influence of impressions, whether psychical or physical. (Todd.) The mixed nerves carry the influence of stimuli both to and from, combining in themselves the functions of common sensation and of motion. Although the sympathetic nerves also undoubtedly carry the influences of impressions, the direction of these cannot be ascertained, from their numerous anastomoses, as well as from the ganglia scattered over them, all of which act as minute nervous centres. But there *are* cases where certain psychical stimuli (as the emotions) act on organs through these nerves, and where certain diseases (as colic, gallstones, &c.) excite through them sensations of pain.

Sensation may be defined to be *the consciousness of an impression;* and that it may take place, it is necessary,—1*st,* That a stimulus should be applied to a sensitive nerve, which produces an impression; 2*d,* That, in consequence of this impression, a something should be generated, we designate an influence, which influence is conducted along the nerve to the hemispherical ganglion; 3*d,* On arriving there, it calls into action that faculty of the mind called consciousness or perception, and sensation is the result. It follows that sensation may be lost by any circumstance which destroys the sensibility of the nerve to impressions; which impedes the process of conducting the influence generated by these impressions; or, lastly, which renders the mind unconscious of them. Illustrations of how sensation may be affected in all these ways must be familiar to every one, from circumstances influencing the ultimate extremity of a nerve, as on exposing the foot to cold; from injury to the spinal cord, by which the communication with the brain is cut off; or from the mind being inattentive, excited, or suspended.

The independent endowment of nerves is remarkably well illustrated by the fact, that whatever be the stimulus which calls their sensibility into action, the same result is occasioned. Mechanical, chemical, galvanic, or other *physical* stimuli, when applied to the course or the extremities of a nerve, cause the very same results as may originate from suggestive ideas, perverted imagination, or other *psychical* stimuli. Thus a chemical irritant, galvanism, or pricking and pinching a nerve of motion, will cause convulsion or spasms of the muscles to which it is distributed. The same stimuli applied to a nerve of common sensation will cause pain, to the optic nerve flashes of light, to the auditory nerve ringing sounds, and to the tip of the tongue peculiar tastes. Again, we have lately had abundant opportunities of witnessing suggestive ideas, or stimuli originating in the mind, induce peculiar effects on the muscles, give rise to pain or insensibility, and cause perversion of all the special senses. (See "Mono-ideism," in a subsequent section of this article.)

Motion is accomplished through the agency of muscles, which are endowed with a peculiar vital property called contractility, in the same way that nerve is endowed with the property of sensibility. Contractility may be called into action altogether independent of the nerves (Haller), as by stimulating an isolated muscular fasciculus directly. (Weber.) It may also be excited by physical or psychical stimuli, operating through the nerves. *Physical* stimuli

(as pricking, pinching, galvanism, &c.), applied to the extremities or course of a nerve, may cause convulsions of the parts to which the motor filaments are distributed directly, or they may induce combined movements in other parts of the body *diastaltically* (Marshall Hall),—that is, through the spinal cord. In this latter case the following series of actions take place :—1*st*, The influence of the impression is conducted to the spinal cord by the afferent or *esodic* filaments which enter the gray matter. 2*d*, A motor influence is transmitted outwards by one or more efferent or *exodic* nerves. 3*d*, This stimulates the contractility of the muscles to which the latter are distributed, and motion is the result. *Lastly*, Contractility may be called into action by *psychical* stimuli or mental acts,—such as by the will and by certain emotions. Integrity of the muscles alone is necessary for contractile movements; but also of the spinal cord for diastaltic or reflex movements, and of the brain proper for voluntary or emotional movements.

Thus, then, we may consider that the brain acting alone furnishes the conditions necessary for intelligence; the spinal cord acting alone furnishes the conditions essential for the co-operative movements necessary to the vital functions; and the brain and spinal cord acting together furnish the conditions necessary for voluntary motion and sensation.

The following aphorisms will be found useful, in endeavouring to reason correctly on the functions of the nervous system :—

1. The brain proper is that portion of the encephalon situated above the *corpus callosum*.

2. The spinal cord is divided into a cranial and a vertebral portion.

3. The gray matter evolves, and the white conducts, nervous power.

4. *Contractility* is the property peculiar to fibrous texture, whereby it is capable of shortening its fibres. Motion is of three kinds—*contractile*, dependent on muscle; *diastaltic*, dependent on muscle and spinal cord; *voluntary*, dependent on muscle, spinal cord, and brain.

5. *Sensibility* is the property peculiar to nervous texture, whereby it is capable of receiving impressions. *Sensation* is the consciousness of receiving such impressions.

Senso-Motory Electrical Phenomena.—The manner in which the nervous force is generated and conducted along the nerves to distant parts of the body has given rise to the idea that it resembles electricity. But that there is any identity between them is disproved by the following facts:—1. The firm application of a ligature to a nerve stops the propagation of the nervous influence below the point of application, but not of electricity. Indeed, the nervous trunk is as good a conductor of electricity after as it was before the application of the ligature. 2. If a small piece of a nervous trunk be cut out, and replaced by an electric conductor, electricity will still pass along the nerve; but no nervous force, excited by the strongest irritation above the section will be propagated through the conductor to the parts below. 3. A nerve is not so good a conductor of electricity as some other tissues. Matteuci assigns to muscles a conducting power four times greater than that of nerve or cerebral matter; and from the results of some experiments by Dr Todd, with the most delicate instruments, he concludes that both nerve and muscle are infinitely worse conductors than copper. In fact, their power of conduction does not rank above that of water holding in solution a small quantity of saline matter. 4. That in all those animals which undoubtedly evolve electricity, a peculiar apparatus, resembling a series of galvanic piles, is superadded, proving that other conditions are required than those ordinarily existing in the nervous system to produce the electric force. In the present state of science, therefore, facts are opposed to the idea of nervous power being identical with electricity. It is very possible, however, that future observations may prove one to be a modification of the other. It should not be forgotten that it is only lately that the relations have been discovered which exist between electricity, galvanism, and magnetism; and, as Mr Faraday remarks, "If there be reason for supposing that magnetism is a higher relation of force than electricity, so it may well be imagined that the nervous power may be still more of an exalted character, and yet within the reach of experiment."

Dr Todd considers that the change which takes place in nerve during its excitation is analogous to that which occurs in the particles of a piece of soft iron, in virtue of which the iron acquires the properties of a magnet so long as it is maintained in a certain relation to a galvanic current. The magnetic power being instantly communicated when the circuit is completed, and as rapidly removed when it is interrupted, he thus considers that a *state of polarity* of the particles of the nerve stimulated is induced. This polar state, he thinks, may be occasioned in tissues, either muscular or nervous, with which the nerve stimulated may be in organic connection; just as the polar state of the electrical apparatus is capable of being communicated to the piece of soft iron, which thereby acquires the well-known magnetic properties during the continuance of the excited polarity. This analogy may be admitted, although it has in noway been proved that what is here called *nervous polarity* is in any way identical with electrical or magnetic polarity. Some animals, as the glow-worm, fire-fly, and others, generate light, which, like the evolution of electricity, is connected with the presence of a peculiar organ or apparatus. It cannot be maintained that light and nervous influence are the same; and we are therefore compelled to conclude, that the generation both of electricity and light in animals is a vital property special to peculiar organs, which, like other vital properties, though connected with, and influenced by, the nervous system, is altogether distinct from it.

Several fishes, but more especially the genera Torpedo, Gymnotus, and Malapterurus, give out electrical shocks when touched or irritated, which gradually become weaker, and cease altogether from frequent repetition, but return after a certain period of repose. The agent producing these has been proved to be electricity, by being communicable to chains of individuals, by causing chemical decomposition, and a luminous spark on its sudden discharge. It is isolated by non-conductors, deflects the magnetic needle, and communicates magnetic properties to soft iron when transmitted through a coil of wire surrounding it. The discharge of the gymnotus has been estimated to be equal to that of a battery of Leyden jars of 3500 square inches, fully charged. We can have no doubt, therefore, that an animal can generate electricity, and discharge it at will, for the purpose of stupifying or killing other creatures, or as a result of reflex nervous action, whilst its own body is entirely free from the sensitive and motor consequences of the shocks which it produces. The electrical organ in these animals consist of piles of very numerous and closely-set thin membranous plates, among which numerous fine nerves are distributed. Between these plates are small cavities filled with an albuminous fluid, so that the apparatus closely resembles a number of moist galvanic piles or batteries closely aggregated together. This structure, though differently arranged in the various kinds of fish, is richly supplied by motor and sensitive nerves and by blood-vessels. The nerves are distributed on one surface only of the plates, whilst the blood-vessels go to another, on which nucleated cells are distributed. (Pacini.) There is also a special lobe of the brain situated on the *medulla oblongata*, close to the origin of the vagus nerve, which is called the electric lobe. It contains large ganglionic corpuscles from which nerve-tubes arise. When this lobe is destroyed, the power of ge-

nerating electricity is destroyed with it; whereas the whole brain above it may be removed without immediately impairing the function of the batteries. This fact has led some to suppose that the electricity is generated in the brain; but there can be little doubt that it is formed in the batteries, which, however, differ in different animals. Thus, in the torpedo the action resembles that of a thermo-electric pile,—the nerve and vascular surfaces corresponding to the bismuth and copper elements, whilst the nervous influence corresponds with heat. When, therefore, a shock is induced in the torpedo, either voluntarily or by reflex action, the nervous influence sent to one surface of the electrical plate throws the other into an opposite electrical condition, and a current is the consequence. In the gymnotus, on the other hand, the apparatus has been compared to the hollow cylinder of porous clay, which, in a Bunsen's or Grove's galvanic arrangement, separates the negative from the positive elements. (Pacini.)

Although in other animals little electricity seems to be generated, electric currents have been demonstrated in the muscles and in the nerves. Galvani first noticed the fact, that when the exposed muscles of a frog's limb are brought into contact with the sciatic nerve, the muscles are slightly contracted. Nobili found that when the circuit of the nerve and muscles was closed by a galvanometer, a deviation of the needle took place to the extent of 10°, 20°, or 30°, in consequence of a current which passed in the limb from the toes upwards, and which could be increased by inclosing in the circuit several frogs arranged as a battery. Matteuci showed that these currents were independent of the nervous texture; and Du Bois-Reymond that the longitudinal section of a muscle, natural or artificial, is invariably positive to the transverse one. According to him, the muscular substance during life, and in the intervals of contraction, is in a state of electric tension, which is much diminished, or disappears during its action. He succeeded in showing this experimentally in the human subject. The fore-fingers of a muscular individual being dipped in a saline solution, together with the electrodes of the galvanometer, no deflexion of the needle occurs. If all the muscles of one arm be now strongly and continuously contracted, a current is indicated passing from the finger to the shoulder in the contracted arm, and in the opposite direction in the relaxed one. Other experiments showed,—*1st*, That the current varies in different individual muscles, in some running from the head to the foot, in others in the opposite direction; *2d*, That the electro-motor power of a muscle is directly as its length and thickness; and *3d*, That if two muscles are opposed to one another in a circuit, the thicker or the longer overcomes the other. Hence the current in one entire organism represents the superior force of the currents of the stronger muscles. As regards nerve, Matteuci failed in detecting any electrical current in it; but Du Bois-Reymond has done so by employing a very delicate galvanometer. He has determined that the nervous electric current has the same relation to the longitudinal and transverse sections as is observed in muscle, and that in this respect all the nerves are alike. It would also appear from his observations, that when a nerve is completely excited or tetanized by electricity, its usual electromotor power is diminished, or in abeyance, and that a similar loss accompanies intense functional excitement from ordinary agents. No difference as to electrical relations exist between motor and sensory nerves, and in both kinds innervation advances in either direction with equal facility. The muscles, when they are caused to contract in consequence of electricity sent along a nerve, do so only at the opening and closing of the circuit. From these researches it would appear, that in an organized being electrical currents are induced by arrangements of its fluids, textures, and organs, although the physiological importance of these remains to be discovered. It must be clear, however, that such currents are intimately connected with the normal functions of the parts which exhibit them, a circumstance which indicates the advantage of applied electricity in various paralytic and spasmodic diseases. This subject is now being investigated on scientific rather than on empirical grounds, especially by Remak.

Special Functions of the Nervous System.

On proceeding to determine more closely what are the special functions of the individual parts of the nervous system,

we should never forget that the various ways in which they have been investigated have led to opposing results, and that such is the excessive difficulty of the inquiry, that we should be especially on our guard against specious hypotheses and unfounded theories. Anatomy, human and comparative, has furnished us with many valuable facts; but it is not easy to determine what are the nervous ganglia or other parts in the lower animals which correspond with what exists in man; whilst erroneous interpretations as to the habits and motions of these creatures are too readily formed. Again, in making experiments on animals, it is often impossible to ascertain how far the shock of the operation, the flow of blood, or the destruction of other parts may vitiate the results. Lastly, an observation of the effects of disease often leaves us in doubt how far the organic mischief extends, and what phenomena may be rightly attributed to it, and what to the congestion of the blood-vessels which accompany it. This last, however, is by far the most important means of research open to us; and if to the result of pathological observation, a similar one is obtained from well-performed experiments, our views derived from either will be confirmed. If to this, anatomy reveals such connections as will warrant and bear out such conclusions, we may consider that every proof is given which conviction requires. It should be remembered, therefore, that such is the fallacy inherent in each individual method of research that little dependence can be placed upon it, and that at least two of these must be united to give probability to any given theory.

Functions of the Cerebral Lobes.—The cerebral lobes (diagram, A, A, A), as has been previously stated, are undoubtedly concerned in the evolution and manifestation of intellect. This result is supported by every known mode of investigation, which also indicates that the former depends on the cortical, and the latter on the conducting or tubular portion. Further than this we are not warranted in going, for the facts which establish these great conclusions entirely negative all those theories which have been advanced having for their object a localization of the different faculties into which the mind has been arbitrarily divided. When, indeed, we endeavour to analyse these, and separate the reasoning powers from instinctive actions, the difficulty of the inquiry seems at first to be overwhelming. To analyse the intricate combinations of our own minds is a difficult task; but how much more laborious is it to study the variations in the minds of others, and to investigate the habits of the countless tribes of animals with the view of distinguishing which depend on reason, and which on blind instinct! The attempts of metaphysicians in this direction are not satisfactory. According to them, however, the purely mental faculties are,—Consciousness, Perception, Attention, Conception, Abstraction, Association of Ideas, Memory, Imagination, and Judgment or Reasoning. To these may be added the Affections, Desires, Self-love, and the Moral Faculty. (Stewart.)

Gall and Spurzheim have divided mind into thirty-three faculties, to which Mr Combe added two more, making thirty-five in all. These are—1*st*, *Amativeness*; 2*d*, *Philoprogenitiveness*, or love of offspring; 3*d*, *Concentrativeness*, or the power of continuing impressions and ideas; 4*th*, *Adhesiveness*, or the desire to attach ourselves to persons or objects; 5*th*, *Combativeness*, or the inclination to fight and be embroiled in contentions; 6*th*, *Destructiveness*, or the desire of destroying life; 7*th*, *Constructiveness*, or a disposition to apply oneself to the mechanical arts; 8*th*, *Covetousness*, or the desire to covet, to amass, or acquire; 9*th*, *Secretiveness*, to conceal; 10*th*, *Self-Esteem*, or self-love; 11*th*, *Love of Approbation*, or the pleasure we derive from the commendations we receive from others; 12*th*, *Cautiousness*; 13*th*, *Benevolence*, or meekness and gentleness of disposition; 14*th*, *Veneration*, by which we worship the Deity and material objects; 15*th*, *Hope*; 16*th*, *Ideality*, or the poetical disposition; 17*th*, the faculty of *Conscientiousness*, or of justice and equality; 18*th*, *Determinativeness*, or firmness of character or purpose; 19*th*, *Individuality*, or the power we possess of knowing external things; 20*th*, *Form*, by which we take cognisance of the forms of external objects; 21*st*, *Size*, that power which seizes hold of dimensions; 22*d*, *Weight*, that faculty by which we estimate weight, density, resistance, &c.; 23*d*, *Colour*, the faculty of perceiving colours; 24*th*, *Space* or *Locality*, the power of local memory; 25*th*, *Order*, or a love of methodical arrangement; 26*th*, *Time*, or the faculty which enters into speculations on duration; 27*th*, *Number*, or the power of calculation; 28*th*, *Tune*, or the perception of musical tone; 29*th*, *Language*, the faculty by which we learn artificial signs; 30*th*, *Comparison*, by which we recognise differences, analogies, similitudes, &c.; 31*st*, *Causality*, that power which directs our attention to the causes of things; 32*d*, *Wit*, the faculty of jesting, raillery, mocking, &c.; 33*d*, *Imitation*, the power of imitating sounds, gestures, manners, &c. These are the several faculties of mind laid down by Drs Gall and Spurzheim; but to this catalogue Mr Combe has added two others,—34*th*, *Wonder*, or that which relates to the marvellous, supernatural, &c.; and 35*th*, *Eventuality*, or that which takes cognisance of changes, events, and active phenomena.

The objections to this division of the mental faculties are,—1*st*, Its complexity; and, according to the phrenological system, one faculty is considerably influenced by others; so that compound characters may be easily manufactured at will, and thus numerous sources of fallacy thrown open. 2*d*, It is redundant in some faculties, and deficient in others. It is redundant, for instance, in having two organs for Form and Size, for Combativeness and Destructiveness, for Causality and Concentrativeness. Each of these two, if not identical, are, at all events, closely allied. It is deficient in having no such faculties as Memory, Reasoning, and Judgment, which every man is conscious he possesses. But it is said every organ has a power of remembering, reasoning, and judging; so that there are other faculties which govern or attend upon all the thirty-five organs. There are also obvious deficiencies in the propensities or instincts; for mankind not only love, steal, fight, kill, secrete, and build, but run, swim, walk, talk, sing, learn, and so on, which have no place in the phrenological system. Perhaps there is no instinct so strong in man and animals as that of self-preservation, and yet this has no organ ascribed to it by the phrenologists. As a philosophical and metaphysical system of the mental faculties, therefore, the classifications of Stewart and Brown seem to us greatly superior, especially in all the higher properties of the intellect; although, so far as the instincts and passions are concerned, they are, perhaps, inferior.

If our knowledge of what the faculties of the mind really are, and how they should be divided, is so imperfect, it may appear unnecessary to attempt to determine in what part of the brain each is situated. As might be expected, all such efforts have failed. That the brain furnishes the conditions necessary for the evolution and manifestation of mind, we have seen is established; and that the gray matter originates, whilst the white matter conducts, the influences generated, we have also shown to be highly probable. But we have no facts which point out that Memory, Consciousness, Judgment, Reasoning, or similar faculties belong to one part of the cerebral convolutions more than to another. Gall and his followers have localized all the thirty-five faculties into which they have divided the mind. He observed that certain individuals who displayed mental powers, moral feelings, or particular propensities, had a fulness or prominence in a certain part of the anterior, middle, or posterior third of the cranium. By paying attention to the

principal characteristics of remarkable men, and the living habits of animals, he found that this fulness or prominence coincided in a number of cases; and he concluded from this that the function of brain which existed below the prominence was the organ giving rise to the characteristic faculty. He then sought to confirm his theory by anatomy, physiology, and pathology; and he and his disciples have accumulated an immense number of these coincidences, which they believe sufficient to establish the phrenological theory.

But, proceeding on the principles which the phrenologists themselves have laid down, it is easy to show that the exceptions are as numerous as the coincidences; whilst the other modes of inquiry to which we have alluded,—namely, anatomy, the results of experiments on living animals, and the observations of the symptoms of disease as compared with the appearances presented after death,—not only give no support, but are directly opposed to the views of Gall. Thus, some remarkable skulls in the museum of the university of Edinburgh are, on the principles of the phrenologists themselves, entirely opposed to their doctrines. Of these, among many, we would point to the skulls of Burke, Pepé, and Haggart,—the two former remarkable murderers, with Destructiveness small; and the latter a most dexterous thief, with Acquisitiveness small. Anatomy proves that, while the lower vertebrate animals possess the anterior and middle lobes of the brain well developed, which are said to be the seat of the intellectual faculties and moral sentiments, they are deficient in those parts where Love of Offspring, Adhesiveness, Destructiveness, and Combativeness are found,—facts wholly incompatible with the theory of Gall. In the same manner, the great majority of facts derived from physiological and pathological research give no support to phrenology. Although, therefore, this doctrine is unquestionably founded upon a large number of data, it cannot lay claim to a correct localization of the mental faculties in any way superior to other systems, which, like it, have been advanced by ingenious men, excited attention for a season, and ultimately abandoned as inconsistent with the present state of our knowledge. The names of Gall, Spurzheim, and Combe, notwithstanding, ought ever to be registered among those whose labours have greatly contributed to advance our knowledge of the physiology of the brain.

Function of the Cerebellum, Corpora Striata, Optic Thalami, and Corpora Quadrigemina.—These different parts of the encephalon contain masses of ganglionic matter differently arranged, connected with the spinal cord below and the cerebrum above. We have as yet no means of determining with certainty the functions of each ganglion, although it is probable that the cerebellum (diagram, B) is connected with the power of voluntary combined movements, and the *corpora quadrigemina* (diagram, E) with the sense of sight, but not exclusively so; for the *corpus striatum* (diagram, C) is also connected with the one, and the optic thalamus (diagram, D) with the other. The whole, perhaps, may be regarded as uniting together the diastaltic function in connection with the head and face; and hence, as being an extension in another form of the gray matter of the spinal cord into the encephalon.

Function of the Pons Varolii and Medulla Oblongata (Diagram, F, G).—These portions of the encephalon possess the same function as the spinal cord, with the addition of being more essential to life, on account of their being the centres (especially the latter) which furnish the necessary power for maintaining the co-ordinate movements of respiration and deglutition. It is by arresting respiration, and paralysing the functions of the important organs to which the vagi nerves are distributed, that sudden injury to the *medulla oblongata* proves so rapidly fatal.

Function of the Spinal Cord (Diagram, H, H).—This nervous centre receives and gives off the different nerves which go to all parts of the body, and is the organ necessary for combined motions, and conducting the sensitive influences essential to sensation. These influences are now known, principally from the experimental researches of Brown-Sequard, to be conducted through the gray matter by means of nerve-tubes connected with the ganglionic cells. If the influences reach the cerebral convolutions, and excite consciousness, sensation is the result. If the influences originating in these convolutions, by an act of volition, pass outwards to a special series of muscles, voluntary motion is produced. But numerous combined muscular actions may go on independent of volition or sensation, and even when the brain is removed. These depend on influences originating in physical irritations applied to an incident nerve, which are conducted through the spinal cord, and from it by excident nerves to the muscles, the contractility of which is thereby excited. The character of these movements gave rise to the idea that they were connected with sensation, and indicated pain. Thus, decapitated animals may be seen to struggle exactly as they would do were the brain entire. They endeavour to avoid the particular injury, push the irritating instrument away with their paws, and writhe as if in agony; so that it is exceedingly difficult for a spectator to convince himself that they are not suffering, and that such motions are not connected with sensation. But we have previously seen, and the slightest analysis of our own sensations and mental operations will soon convince us, that sensation is the *consciousness* of an impression. If then the same sensitive and motor phenomena are produced independent of brain as when it is present, we must either believe that consciousness resides in the spinal marrow, and that therefore they are connected with sensation, or that it resides in the brain, in which case they must be independent of sensation. The former was the notion of Whytt, Haller, Le Gallois, Prochaska, and others, who connected these spinal movements with a so-called *sensorium commune.* It was Dr Marshall Hall who first clearly separated these functions from cerebral or mental acts, and placed them altogether in the spinal cord. He pointed out that they were independent of mind, and *therefore* not connected with sensation. He classified them by themselves, under the name of reflex, excito-motory, or diastaltic actions; described the laws by which they are governed, and their universal application to the pathology and diagnosis of disease. We have previously seen that all such actions require a centre with incident and excident nerves communicating with it, although the exact relation of these, as explanatory of individual diastaltic movements, has not yet been determined.

As examples of diastaltic or purely spinal motions, may be enumerated,—1*st*, Those constantly going on in the eyelids when any object approaches them, in which case the incident nerve is the palpebral branch of the fifth, and the excident the orbicular branch of the seventh pair of nerves. 2*d*, The closure of the larynx in every act of deglutition, and in every effort to vomit, and as occurs on the contact of a drop of water or a crumb of bread, &c., when the incident nerve is the superior and the excident the inferior laryngeal. 3*d*, The various movements associated in the act of respiration, in which the incident nerves are the sensitive branches of the fifth pair, of the pneumogastric and spinal nerves, while the excident are the spinal accessory and motor portions of the intercostal, diaphragmatic, and lower spinal. 4*th*, The different actions associated in the act of swallowing, including those that occur in the pharynx, œsophagus, and the cardiac orifice of the stomach. The incident nerves are united with the excident in the pharyngeal, œsophageal, and cardiac branches of the pneumo-gastric. 5*th*, Numerous actions connected with the outlets of the body, as in defœcation and expulsion from the urinary and generative organs, in which the

incident and excident nerves are united in the branches of the spinal nerves. *6th*, The movements of the fœtus *in utero*. *7th*, Numerous complex actions, acquired at one period, and performed afterwards automatically, without exercise of mind, such as walking, playing certain pieces of music on various instruments, &c. *8th*, Instinctive actions of various animals, as the flying of migratory birds, building their nests, construction of the honey-comb, &c. *9th*, All the spasmodic and convulsive actions of the body, including vomiting, choking from the presence of a foreign body in the larynx or pharynx, nervous twitching of the limbs, convulsions of parts of the whole body in chorea, hysteria, epilepsy, and rigid spasms of tetanus, &c. &c. In these four last kinds of actions, the sensitive nerves of various parts of the body are the incident, and the motor the excident nerves.

These diastaltic actions, though spinal and independent of mind, may, to a certain extent, be controlled by the will. Thus the sudden contact of hot or cold bodies to the skin, the prick of a pin, &c., if unexpected, will cause starting; but if a resolution be formed not to do so, this effect may be prevented. This influence is exercised over different muscles in different degrees; and it varies in persons from constitutional and unknown causes. Other spinal actions apparently require the co-operation of the mind, such as coughing, sneezing, laughing, sobbing, yawning, and hiccough. In these cases it frequently happens that the most determined effort of the will fails to control them; whilst arresting or withdrawing the attention checks them at once. Hence we have one class of motions purely voluntary, and another partly voluntary and partly spinal, such as coughing, laughing, sneezing, &c., which it is difficult to conceive being produced without a certain mental effort. Then we have a class of motions altogether involuntary, wholly spinal, which may be carried on for a certain time in a decapitated animal.

Functions of the Cerebro-Spinal Nerves.—There are generally enumerated, after Willis, nine cerebral pairs and thirty-one spinal pairs of nerves. (See left side of diagram.) All the so-called cerebral nerves, with the exception of the first pair, which is in truth a ganglion, may be regarded as belonging to the cranial portion of the spinal cord. The first pair of nerves, called the *olfactory*, serve to receive and convey the influences excited by odours on the Schneiderean membrane of the nose, to which it is distributed, direct to the brain, to produce the sensation of smell. The second pair, or *optic* nerves, receive and convey to the brain the influences excited by light, so as to produce the sensation of sight. The third pair of nerves, or the motor nerves of the eyeball, are purely motor, and regulate all the movements of the eyeball, except those which depend on the external rectus and superior oblique muscles. The fourth pair of nerves, or *pathetic*, also called *trochlear*, are purely motor, and govern the movements of the trochlearis, or oblique muscle of the eye. The fifth pair of nerves, called *trifacial* or *trigeminal*, divide into three branches,—two of which are purely sensitive, and the third is senso-motory. The sensitive branches terminate in the face, and communicate sensibility to the skin, various organs of the head, and to the external parts of the organs of special sense. It is also the great exciter nerve of these parts. Its communications also with the ganglia of the sympathetic system render its integrity of the greatest importance to various excito-motory, excito-sensory, and excito-nutrient actions of the head and face. The non-ganglionic branch distributed to the muscles of the jaws is motor, and governs the movements of mastication. The sixth pair of nerves, called *abducent*, are motor, and govern the motions of the external rectus muscle of the eyeball. The seventh pair of nerves are composed of two parts, which are really separate nerves. The hard portion, or *facial nerve*, is motor, and governs the movements of all the muscles of the face. The soft portion, or *auditory nerve*, transmits the influences of sound through the internal ear to the brain, to produce the sensation of hearing. The eighth pair of nerves are divided into three branches,—*1st*, The *glosso-pharyngeal*, distributed to the root of the tongue and pharynx, is a nerve of sensibility, administering to taste and touch in the former situation, while it is the great exciter in the act of deglutition in the latter. The second branch is the *par vagum*, or *pneumo-gastric* nerve, and is distributed to numerous important parts, its branches having different functions. As a whole, it is a motor and sensitive nerve, and contains incident and excident filaments. The pharyngeal and inferior laryngeal branches are wholly motor; its superior laryngeal branch is the sensitive nerve of the larynx, but is mixed with a few motor filaments, which supply the crico-thyroid muscle; the cardiac, pulmonary, œsophageal, and gastric branches are senso-motory. It also forms most important connections with the sympathetic system of nerves; and, like the fifth, is instrumental to numerous excito-motory, excito-secretory, and excito-nutrient functions of the neck, chest, and abdomen. The third branch of the eighth pair, or spinal accessory, is a motor nerve, the external division supplying the external muscles of respiration; the sterno-mastoid and trapezius, and the internal division, adding motor filaments to the vagus. The ninth pair of nerves, or *hypo-glossal*, is the motor nerve of the tongue. There are thirty-one pairs of spinal nerves, all of which are senso-motory,—the posterior ganglionic root being sensory, and the anterior motor. These, united, form a corresponding nerve, containing sensitive and motor filaments necessary for sensation and combined motions, including incident and excident filaments in connection with distinct portions or arcs of the spinal cord as centres of diastaltic movements.

Functions of the Sympathetic Nerves.—This system of nerves has also been called *ganglionic*, *organic*, and *trisplanchnic*. It consists essentially of a number of ganglia containing numerous nerve-cells, communicating by one series of connecting nerve-tubes with each other, and by another series with the cerebro-spinal nerves. (See right side of diagram, p. 672.) The ganglia are arranged, according to their situation, into cephalic, cervical, thoracic, and abdominal; while the connecting filaments forming plexuses have received numerous names in different parts, such as carotid, cardiac, diaphragmatic, supra-renal, hepatic, splenic, superior and inferior mesenteric, &c. &c. The connection between the cerebro-spinal nerves and those of the sympathetic system is indirect through ganglia, which break the conducting power of the nerves or modify it,—probably both. Under ordinary circumstances, no act of volition or of the mind can induce movements in parts supplied by the sympathetic; but under peculiar circumstances, or under the influence of unusual stimuli, movements are induced. Thus the emotions and desires, shame or fear, influence the movements of the heart and the contractile power of the capillaries, which an effort of volition cannot do. Such results are only explicable by the connection of the sympathetic system with nerves coming direct from the brain. Direct irritation of the sympathetic ganglia will also cause movements in the non-voluntary muscular parts receiving filaments from them. In the same way, for the most part, the internal organs and surfaces supplied by these nerves are not endowed with ordinary sensibility, and the mind is unconscious of their action; but occasionally very severe pain is produced from their being the seat of disease, as in certain agonizing pains of the heart (*angina pectoris*), in the intestines (colic), in the stomach, liver, kidneys, &c. &c. Thus, although in health the sympathetic system so diffuses the influences conducted that they are not obedient to or excite mental acts, there is abundant proof that the cerebro-

spinal filaments passing through the ganglia are constantly operating, although insensibly, in subjection to the cerebro-spinal centres. The ganglia, however, not only diffuse the influence of impressions coming from and sent to the cerebral and spinal centres, but they are nervous centres themselves, and especially centres of numerous reflex acts in non-voluntary muscles.

In addition to this excito-motory function of the sympathetic system, there is another of great importance, recently denominated by Dr Campbell of the United States *excito-secretory*. We have previously seen, however, that secretion in glands is only a form of nutrition; and the influence of this system would appear not only to be exerted on glands, but on blood-vessels and nutrition generally. It is therefore also excito-nutrient, and carried on wholly independent of the cerebro-spinal system. Thus it has been shown by Sir B. Brodie that division of the crural and sciatic nerves neither retarded nor impaired wounds and fractures of the inferior extremities; while numerous modern experiments have proved that injury to the large sympathetic ganglia occasion the most destructive effects to the nutrition of the parts which receive nerves from them. The recent experiments of Brown-Sequard and Harley on the supra-renal capsules, have shown that it is difficult to preserve animals if the semilunar or solar ganglion be much injured in the operation; but if this be avoided, animals can live without the supra-renal capsules for a length of time. Again, as illustrative of the general influence of the sympathetic system over nutrition, is the fact that certain fœtuses have been born with well-developed textures, without a brain or spinal cord, in the same manner that many of the lower animals are destitute of these organs.

As local examples of this excito-secretory and excito-nutrient function of the sympathetic system of nerves, may be cited,—1*st*, The effusion of tears from the lacrymal gland on the application of an irritant. In this case the incident nerve is the palpebral branch of the fifth, and the excident or secretory the lacrymal branches from the carotid plexus. 2*d*, The secretion of saliva on irritation of the gums, or exciting the mouth by food and mastication. Here the incident nerves are the buccal branches of the fifth, and the excident or secretory the parotid branches derived from the carotid plexus. 3*d*, Dentition in infants and children give numerous examples of excito-secretory and excito-nutrient actions. Thus, from tender gums, and irritation of the dental branches of the fifth, the eye may become lacrymose and congested; the Schneiderean membrane congested, and its secretion increased; while diarrhœa is one of the most common symptoms. In these cases the excident nerves are derived from the ciliary and Meckel's ganglia, distributed to the conjunctiva and Schneiderean membranes, and through the splanchnic, with the intestines. 4*th*, The process of lactation exhibits the remarkable influence of excitation applied to the sensitive surface of the nipple. This, when grasped and suction made upon it by the infant, not only occasions increased flow of milk, but causes that peculiar feeling of the rush which mothers describe, and which is apparently owing to congestion of the blood-vessels. Keeping up the flow of milk by constant milking long after it is required for suckling, as is constantly done for domestic purposes among our cattle, is an excellent example of the power of exciting such secretions locally. 5*th*, The secretion of starch from the liver, and its ready transformation into sugar, is influenced by irritations of branches of the eighth pair in the lungs, and by direct injury of the pneumo-gastric nerves, through the sympathetic branches of the cœliac and solar plexuses going to the liver. 6*th*, The results of section or destruction of the cervical ganglia by Petit, Dupuy, Bernard, and others, and the effects of galvanism applied to the cut extremities of the ganglionic trunks by Brown-Sequard, exhibit how the former injuries cause redness and increased heat in the neighbouring parts, while the latter cause paleness and coldness. This is accomplished in the last experiment by producing contraction or spasm, and in the first by occasioning enlargement and paralysis of the extreme vessels, and thus influencing nutrition. Further examples may be sought in the influence of excitants on all secretions—in the growth of the fœtus *in utero*, the phenomena resulting from shock after injuries, and in numerous diseases, especially of fever, inflammation, cholera, cutaneous eruptions, &c. &c.

It follows that the great functions of the sympathetic system of nerves are,—1*st*, Excito-motory, thereby regulating the contractions of the non-voluntary muscular fibres; 2*d*, Excito-secretory, whereby the various secretions are governed; 3*d*, Excito-nutrient, operating more especially on the blood-vessels, and thereby regulating the circulation in the capillaries.

It is impossible to review our knowledge of the physiology of the nervous system without recognising three great epochs or eras in discovery, which are inseparably connected with the names of three distinguished men. The first of these epochs is characterized by the establishment of contractility and sensibility as inherent properties of the muscular and nervous tissues. Such was the great work of Haller. The second is indicated by the indication of motor and sensitive columns in the spinal cord, and by the existence of nerves of sensation, of nerves of motion, and of mixed nerves in connection with these columns. Such was the doctrine established by Charles Bell. The third epoch is marked by the separation of numerous combined actions, from sensation, volition, and contractile movements; the demonstration that the spinal cord was their centre, and the fact that it was endowed with a reflex function acting through a series of incident and excident nerves, which were named. Such were the views introduced and successfully maintained by Marshall Hall. Each of these great doctrines has given rise to an astonishing amount of discussion, mingled with no small degree of acrimony. The controversy between Haller and Whytt, on the doctrine of inherent irritability and sensibility may still be considered as one of the most important and famous to be found in the whole history of medicine. Sir Charles Bell's life was embittered by the necessity of combating the claims of Dr Walker, who first conceived the idea of distinct function in the anterior and posterior columns of the spinal cord, and of Magendie, who maintained he had first demonstrated it experimentally. Lastly, Dr Marshall Hall has been accused, first, of having merely given to the sympathetic actions of Whytt a new name; and, secondly, of having borrowed all his ideas from Unzer and Prochaska. It would occupy far too much space to enter into the history of these discussions. The two former have ceased to excite attention; while the merits of Marshall Hall, with regard to the important theory of reflex nervous actions, is now universally acknowledged.

The experiments illustrative of reflex action are in their nature the same as those performed by Le Gallois and Sir Gilbert Blane, and the same results were derived from them as were observed by Flourens, Rolando, Hertwig, and by many others, who found that after removing the brain from animals, they could walk or fly. It is the inference derived from these experiments which we regard as important, and the demonstration that such actions are independent of sensation and volition, and strictly connected with integrity of the spinal cord. Now, this was not clearly stated by Unzer or Prochaska, for whom priority in this matter has been claimed. The latter physiologist, after enumerating the different seats given to the common sensory by his predecessors, all of whom understood by it the seat of sensation, distinctly says,—" The *sensorium com-*

mune, properly so called, seems not improbably to extend through the *medulla oblongata*, the crura of the cerebrum and cerebellum, also part of the *thalami optici*, and the whole of the *medulla spinalis*; in a word, it is co-extensive with the origin of the nerves." It is true, he distinctly says, that reflexions of sensorial impressions may take place either with consciousness or without consciousness, but then he proceeds to confound together convulsions in apoplectics, and other motions truly spinal, with the movements of the heart, stomach, and intestines. Unzer taught that the ganglia reflected motions without going to the *sensorium commune*, and that they were special sensoria.

A careful analysis of the writings of Unzer and Prochaska should be made conjointly with a critical study of the works of Haller, and then we think it will be evident that great confusion has been thrown over the whole subject by the use of the term *sensorium commune*, which, since the days of Willis, has been considered as the seat of sensation. It is easy now, when the subject has been unravelled, and the nature of sensation understood—at all events in its relation to consciousness—to maintain that Prochaska meant something different by *sensorium commune* from what Haller did. We nowhere see any evidence of this; and the proof that so essential a point was not made clear in connection with reflex function is, that all his contemporaries, as well as physiologists since his day, never understood it in this sense until Marshall Hall wrote.

SPECIAL SENSES.

The nature of sensation has already been dwelt upon; and it has been shown to depend essentially on the existence of mind, or the consciousness of impressions made on the sensitive nerves. The impressions which result from the stimuli of odours, sapid bodies, contact of hard or irritating substances, of light and of sound, are different. For the reception of these also, nerves with peculiar endowments are provided; and to these are added a special structure or organ adapted for the purposes of smell, taste, touch, vision, and hearing. Much discussion has taken place as to whether a sixth sense exists, viz., a muscular sense, or a sense of weight. Two masses of matter apparently similar may be undetectable by sight or touch, but when balanced in the hand are at once recognised by their difference in weight. Whether this sensation is dependent on the muscles or joints is doubtful; but that it is distinctive and peculiar, cannot be questioned.

Smell.—The acuteness of scent varies in different animals, and bears a certain relation to the size of the nostrils and turbinated bones, being greater where these are large and extended. Odours which depend on substances suspended in the air, when in an extremely fine state of division, thereby obtain more ready access to the membrane on which the olfactory nerve is distributed. This in animals that live in air is accomplished by the act of inspiration. Hence suspension of respiration prevents the perception of odours; whilst repeated quick inspirations, as in the act of sniffing, renders it more intense and prolonged. It is necessary that the mucous surface covering the expansion of the olfactory nerves should be moderately moist; for if it be too dry on the one hand, or too moist on the other, the sense is impaired or lost. The situation of the sensitive surface high up in the nostrils secures it from the direct contact of air, so as to prevent rapid evaporation and dryness; while the convolutions of the turbinated bones, over which the currents of air pass before reaching the seat of special sense, communicate heat to them, and thus prevent the action of cold. The sense of smell may be exalted, perverted, or lost. It is apparently increased by education, of which the case of James Mitchell is an interesting example. This boy was born blind and deaf, and chiefly depended on smell for keeping up a connection with the external world. He employed it on all occasions, like a domestic dog, in distinguishing persons and things. In some cases smell is exceedingly acute for particular substances, so as to be intolerable and distracting to those who suffer from it. Certain flowers or particular odours have in this way caused fainting or other bodily disorder. In other cases the smell is perverted or diminished, and occasionally is lost, as when the Schneiderean membrane is inflamed, or very rarely from congenital absence of the olfactory nerve.

Taste.—This sense is dependent on the fifth and glosso-pharyngeal nerves,—the former distributed to the two anterior thirds, and the latter to the posterior third of the tongue. This organ is covered over with minute prominences, which, when magnified, present four principal forms, viz.,—*1st*, Simple papillæ; *2d*, Conical or filiform papillæ; *3d*, Fungiform papillæ; and *4th*, Circumvallate or calciform papillæ. It is supposed that the two former are more especially concerned in the sense of touch, with which the tongue is also highly endowed; whilst the two latter, but particularly the last, constitute more especially the apparatus of taste. Sapid bodies pressed against these papillæ give rise to impressions which, when transmitted to the brain, occasion the peculiar sensation. The sense is more acute in some persons than in others; may be rendered more so by education, as is remarkably well observed in wine tasters; and is diminished or lost in febrile or other disorders which alter the condition of the mucous surface of the tongue and mouth.

Touch.—This sense is dependent on the nerves of common sensibility distributed to all parts of the surface. But here also we observe that a distinct structure is necessary for the manifestation of the peculiar property. This consists in the papillæ of the true skin, which are variously modified in different parts of the body, in proportion to the acuteness of the sense. The experiments of Weber and Valentin have shown that the extremity of the third finger and the point of the tongue are the parts most sensitive, as in these places the difference of half a line between the points of a pair of compasses could be distinguished. Next in sensitiveness to these is the mucous surface of the lips, whilst the parts in which touch is least acute are the neck, the middle of the back, and the middle of the arm and thigh. In the papillæ of the fingers and a few other places minute indurated bodies of condensed fibrous tissue have been recently discovered, called the Touch Bodies of Wagner, which have been supposed capable of rendering this sense more acute. They are in immediate relation to a nerve; and the well-known effects of pressing such nerve against a hard body, as in the case of a corn, may well be supposed capable of exalting the sensibility.

Sight.—This sense is dependent on the optic nerve, and a very complex apparatus, consisting, in man,—*1st*, Of external protective parts; *2d*, Of a set of muscles destined to move the organ of vision in various directions; *3d*, Of the expansion of the nerves, and the addition of a ganglionic structure, whereby the rays of light are received, and the influence of the impressions they excite conveyed to the brain; and *4th*, Of an optical apparatus, consisting of transparent media, which refract the rays of light upon the retina. The eyeball itself consists of an external fibrous coat, a middle or vascular coat, an internal or nervous coat, and of contents composed of refractive media. (For a minute description of these anatomical parts, see the article ANATOMY.) All that need be referred to here is the uses,—*1st*, Of the individual parts; and, *2d*, Of the entire organ as subservient to the sense of sight.

1. The external protective parts, composed of the eyebrows, the eyelids, and eyelashes, serve to shade the eye from excess of light, to diffuse over the cornea the sebaceous matter and lacrymal fluid, whereby the surface is

kept ductile and moist; and, lastly, to prevent the access of dust floating in the atmosphere. These different actions are for the most part involuntary, and carried on partly by the cerebro-spinal, and partly by the ganglionic system of nerves performing excito-motory, excito-secretory, and excito-nutrient functions. The watery fluid secreted by the lacrymal gland, and which is diffused over the anterior surface of the eye by the motion of the lids, keeping it moist and translucent, is conducted by two openings in the inner corner of the eye through the lacrymal duct into the nose, from whence it is discharged. 2. The eye-ball has a remarkable amount of mobility, in consequence of six muscles, four straight and two oblique, which act upon it in various ways. They are supplied by the third, fourth, and sixth pairs of motor nerves, and by a sensitive branch of the fifth pair. The object of so many nerves being distributed to them seems to be the correction or prevention of the simultaneous action which would take place in the two eyes if all their muscles were supplied by branches of the same nerve. 3. The optic nerve, on entering the eyeball, is a little compressed, but on reaching the internal surface branches out to form a membrane. On the inside of this membrane, however, are placed several layers of ganglionic cells, and externally, a membrane (Jacob's membrane) composed of minute columns or rods, standing vertical to the retina, and composed of a structureless, transparent substance like glass. The whole retina is transparent, and it is now supposed that the rays of light pass through it backwards, and are reflected by these rods, or Jacob's membrane, forwards to the sensitive branches of the optic nerve, which conveys the influence of the impressions so excited to the brain, to produce the sense of vision. For this purpose, the rods appear to be connected with the filaments of nerve by means of connective fibres. 4. The optical apparatus consists of four lenses of different structures, densities, and curves, filling up the substance of the ball, and forming, with the strong external case, or sclerotica, a perfect achromatic camera obscura. The most anterior of these lenses is the cornea, composed of condensed epidermis resembling horn; and hence its name. The second lens, proceeding backwards, is composed of a watery fluid, or aqueous humour, principally accumulated between the cornea and the iris. The third lens is the crystalline,—one of the most remarkable bodies in nature,—composed of concentric laminæ, like those of an onion, united by serrated or notched surfaces, and increasing in density from the circumference to the centre. The fourth lens, or vitreous humour, is of gelatinous consistence, fills up the large proportion of the ball, and appears to be a watery fluid inclosed within fibrous meshes of the greatest tenuity and fineness. These horny, watery, glassy, and gelatinous lenses, united, fulfil all the conditions optically required to produce achromatism so perfectly as to set the optician's art at defiance. In addition to the lenses, the eyeball is lined by a black opaque membrane, the choroid, to absorb unnecessary rays of light, the entrance of which is further regulated by a moveable aperture in the contractile iris, called the *pupil*, which is operated upon by excito-motory influences, so as to produce its contraction or enlargement.

In regarding the entire eye as an organ of vision, there are various points which deserve consideration. Among these are,—1. The means by which the apparatus is so readily accommodated to various distances. On this subject numerous theories have been advanced, all of which answer the purpose, if the truth of certain data be granted. It has been supposed that the curvature of the cornea is changed; but this has not been demonstrated. It has been imagined that the curvature of the lens is changed; a view which has in recent times again been supported by the observations of Kramer. It has been thought that the lens is drawn forward by a contractile non-voluntary muscle—the ciliary muscle—or is pushed forwards from behind by the turgidity of the ciliary processes. Some have thought that the contractions of the iris have much to do with the focal adaptation of the eye; and others, that it is owing to the pressure on the eyeball of the external muscles which move it. The question is still undecided. 2. The natural power of adaptation is interfered with in myopia, or short-sightedness; in presbyopia, or long-sightedness; and in amblyopia, or a peculiar dimness of vision. The first is owing to too great curvature of the lenses, and is corrected by concave glasses in spectacles; the second is produced by too little curvature of the lenses, and is corrected by convex glasses in spectacles; the third is owing to altered shape or oblique position of the lens, and is corrected by the use of cylindrical glass lenses. 3. Another perversion of vision consists of what is called colour-blindness, or Daltonism. Some persons cannot distinguish colours at all, everything appearing shadowed or light, like an engraving. Others cannot see brown, gray, or neutral tints; whilst a third class confound red, blue, and yellow with green, purple, orange, and brown. Red, blue, and yellow are never confounded with each other; but red and green are most commonly so. This condition may be dependent on some fault in the nerves of vision, possibly in the retina, and more especially in the refractive rods; or it may be owing to some change in the refractive media or lenses. But the theory is not yet determined. 4. All objects refracted on the retina are inverted, and yet we see them in their natural position. To explain this fact, it has been supposed that during infancy this sense, with all the others, undergoes a slow education, and that one so corrects the aberrations of the others that gradually we learn to recognise things as we do. The case of Cheselden, who operated on a young man successfully who had been born blind, in consequence of congenital cataract, contains many facts in favour of this view. 5. The circumstance of our seeing one object, although we receive two images in the two eyes, is explained by the regular action of the muscles of the eyeball. When this is deranged, as in squinting, or from the use of narcotics, we see double. Sometimes only half or a part of an object is seen; a circumstance attributed to paralysis of a portion of the retina, or to some disorder of the brain connected with the terminations in that organ of the optic nerves. 7. The retina, at the point where the optic nerve enters it, is insensible; whereas the foramen of Sömerring, in the direct axis of the eye, perfectly transmits the rays of light. This aperture, however, is not deficient in Jacob's membrane; a circumstance which points out the great importance of that structure as a refracting medium. 8. An impression made on the retina remains a certain time. This is proved by looking at a dazzling light or bright colour, and observing that, on turning away the head suddenly, it continues for a longer or shorter period. 9. Some persons are subject to ocular spectra. Remarkable objects, inanimate or living, may appear before them, and have all the appearance of reality. They always depend on a state of nervous exhaustion, from ill health, depression, or the use of certain drugs, as alcohol, opium, or other narcotic substances.

Hearing.—It is necessary for hearing that certain oscillations in the air, water, or solid bodies should reach the expanded filaments of the auditory nerve, and that the influence of impressions so produced should be conveyed to the brain. This is accomplished through the medium of a very complicated organ or acoustic apparatus, the ear, for a description of which we must refer to the article ANATOMY. The most essential part of the organ is the vestibule, that exists in every class of animals in which an auditory apparatus is to be detected. There also the principal expansion of the auditory nerve takes place, and there it is brought into connection with the vibrations of sound from the exterior. In man, such is the complication of parts super-

added to the vestibule or central ear,—viz., the cochlea and semicircular canals,—that the whole is denominated the *labyrinth*. It consists of chambers and canals hollowed out in the solid part of the temporal bone, containing a fluid, in which various branches of the auditory nerve are ramified, and so arranged that the slightest vibration communicated to the fluid must affect the nerve. In man, sonorous vibrations reach the labyrinth in two ways:—1*st*, Through the external ear; and, 2*d*, Through the bones of the head. The ticking of a watch is heard as distinctly when placed between the teeth as when applied to the ear, and the note of a tuning-fork, when it can be no longer heard by the ear, again gives rise to sound when placed in contact with the teeth. It is by the direct vibration of the bones of the head also that we become cognisant of the sound of our own voices. It has been supposed that the cochlea is that part of the labyrinth more immediately connected with those direct vibrations; whilst the vestibule and semicircular canals is that portion of it which enables the nerve to receive vibrations from without, indirectly, through the air. These latter vibrations, however, are diminished or intensified by means of the external and middle portions of the ear. The former, or auricle, serves to collect the sounds, and convey it through the short channel, or meatus, to the membrane or drum of the ear, which closes it internally. In this passage a number of ceruminous glands pour out a waxy secretion of a bitter taste, which, with the hairs that grow from it, serve as a very sufficient protection from foreign bodies, and especially insects. The *membrana tympani*, or drum of the ear, is connected with one end of a chain of small bones (called the *malleus*, *incus*, and *stapes*), which pass across the middle ear, or cavity of the tympanum; the other being attached to a membrane which closes the oval opening into the cavity of the vestibule. These moveable bones render their membranes tense or lax according to the intensity of the sonorous vibrations impinged upon them. This is accomplished through the agency of minute muscles which contract according to the influences transmitted by a series of excito-motory nerves. Hence this part of the apparatus is admirably adapted to carry the nicest vibrations in such a manner as will enable them best to conduce to the production of impressions on the auditory nerve. The cavity of the tympanum or middle ear is filled with air, which passes through the Eustachian tube. This not only permits the free vibration of the chain of ossicles, but further serves to keep the air of a uniform temperature; a circumstance of the greatest importance to the continuance of good hearing.

There is much similarity between the laws which govern the reception and reflexion of nervous vibrations and of rays of light; and, looking at the means necessary to effect this, there is a close analogy between the ear and the eye as organs of hearing and vision. The intensity of light and of sound are both regulated by muscular parts, independent of the will, operating through a ganglion and excito-motory nerves; the ciliary resembles the cochlear muscle, and the reflecting-rods of Jacob's membrane have their analogue in certain vibratory rods attached to the acoustic nerve where it is expanded on the *lamina spiralis* of the cochlea. But not to carry the comparison further, it may be noticed, that impressions made on the auditory nerve, like those on the retina, remain a certain time, as is shown not only by interrupted vibrations producing continuous musical tones, but by the experiments of Savart, who found that the removal of one or more teeth from toothed wheels when in motion occasioned no appreciable difference of sound.

Voice and Speech.

Voice is a function of the larynx, while speech is performed by the tongue, lips, and cheeks, in conjunction with the larynx. (For the anatomical description of this organ, see the article ANATOMY.) All that need be said here is, that it is composed of a tube made up of cartilages, which are connected together by ligaments, and moved upon one another by muscles. In the interior of the tube is a narrow chink in the shape of the letter V, having the point forwards, formed by two folds of membrane called the *vocal cords*, and which, thrown into vibration by the air rushing from the lungs, gives rise to sound. Different degrees of tensity are given to these cords; and the chink, or *rima*, of the glottis is widened or narrowed by the various muscles of the larynx, and position of the cartilages; points that can only be understood by a careful study of the organ, which, in construction, resembles the mouthpiece of a clarionet or hautboy.

Voice.—Nearly all air-breathing animals possess a voice; in man and a few birds only can it be so modified as to be capable of producing articulation. The vocal cords are caused to vibrate by the currents of air coming from below, and at once lose this power by destruction of the laryngeal nerves, which, by paralysing the muscles that regulate their necessary tensity, prevents their vibration and the production of sound. These vocal cords, therefore, are the essential parts of the organ of voice. Their tensity is varied sometimes by muscular action, and sometimes by the column of air. Thus, to produce low notes they are relaxed, and even wrinkled when at rest, but obtain the necessary degree of stretching by the pressure of the column of air. High notes, on the other hand, are caused by producing great tensity of the cords, and narrowing of the glottis; and intermediate notes, by intermediate degrees of tensity, and narrowing. The quality as well as the compass of the voice varies in different persons. In the male the deepest is the bass, the highest the tenor, and the intermediate the baritone. The corresponding tones in the female are the contralto, the soprano, and the mezzo-soprano. In men, owing to the prominence of the thyroid cartilage, the vocal cords are longer than in the female, as 3 to 2; and his voice in consequence is deeper, and in the musical scale an octave lower. Boys have treble voices, like women; but as manhood approaches, the thyroid cartilage undergoes a change in its form, and while doing so the voice is cracked or broken. Afterwards it becomes manly and deep; so that the highest soprano of a boy may be converted into the deepest bass of the man. Male voices also possess two series of notes,—chest or true notes, and false or falsetto notes. How the latter are produced is unknown. The strength of the voice does not so much depend upon the current of air, as upon the strength and accuracy of the muscular movements regulating the vocal cords. Hence why practice, which gives accuracy and tone to the muscles, is of such importance in the schools of singing.

Speech.—The voice, so modified by the additional action of the tongue, cheeks, and lips, as to signify objects, actions, and the properties of things, constitutes language. Languages vary greatly as to the sounds which enter into them, and hence the difficulty persons who have been educated in one, experience in learning others. Words, however, may be produced by the mouth and fauces alone, without the voice. This is whispering. Hence there may be speech without voice, as there is voice without speech. Vocal language, however, can only be accomplished by the combined use of the laryngeal and oral apparatuses. Articulate sounds are divided into vowels and consonants. Vowels are formed in the larynx, whilst consonants are produced in the air-passages above it. Many of these last, however, cannot be uttered unless the elements of a vowel are pronounced with them consonantly; hence their name. Thus *g* and *k* are formed of the vowels *e* and *a*, modified by the oral aperture. It is by different degrees in the opening and contraction of the mouth and oral canal

that most continuous sounds are formed; others are sudden and momentary, cannot be sustained, and are called explosive sounds, such as *b*, *p*, *d*, and *g*. Hence they are difficult to pronounce well in singing; and this is why the Italian language, in which they are seldom heard, is so much better adapted to songs than English or German. When the laryngeal and oral parts of the organ of speech cannot be combined, some letters, especially the explosive ones, as *t* and *p*, are not consonant with the vowel; and stammering is the result. It is to be corrected by a careful study of the mode of pronouncing the various consonants, constant practice, and avoiding hurry and nervous agitation, which render all muscular action uncertain. Ventriloquism is speaking without giving external evidence of utterance, and keeping the oral aperture immoveable while the attention of the audience is directed as much as possible to the thing or place from which the voice is supposed to come.

SLEEP—DREAMS—SOMNAMBULISM—MONO-IDEISM.

Sleep is that temporary suspension of the cerebral functions which in animals alternates with their exercise for a certain time, which suspension, however, is capable of interruption on the application of stimuli to the sensory nerves. Unless this last condition could be carried out, the individual would labour under coma, syncope, or asphyxia,—states more or less allied to sleep. All action in the living economy produces waste of tissue; and hence the necessity of rest in order that substance may be added. The cerebral functions, especially, are governed by this law, and we are obliged to submit to their suspension for a certain period, which is natural sleep. On awakening, we feel refreshed; greater strength is imparted to the muscles, higher sensibility to the nerves, and greater power to the mind. Sleep is more or less profound according as the body is more or less fatigued, and according to the constitution of the individual; as in some persons it is naturally light, whilst in others it assumes a soporose character. Habit and temperament also exert a strong influence over sleep, some persons falling into or arousing from it at particular hours, independent of all other circumstances. Its invasion may be sudden or gradual. As a general rule the senses and reasoning faculties sleep first, whilst imagination and the lighter ones remain longer awake. We may also awake suddenly; but there is usually an intermediate condition between sleep and waking. It is in these intermediate conditions that the sleep is lightest, and that persons can be aroused with the greatest facility. The amount of sleep required by man varies according to age, temperament, habit, and previous fatigue. In infancy and extreme old age life is almost a continuous sleep. In adults there is no rule, some persons requiring more and some less. The average period spent by mankind in sleep is eight hours in the twenty-four, being one-third of human life.

Dreams.—Not unfrequently while some mental faculties are suspended others are still active, and are busy with numerous ideas, which succeed each other with more or less regularity. This is dreaming. There is an absence of consciousness regarding external things, and a want of control in regulating the current of thought; so that the principle of suggestion—that is, one thought calling up another in a certain sequence—has unlimited governance of the mind. In some rare cases the dreaming thoughts are very consistent and vivid, but generally speaking they are more or less confused or incongruous. Not unfrequently, when seemingly in danger, we are governed by an intense desire to escape from it, while we possess an agonizing consciousness that we have not the slightest power to do so. This is *incubus*, or nightmare. Another curious circumstance is the rapidity with which, when dreaming, trains of thought pass through the mind, the events of years being apparently compressed into moments. The most mentally agitating dreams need not occasion the slightest change of position or muscular movement, although sometimes they produce restlessness, various gestures, or emotional indications. But when the ideas of a dream govern the motions and conversation of an individual, while the memory and other faculties of the mind are still so suspended that on awakening he is quite unaware of what has occurred, the condition is called *somnambulism*.

Somnambulism.—The peculiarity of this state consists in the mind being wholly occupied with one idea or train of thought, to the exclusion of all other considerations. Thus there may be complete insensibility to bodily pain, to loud sounds, flashes of light, or other ordinary stimuli; although whatever is spoken or done in harmony with the subject thought of is heard and appreciated, often with unusual acuteness. We can frequently change the current of the ideas by audibly suggesting others, when all the feelings and emotions in connexion with the new subject are called into action, to the exclusion of those which previously existed. Thus if the attention be strongly fixed on a distant object, impressions made on the skin will not induce sensation; but if the attention be directed to the skin, its sensibility often becomes wonderfully excited, and pain is experienced from the contact of bodies that, under ordinary circumstances, would scarcely be felt. The same rule applies to all the other senses. In the same manner the reasoning power is often increased on a particular point, and a variety of things performed, or movements gone through, that the individual otherwise could never have accomplished. Some men perform all the acts which at the time are suggested to them, or describe the various scenes which in imagination are placed before them. In this way a somnambulist may be made not only to think and converse on any subject, but to go through any kind of action, however ridiculous or even fatiguing. He will place himself under every variety of condition presented to his mind, and perform the appropriate motions, as well as give utterance to the ideas which such conditions would naturally give rise to. Thus he may be made to hunt, swim, fight, appear intoxicated, visit distant cities or lands, &c. None of these acts and ideas are remembered in the ordinary waking condition, although when again thrown into a similar state, they may be taken up and continued. Such a person may be said to have two kinds of memory,—one when awake, and one when dreaming; or, as it has been called by some, a *double consciousness*. Somnambulism may come on involuntarily, at regular or irregular periods, or it may be excited artificially. In either case it may be accompanied by various nervous phenomena, denominated *catalepsy*, *trance*, *ecstacy*, and so on.

Mono-ideism.—Dreaming and the phenomena of somnambulism may be excited in some persons artificially, when the acts of the mind, sensation, and motion may be completely governed by means of suggestive ideas, even although the individual be conscious. This state has been called *monoideism*. (Braid.) The mode of effecting this is to cause a certain number of persons to fix their attention on a small object, as a coin, or submit to have monotonous passes made with the hands before their face. On an average, at least one person in twenty so treated feels in a shorter or longer time, first a mistiness of vision or stiffness in the eyelids, and occasionally deep-drawn sighs, hurried respiration, and signs of general excitement are visible. If now such persons are respectively told in a confident manner that they cannot open their eyes, it will be found that they cannot do so, especially if their attention be more strongly directed to the eyelids by touching or by pointing to them. But on receiving permission, or on being commanded to open them, this is done at once. Such persons may now, as in certain cases of somnambulism, have every kind of motion, sensa-

tion, or mental act produced, governed, or arrested, according to the endless train of suggestive ideas that may be communicated to the individual. Many of the lower animals also appear to be susceptible of being impressed by what strongly arrests their attention, in such a way that they are rendered incapable of voluntary motion, or irresistibly impelled towards the object. Hence the long glittering bodies of serpents, or the glaring eyes of other animals, *fascinate* birds and small quadrupeds, and render them an easy prey to their enemies. Similar effects are produced in individuals who look from heights and precipices, and experience an uncontrollable desire to leap down, although it be to certain destruction.

Like phenomena have occurred in all ages, produced in certain persons by predominant ideas, and variously modified according to the education, politics, or religion of the period. Thus the effects produced on many votaries during their initiation into the ancient mysteries; the ecstacies of the Pythian and other priestesses; the influence of religious enthusiasm; the dancing epidemics of St Vitus or of Tarantism in the middle ages; the hallucinations of the Convulsionaires at the tomb of St Medard, in Paris, &c. &c., are of a like character. Numerous perversions of the nervous functions, identical in their nature with those described, consisting of sensory illusions, muscular convulsions or rigidity, and peculiar trains of thought influencing acts and conversation, may be found in the histories of witchcraft or demonology, in the legends of the saints, the journal of Mr Wesley, and in the accounts given by travellers of the religious camp-meetings in the woods of America. They are perhaps more common now than formerly, and excite even more astonishment among the ignorant; the only difference being, that the same phenomena, which in a dark age were attributed to divination or incantation, now assume the garb of science, and are ascribed to magnetism or electricity.

It is unnecessary to enter into any lengthened argument to refute the numerous hypotheses which ascribe these effects to external influences. There is no series of well-ascertained facts capable of supporting such a doctrine; whereas it would be easy to prove that all the phenomena really occasioned depend on suggestive ideas communicated to the person affected. But while these theories scarcely merit attention, the facts themselves are highly important, and demand the careful consideration of the physiologist and medical practitioner. The effect of mind on the body has from the earliest periods been seized upon by individuals as a ground for veneration or astonishment. In ancient times the heathen priests were the physicians, and the temples were converted into so many dispensaries, at which the sick applied for relief. In Catholic countries, during the middle ages, the offices of priest and physician were frequently united in one person; so that the powerful effects of certain shrines, and the benefits of pilgrimages in cases not admitting of simple cure, met with every encouragement. From what has preceded, it must be allowed that, so far from its being improbable that real cures were so effected, all that we know of the effects of confident promises on the one hand, and belief on the other, render it very likely that many such occurred. The legends of the saints, the history of witchcraft, the journal of Mr Wesley, the accounts of celebrated pilgrimages, and of the virtues of particular shrines, and the writings of religious enthusiasts generally, abound in wonderful cures. Charms, amulets, and relics are stated to have at once banished all kinds of agony, and removed numerous nervous diseases. Many of these are certainly incredible, whilst others are perfectly conceivable. The benefits of the royal touch are confirmed by the observations of Richard Wiseman, and the cures performed by Greatrakes are warranted by Robert Boyle. In all these cases, there can be little doubt that any benefit which did occur may be attributed to a strong belief, on the part of the patient, in the efficacy of the means employed. There can be little doubt that the facts recently ascertained in connection with this subject open up a new field for investigation, not only in physiology and practical medicine, but in what relates to evidence as it is now received in courts of law.

As regards the nature of this condition, it seems analogous to that of sleep or dreaming, in which certain faculties of the mind are active, and may be even stimulated into excessive action, whilst others are suspended. All the phenomena produced are strictly analogous to what medical men are acquainted with in various morbid states; and it must now be considered as well established, that in certain conditions of the nervous system they may be induced at will. This conclusion, however, is something new, for it has but recently been received in physiology or pathology, that a condition of the cerebral functions may be occasioned in apparently healthy persons in which suggestive ideas are capable of producing those phenomena we have described, and which render them, for the time, as irresponsible as monomaniacs. Yet such is really the fact, and once admitted into physiology, must have an important influence on the theory and practice of medicine. Such a condition may probably be accounted for physiologically in the following manner:—

We have previously seen that the cerebral lobes contain white fibres, which run in three directions:—1*st*, Those which pass from below upwards, and connect the hemispherical ganglion with the spinal cord; 2*d*, Those which pass transversely, forming the commissures, and which unite the two hemispheres; and, 3*d*, Those which run from before backwards, uniting the anterior with the posterior lobes on each side. It has also been stated that these fibres are probably subservient to that combination of the mental faculties which characterizes thought. Now all metaphysicians and physiologists are agreed that the mind is composed of various faculties, and that different portions of the nervous mass are necessary for their manifestation. True, it is by no means determined what or how many faculties mind should be divided into; still less is it known which parts of the brain are necessary for the manifestation of each. But let the first proposition be granted, then there is no difficulty in supposing that one or more of these may be paralysed or suspended, whilst others are entire, any more than there is in knowing that sensation may be lost whilst motion remains intact, although the nerve fibres of both run side by side. It may be presumed, then, that certain mental faculties are, as the result of exhausted attention, temporarily paralysed or suspended, whilst others are rendered active in consequence of being stimulated by suggestive ideas; that the psychical stimuli of the former make no impressions on the cerebral conducting fibres, whilst those of the latter are increased in intensity; that the proper balance of the mind is thereby disturbed, and thus the individual for the time being acts and talks as if the predominant idea was a reality. The condition is analogous so far with ordinary somnambulism, certain forms of hypochondriasis, and monomania, but admits of infinite changes, from the nature of the idea suggested.

According to this theory, therefore, we suppose that a psychical stimulus is generated, which, uncontrolled by the other mental operations acting under ordinary circumstances, induces impressions on the peripheral extremities of the cerebral fibres, the influence of which only is conveyed outwards to the muscles moved. In the same manner, the remembrance of sensations can always be called up by the mind; but under ordinary circumstances we know they are *only* remembrances, from the exercise of judgment, comparison, and other mental faculties; but these being exhausted, in the condition under consideration, while

the suggested idea is predominant, leave the individual a believer in its reality.

In this manner we attribute to the faculties of the mind a certain power of correcting the fallacies which each is liable to fall into, in the same way that the illusions of one sense are capable of being detected by the healthy use of the other senses. We further believe that the apparatus necessary for the former operations consists of the nerve-fibres which unite different parts of the hemispherical ganglion, whilst that necessary for the latter are the nerve-fibres connecting together the organs of sense and the ganglia at the base of the encephalon. A healthy and sound mind is characterized by the proper balance of all the mental faculties, in the same manner that a healthy body is dependent on the proper action of all the nerves. There are mental and sensorial illusions, one caused by predominant ideas, and corrected by proper reasoning; the other caused by perversion of one sense, and corrected by the right application of the others. Both these conditions are intimately united, and operate on each other, inasmuch as voluntary and emotional movements and sensation are mental operations.

This theory, if further elaborated, appears to be consistent with all known facts, and capable of explaining them on physiological principles.

FUNCTION OF REPRODUCTION.

The process whereby the countless variety of organisms which constitute the vegetable and animal worlds is perpetuated on the surface of the globe has from the earliest periods attracted the attention of physiologists, naturalists, and philosophers. In recent times, the excellence of the achromatic microscope has enabled us to penetrate much further into the mysteries involved in it, and the whole subject is now one of vast extent. We shall speak of this function as consisting of three stages:—*1st*, The production and discharge of germs; *2d*, Of the fecundation of such germs; *3d*, The changes which follow fecundation.

THE PRODUCTION AND DISCHARGE OF GERMS.

We have seen that at the earliest period of development in all organized beings, without exception, there is formed a molecular blastema which originates a nucleated cell. Up to that point where sexes are manifest, the process of reproduction is identically the same with that of cell growth. The peculiarity of the function of generation in the higher organisms consists in the superaddition to this process of a particular act, whereby the further development of germ-cells is occasioned. There is a special apparatus in animals and in plants,—the ovary,—the function of which is to mature a germ, that from the time of its first formation is capable of becoming the rudiment or embryo of a new being, and which is often separated from its parent in a form altogether dissimilar to that which it is ultimately to assume. This sometimes takes place as a spore, at others as an egg; and hence the terms *sporuliferous* and *oviparous*, as distinguished from *viparous* reproduction. The more heterogeneous a structure becomes,—that is, the more difference is manifested in the structure and properties of its separate parts,—the less title has any one to be regarded as a separate individual, since it cannot maintain an independent existence, nor reproduce the entire structure. When an organism merely consists in a multiplication of similar parts, these parts may separate, and constitute independent existences, as in the Algæ among plants, and in the Polypes and Radiata among animals. This has been called *fissiparous* generation—a mode of reproduction that can never take place in the more highly organized beings. This manner of propagation is identical with that of multiplication by cells alone, with this difference, that at one period groups of cells are aggregated and united together, and afterwards separate.

Germ-cells are constantly forming and ripening in the ovaries of plants and animals, and are separated from them at particular times. In the separation of these oviparous cells, indeed, a tendency to periodicity is manifested. Thus plants flower at certain seasons,—some in spring, others in summer, and a third class in autumn or winter,—with great regularity. Throughout the whole range of animals the same thing is observable. They all present a breeding period, at which time only, ova are fully developed, and capable of being fecundated. The reproductive organs of plants and animals at this time become elevated in temperature. Among plants, this is most appreciable in the Arum tribe, where flowers are collected in great numbers within cases which act as non-conductors. On one occasion, Brogniart observed that in the *Colocasia odora* the temperature had been demonstrated to be 8° above that of the surrounding air. This was increased in the following day to 18°, and during the emission of pollen on the three succeeding days to 20°, after which it began to diminish with the fading of the flower. In animals, the same elevation of temperature has caused agriculturists to denominate this season as the period of heat. It originates in them from excessive congestion in the capillaries of the part, causing great local and more or less general disturbance of the system, the result of an augmented nutrition in the ovaries necessary for the development of the ova. This congestion causes rupture of the vessels and discharge of blood, which in the human female, and in a few of the monkey tribes, causes an external flow, known as the *menstrual fluid*, while the process in them has received the name of *menstruation*. The essential act, however, is not the discharge of a fluid externally, but the formation, ripening, and separation of ova from the ovaries. Multitudes of seeds and of ova are formed in this manner, at regular periods, in plants and animals, which prove abortive, and the history of which is identical with the formation, ripening, and disintegration of simple nucleated cells, which have no power of reproduction.

The manner in which ova are formed in the ovary has been well studied by Martin Barry, who informs us that molecules and granules are deposited in groups among the fibrous stroma of the organ. Around a large granule smaller ones are aggregated, and become surrounded by a membrane,—the *ovisac*,—so as to form a nucleated cell containing granular matter. This granular matter now separates into two portions. The inner forms a membrane that immediately surrounds the yolk, and from its transparent appearance has been called the *zona pellucida*. The outer divides into two layers, one of which, covering the *zona pellucida*, he called the *tunica granulosa;* and the other, which lines the ovisac, the *membrana granulosa*. These two membranes are united together by four bands,—the *retinacula*,—having transparent fluid between them. The whole structure now forms a vesicle, which, from its first describer, De Graaf, has received the name of *Graafian vesicle*, and consists of an outer fibrous and vascular membrane; another inner one,—the ovisac of Barry,—having suspended from it, by the *retinacula*, the ovum, composed of *zona pellucida*, yolk, and germinal vesicle. Graafian vesicles may frequently be seen before puberty in the ovary, but after that period they increase in number, and may be observed in all stages of development scattered through the substance of the organ, those most advanced being near the surface. Towards the end of each menstrual period, such as are ripe burst from the quantity of sanguinolent serum or blood which is poured into them from the external vascular membrane, and the ovum escapes from the surface into the fimbriated extremity of the Fallopian tube, which closes round the ovary, in order to receive it, and through which it is conveyed to the uterus.

The cavity thus left in the ovary is most frequently

filled with coagulated blood, the result of hæmorrhage from the vascular or external layer of the Graafian vesicle, which participates in the congestion of the menstrual period. This coagulum of blood becomes gradually absorbed, in the course of which it changes its colour, and assumes a yellow and puckered appearance. In this state it has been called *corpus luteum*, and it has been supposed to present such peculiar appearances when fecundation has occurred as to warrant medical men in asserting that pregnancy had taken place—a grave error, which modern science has completely exploded. These appearances are described as being,—1*st*, An irregular form in the false, but a regular one in the true *corpus luteum;* 2*d*, An absence of a central cavity lined by a membrane in the false, whilst in the true there are both; 3*d*, Absence of concentric radii in the false, while in the true they are present; 4*th*, The false may be present in both ovaries, while the true only exist in one. All these signs have been shown to be in no way distinctive by numerous recent observations. Thus, in women who have never had children, there have been found *corpora lutea* exactly resembling those supposed to follow pregnancy. In the lower animals, also, four or five *corpora lutea* have been found in the ovaries, resembling each other, although one fœtus only was found in the uterus. It must be manifest that these ideas were the result of the notion that fecundation took place in the ovary, which assuredly it never does. Whether a *corpus luteum* during pregnancy disappears less rapidly than in the unimpregnated state is not known, but such is the only possible difference which can exist in the two states. That it is possible for any physiologist or pathologist to pronounce with certainty between the bodies which do or do not coincide with pregnancy, has been demonstrated in the negative by several remarkable cases which have been raised in the courts of law.

The capability for procreation marks a peculiar period of life, which has been called puberty, on account of the development the pubes then undergoes. In woman, this generally occurs between the thirteenth and sixteenth year, but is earlier in warm climates, and later in cold ones. It has also been observed to be earlier in manufacturing towns than in thinly-peopled districts. Mental and bodily habits exercise an influence; girls accustomed to luxury and indulgence undergoing this change earlier than those reared in hardihood and self-denial. At this time those general and local changes occur which distinguish the adult woman: the mammary glands enlarge; a deposition of fat takes place in the cellular tissue of the skin, which gives to the female form its roundness and fulness; and the menstrual fluid, the most unequivocal sign of puberty, commences to flow. In man, puberty is marked by the low and rough voice—from the size of the larynx and elongation of the vocal cords; by the growth of hair on the chin, upper lips, and cheeks, as well as over the body and limbs; the greater physical power and activity, as compared with the female; the capability of enduring more fatigue; and a larger amount of courage and daring.

FECUNDATION OF GERMS.

The germ-cells, prepared and formed in the ovaries, are discharged from those organs at each menstrual period, and would be excreted from the economy without being further developed, unless they encountered vibratile particles formed in another organ. In phanerogamous plants, the pollen tube enters that of the pistil, and the pollen itself is conveyed to the ovule at its base. The contact of the pulverulent pollen with this ovule fecundates the latter. Of the nature of the stimulus so imparted we know nothing; but the fact is well established in science, that no ovule can furnish productive seeds unless the pollen has had access to it. In all animals in which ova are formed the same thing takes place. Two sets of organs analogous to those in plants are found. In some creatures, as in certain Mollusca, these are also associated in one individual; but in all the vertebrate tribes they exist in different animals, male and female. The former is furnished with organs called the testes, which secrete the spermatic or seminal fluid. This contains minute bodies, possessed of independent motion, which they retain for several days after they have been excreted. In them the fecundating power resides, for it is only when these come in contact with the ova discharged from the ovary of the female that the latter are ever developed into distinct living beings. From this moment that series of changes commences in the ovum whereby an embryo is formed. For this purpose, however, various circumstances are necessary, especially a fitting locality, proper temperature, moisture, &c. Seeds which have been impregnated retain a dormant degree of vitality for many years, and when at length placed in these favourable circumstances, they develop themselves. Generally speaking, instinct guides the lower tribes to deposit their eggs in appropriate localities, and the extraordinary variety of such positions selected by insect tribes, by fishes and reptiles, has furnished a curious subject of observation for the naturalist. In birds, the fecundated ova are hatched by the mother, who elevates them to a proper temperature with the heat of her own body. In mammiferous animals, the young are not born as ova; an organ,—the uterus,—is provided for their reception, where they grow and become developed; and when at length they are capable of supporting an independent existence, they are excreted or parted from the body of the parent by the process of parturition.

The form of the vibratile seminal particle varies in different animals. In mammals generally, it has a round or oval extremity, a so-called head, and a filiform appendage called a tail, and varies in length from the 100th to the 500th of an inch in length. In birds, the thick extremity is more tapering, and the whole is of a spiral form. In certain reptiles and fishes, the filament is much longer, and thickest in the middle, tapering at both extremities, having occasionally a delicate continuation wound spirally round the thicker portion. In some insects and crustacea, they present curious irregular forms, without a filament, and are immoveable. In the vast majority of cases, however, they present active contractile movements. In mammals especially, when watching these under the microscope, it is difficult to divest oneself of the idea that they are animalcules, as they progress through the fluid with the heads forward, propelled by continued vibratile lashings of the tail. The notion put forth by some observers, that they possess internal organs, we have never, after careful research, been able to confirm; and the circumstance that similar structures, with like movements, exist in the reproductive organs of many plants, negatives the idea of their being distinct animalcules.

The mode of fecundation varies in different animals. In some molluscous tribes male and female organs are united in one animal. It is an hermaphrodite, like many plants, and is self-impregnated. In fishes, the female sheds its spawn, and the male, swimming over it, sprinkles the spermatic fluid on the ova, and may be observed at the breeding season to follow her for that purpose. In the higher animals, union of the sexes takes place for the same end. In reptiles, especially in the frog and toad, the male sits on the back of the female, and sheds the semen over the ova immediately after they have left the cloaca. In birds and mammals, it is necessary that the spermatic fluid be deposited in the vagina of the female by the intromission of the penis. From the circumstance that fecundation may take place in fishes and reptiles, as in plants, by simply sprinkling the male element over the female ova, has originated the

modern practice of artificial impregnation. In the same way that horticulturists can multiply varieties, and even fertilize plants with pollen received from a distance; so, by sprinkling the fluid from the milts of male fishes over the innumerable ova which may be squeezed from the roe of the female, they may be fecundated, preserved, and reared in artificial ponds. At this moment, many of the rivers and lakes of France and Scotland are being stored with large accessions of valuable fish so raised, in order to increase the amount of food for the people.

For a long time it was supposed that the mere contact of the vibratile spermatozoids with the ova was all that was sufficient to produce fecundation; but it was first shown by Martin Barry, and has been subsequently confirmed by many other physiologists, that the spermatozoid actually finds its way into the ovum by a minute aperture, and that the male and female elements ultimately blend or melt into one another. This fact may now be considered to be well established, and serves to explain many circumstances long known as to the resemblances which exist in feature and in qualities, mental and bodily, between parents and their offspring. Thus, it has long been a matter of popular observation, that the child in all that relates to the outward form, the gait and manners, takes after the father; while as regards the size, internal qualities, and dispositions, the mother predominates. Not, however, that the male is wholly without influence on the internal organs and vital functions, or the female wholly without influence on the external organs and locomotive powers of their offspring. The law is only general, although it holds very extensively among cattle, as shown by Mr Orton and Dr Harvey. Such facts seem in their turn to be accounted for by the circumstance, that the spermatozoid enters and melts down in the external parts of the yolk of the egg,—that is, in connection with those layers of the germinal membrane which, as we shall subsequently see, form the nervous system and muscles; whereas the glands and internal organs are formed from the mucous layer, which is that part of the membrane furthest removed from the action of the male element.

CHANGES IN THE OVUM WHICH FOLLOW FECUNDATION.

We have seen that ova are formed and discharged from the ovary at regular intervals by the adult female, but that it is only when the spermatozoid enters them that fecundation is produced. At that period the ovum presents the characters of a nucleated cell;—the ovisac, or *zona pellucida*, being the cell-wall; the germinal vesicle being the nucleus; while the fluid between them is opaque and granular, and called the *vitellus*, or yolk. (See figs. 1 and 2.) The size and relative amount of these three parts of each ovum vary in different animals, but they are present in all. There is also generally observed at one part of the germinal vesicle a collection of granules, called the *germinal spot.* (See fig. 2, *a.*) If fecundation does not take place, the ovum degenerates, breaks down, and is ultimately excreted in the mucous discharge from the external passages. But if it encounter the spermatozoids, and one penetrates it, then those changes commence which terminate in the formation of an embryo. These changes have now been followed in numerous animals, and the principal efforts of zoologists are at present directed to the elucidation of the transformations which take place in living beings; so that the whole subject is not only very extensive, but is constantly acquiring new facts. The study of human embryology is incomplete, for, although an ovum has been twice discovered after death in the Fallopian tube of woman, it has never been seen at that period when it enters the uterus. In the dog, rabbit, sheep, and other mammals, however, the various transformations have been very carefully described; and, as it is certain that the same essential mode of development occurs in them as in man, the changes observed in the dog will be selected as a type of what takes place in the impregnated ovum of the higher animals.

Physiology

When the ovum leaves the Graafian vesicle, there is adherent to it externally a greater or less number of the cells which form the granular membrane. On removing these artificially, the ovum presents the appearance represented in fig. 1, when magnified fifty diameters linear. It is composed of a dark, opaque yolk, surrounded by the *zona pellucida*, or vitelline membrane. On cracking this ovum between two glasses, or on tearing it with a needle, the granular yolk flows out, and the germinal vesicle escapes, as in fig. 2, *a*. If such an ovum encounter spermatozoids, the changes subsequently represented take place. One

Fig. 1. Fig. 2. Fig. 3. Fig. 4.

enters the ovum, when both it and the germinal vesicle are dissolved in the yolk,—a circumstance to which the whole structure is indebted for its continuance and for its power of, as well as direction in, development. We next observe that the granular yolk begins to separate into two parts, a process which is accomplished by the spontaneous aggregation of the molecules of which it is composed into two masses instead of one (fig. 3). Each of these two subdivide, producing four (fig. 4); each of these into other two

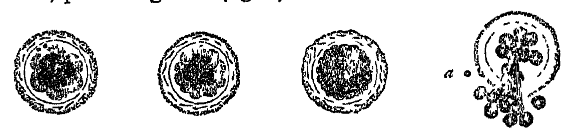

Fig. 5. Fig. 6. Fig. 7. Fig. 8.

(fig. 5); and so on, until at length the whole is reduced into a mass of molecular corpuscles (fig. 7), having a clear space or nucleus in their centres, and subsequently distinct cell-walls (fig. 8). These next arrange themselves in a layer externally, immediately lining the *zona pellucida* so as to form a membrane, which is called the *germinal membrane* (fig. 9). At one part of this it will be observed that the

EXPLANATION OF THE FIGURES.

The mode of development of the embryo is so difficult to understand, that it has been thought right to illustrate this part of the subject copiously by woodcuts, which will serve to indicate better than mere description can do how the various parts and organs successively come into view. They are copied from the accurate plates of Bischoff illustrative of the embryonal development of the dog, but diminished one-half.

Fig. 1.—An Ovum from the bitch freed from the granular membrane, showing the dark internal yolk, and clear external *zona pellucida.* (*Magnified* 50 *diameters.*)

Fig. 2.—The same Ovum lacerated with a needle. The yolk has flowed out, showing the germinal vesicle *a*, with its germinal spot. (50 *diam.*)

Fig. 3.—The Ovum has encountered spermatozoids, which are seen adherent externally to the *zona pellucida.* Fecundation has taken place; the spermatozoid, which has penetrated the transparent zone, together with the germinal vesicle, have been dissolved in the yolk, which is divided into two masses. (50 *diam.*)

Fig. 4.—The Yolk divided into four masses. (50 *diam.*)

Figs. 5 *and* 6.—The process of division in the yolk further illustrated. (50 *diam.*)

Fig. 7.—The Yolk now reduced by division to a large number of molecular cells. (50 *diam.*)

Fig. 8.—The Molecular Cells rendered visible by laceration of the Ovum. They contain a clear space in their centres. (50 *diam.*)

cells and their granular contents are thicker, forming the

Fig 9.

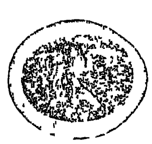

Fig. 10.

germinal area, where the embryo first appears. The ovum has now entered the uterus, and its appearance at this period, magnified ten times, is represented in fig. 10. By cutting or tearing out the portion of the germinal membrane which contains the germinal area, and magnifying it, the subsequent changes it undergoes can be well studied, as in the following figures.

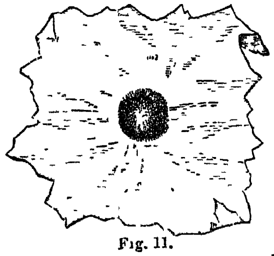

Fig. 11.

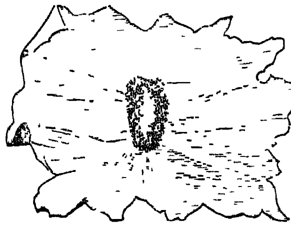

Fig. 12.

The germinal area now enlarges; at first round (fig. 11), it becomes oval (fig.12), and then appears in it a clear space, the *area pellucida*. At the same time, the germinal membrane becomes thicker, and is now easily divisible into two layers,—an upper or outer, called the *serous* or *animal*, and an under or internal, called the *mucous* or *vegetative layer*. The future changes in the embryo may be observed by watching the behaviour of these two layers, and of another that afterwards forms between them in the germinal area. In the centre of the enlarged germinal area there now forms a

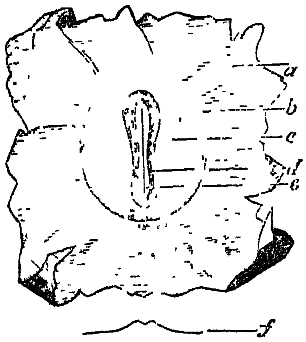

Fig. 13.

groove or channel, the *primitive groove*, by the elevation on each side of the germinal membrane (fig. 13). This enlarges anteriorly, and tapers to a point posteriorly (fig. 14), and ultimately becomes closed by its sides, or *laminæ dorsales*, passing over it and uniting, thus forming the foundation of the cerebro-spinal cavity, and inclosing the *chorda dorsalis*, or embryo brain and spinal cord (figs. 16 and 18). A linear mass of square-shaped cells forms on each side, which is the commencing vertebral column (figs. 14 and 16).

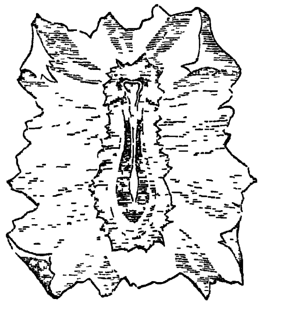

Fig. 14.

Fig 15.

The embryo is now raised prominently upwards above the serous layer (fig. 15), and between it and the mucous layer

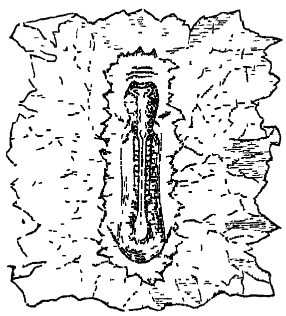

Fig. 16.

Fig. 17.

another mass of cells is formed which constitutes the third or *vascular layer*. Here blood-vessels are developed as a plexus (figs. 16 and 17), which unites itself with the em-

Fig. 9.—An Ovum further developed after it has been placed in water for a short time. In consequence of endosmose, the internal membrane is separated from the *zona pellucida*, and is seen to be formed by the cells which have coalesced. This is the germinal membrane, with the germinal area composed of an extra layer of cells. (50 *diam.*)

Fig. 10.—An Ovum, much larger, taken from the uterus, moistened with water. The germinal membrane is somewhat separated from the *zona pellucida*, and thrown into folds. (10 *diam.*)

Fig. 11.—Portion of the Germinal Membrane surrounding the germinal area, cut out from a further developed ovum. A clear space in the area, called *area pellucida*, is apparent. (10 *diam.*)

Fig. 12.—A similar piece from a somewhat older ovum. The germinal area has become oval. (10 *diam*.)

Fig. 13.—The Germinal Area is now greatly enlarged in the germinal membrane. *a*. Germinal Membrane—*b*. Limit of Vascular Area—*c*. *Area Pellucida*—*d*. *Laminæ Dorsales*—*e*. Primitive Groove.—*f*. Profile of Germinal Area. (10 *diam.*)

Fig 14.—Portion of Germinal Membrane, with the Embryo, from an ovum twenty-four hours older than fig. 13. The primitive groove is not yet closed, but is much stronger, especially above. Here three swellings are observable, which are the three primitive brain-cells. At the inferior end, the groove is of a lancet shape (*sinus rhomboidalis*). In the centre of the groove is a thin streak, the commencement of the *chorda dorsalis*. Six square cells are formed on each side, the commencement of the vertebral column. The germinal membrane is now composed distinctly of two layers, the upper of which (the *serous* or *animal layer*) is cut close round the embryo, showing more distinctly the lower (the *mucous* or *vegetative layer*). (10 *diam.*)

Fig. 15.—The same Embryo, seen sideways, whereby the elevation of the dorsal laminæ, and the groove between them, are better seen. The head is already distinctly elevated above the germinal membrane. (10 *diam.*)

Fig. 16.—An Embryo twelve hours older than the former one. The primitive groove is now for the most part closed over. The first brain-cell is widened out laterally, and bent forwards. The posterior ones are altered in shape from absorption of fluid. There are ten vertebral cells. At both ends of the primitive groove folds of the serous layer are visible—the commencement of the amnios. The serous layer is cut close round the embryo; and upon the mucous layer, fine lines, in the form of a network, are visible—the commencement of the *vascular layer*. (10 *diam.*)

Fig. 17.—The same Embryo turned round and examined on the under or abdominal surface. The head with the broadened-out first brain-cell is seen coming forward. Immediately below this an S-shaped tube is seen, which is the

bryo heart and aorta (figs. 18 and 19), and a circulation is established, which extends over the entire ovum, with the

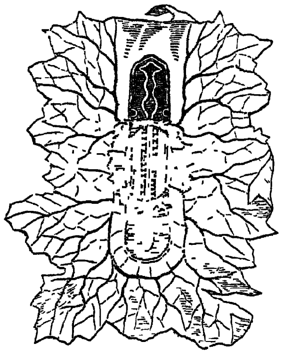

Fig. 18.

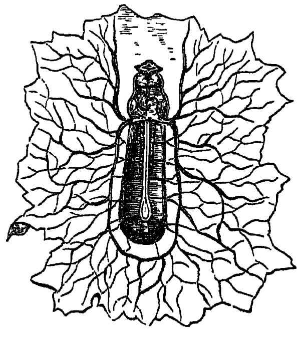

Fig. 19.

exception of its two poles (fig. 20). The embryo now is gradually raised above the surface of the germinal mem-

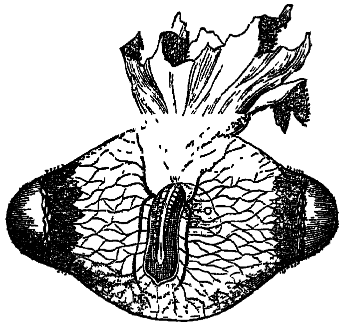

Fig. 20.

brane, while the duplications and re-duplications of its three layers, which are constantly receiving thickness by cell growth, gradually produce the various organs and textures of the body. Three veisicles or sacs are formed in connection with them,—the amnios with the serous, the allan-

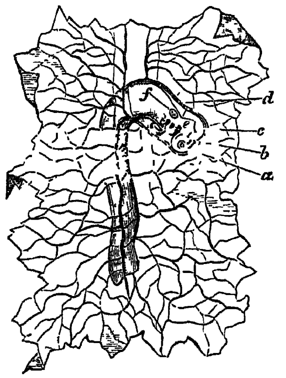

Fig. 21.

tois with the vascular, and the umbilical with the mucous layer. The upper or serous layer of the germinal membrane may be observed from an early period to be reflected backwards, and from before backwards, as well as laterally, gradually to inclose the embryo above (figs. 16 and 18). At length the layer closes, suspending the embryo as it were from one point (fig. 20), which, when it gives way, leaves a sac, which rises from the back of the embryo. This is the *amnios*. From the lower portion of the abdominal groove, and at the inferior extremity of the embryo, a swelling may now be observed (fig. 22, *bb*). This rapidly

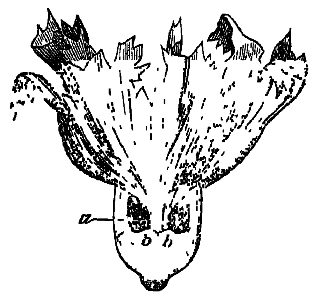

Fig. 22.

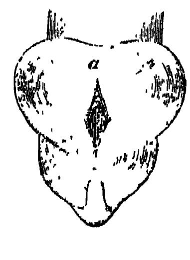

Fig. 23

enlarges, and, at first open in the middle (fig. 23, *a*), coalesces to form another sac, which hangs out of the lower portion of the abdominal opening. This is the *allantois*

rudimentary heart. The lower end branches off on each side to join the vascular network, forming the *venæ omphalo-mesentericæ*. The visceral or abdominal cavity is seen open below, causing the embryo to resemble somewhat the appearance of a partly-decked boat. (10 *diam.*)

Fig. 18.—An Embryo from an Ovum supposed to be twenty-three or twenty-four days old, seen from above. The primitive groove is now completely closed, to form the medullary tube, and exhibits above the three primitive brain-cells. The first of these is seen to be so expanded laterally as to form at each side the embryo eyes. The embryo ears are also seen on each side opposite the third brain-cell. The upper and lower ends of the embryo are now inclosed in a backward fold of the serous layer, which, however, is still open in the centre. The blood-vessels in the vascular layer are now fully formed. (10 *diam.*)

Fig. 19.—The same Embryo seen from below. The head is strongly bent forward, so that the first brain-cell and embryo eyes are best seen on this surface. Below these, two notched processes are seen, which are the first visceral arches. Below these again, the S-shaped heart—terminating, above in the aorta, below in the *venæ omphalo-mesentericæ*. The heart now pulsates, and a circulation is established over the vascular area. (10 *diam.*)

Fig. 20.—An entire Ovum, with the Embryo somewhat older than the last. The villous chorion is raised off the entire centre of the egg, which is suspended by it at one point, where the folds of the serous layer have completely closed over the back to form the amnios. The embryo lies with its inferior half in the plane of the vascular and mucous layers; whilst the head and superior half is prominent, and inclosed by them. At the sides are seen both the *arteriæ* and *venæ omphalo-mesentericæ*, which communicate with the plexus of the vascular layer, and terminate in circular rings, the *venæ terminales*, leaving the two poles of the ovum bare. (5 *diam.*)

Fig. 21.—The same Embryo, removed with its membranes, and viewed from the internal surface of the ovum, sideways. The head and upper portion is seen surrounded by the amnios. In the head is observed the brain, divided into anterior, neighbouring, and middle brain, *a*, *b*, *c*; the third brain cell, *d*; eyes, *e*; ears, *f*; not yet connected with the third brain-cell. There are three visceral arches. The heart is further developed, prominent, and surrounded by the serous membrane. The lower portion of the embryo is covered with the vascular and mucous layers. (5 *diameters.*)

Fig. 22.—The Lower End of an Embryo some hours older than that in the last figure. The mucous and vascular layers are drawn upwards, so that not only is the visceral cavity seen, but the lower portion of the intestinal canal, *a*. At the lower portion of the embryo are two small swellings, *b*, *b*, the commencement of the *allantois*. (10 *diam.*)

Fig. 23.—The Lower End of an Embryo twelve hours older than the last. The *allantois* now forms a sac, the two halves of which, however, are not yet closed. (10 *diameters.*)

(fig. 24). About the same time the inferior layer of the germinal membrane, more or less constricted when it comes

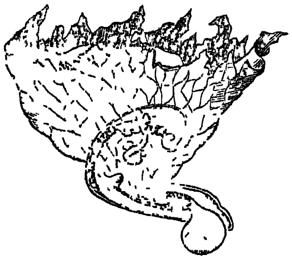

Fig. 24.

out of the abdomen of the embryo, forms a third sac or vesicle, called the *umbilical sac.* The mode of formation and relation of these three sacs will be better understood from the accompanying diagram (fig. 25).

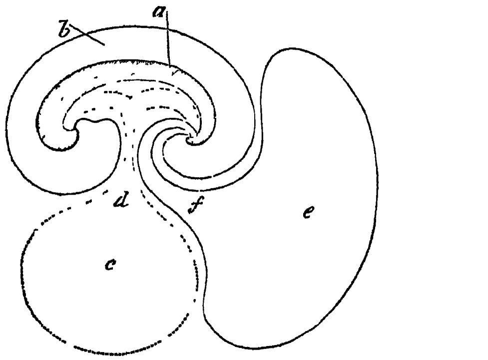

Fig. 25.

The various parts of the body are now rapidly perfected, to the principal of which we may shortly allude,—1*st,* The *chorda dorsalis,* inclosed by the *dorsal laminæ,* which forms the cranio-vertebral canal, are developed below into spinal cord and vertebræ, while superiorly are produced the cerebrum, cerebellum, and cranium (fig. 21, *b, c, d;* and fig. 24). 2*d,* The bent tube, which originally formed the heart, is by a kind of notch first separated into heart and aorta; and the former, by the growth of internal septa, divided into ventricles and auricles. 3*d,* The formation of branches from the aorta, which go to the branchial arches or clefts (fig. 26). 4*th,* The union of these branchial arches to form the bones of the face and jaws; the development of the special senses; and the formation, first, of the upper extremities (fig. 24), and, secondly, of the lower (fig. 27). 5*th,* The appearance of four striated organs deep in the visceral cavity, called Wolffian

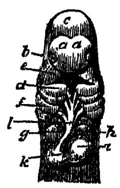

Fig. 26.

Fig. 24.—The Embryo of an Ovum twelve hours older than the last, suspended by the vascular and mucous layers. All the different parts formerly referred to may be seen further developed. The superior extremity is prominent. In the visceral cavity two long striated bodies are seen, the *Wolffian bodies;* and the allantois is now so enlarged as to hang out of the visceral cavity, covered with a network of vessels in connection with the vascular layer. (5 *diam.*)

Fig. 25.—Diagram representing the mode of formation and position of the three Embryonal Sacs. *a.* Embryo—*b.* Amnios—*c.* Umbilical Vesicle—*d.* the Vitelline Duct, or Pedicle of the Umbilical Vesicle—*e.* Allantois—*f.* The Urachus or Pedicle of the Allantois, afterwards the Urinary Bladder.

Fig. 26.—The Head of the same Embryo represented in fig. 24, seen in front. *a.* Anterior Brain-Cells—*b.* Eyes—*c.* Second Brain-Cell—*d.* First Visceral Arch—*e.* Process thereof—*f.* Three Lower Visceral Arches—*g.* Right, and *h,* Left Auricle—*i.* Left, and *k.* Right Ventricle—*l.* Aorta, with aortic branches to the visceral arches. bodies, which are afterwards transformed into the genito-urinary organs (fig, 27, *o*). 6*th,* The inflexions and constriction of the mucous layer to produce the alimentary canal (fig. 27, *m*). And, *finally,* the enlargement of the various

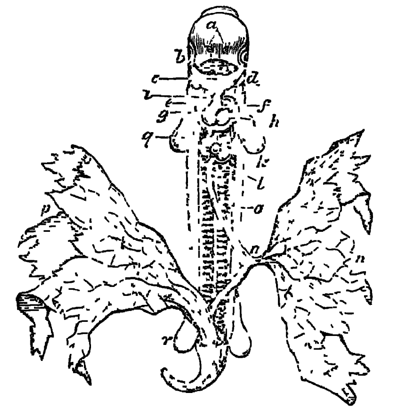

Fig. 27.

glands and internal viscera, and the greater perfection of all the parts referred to (fig. 28); while the abdominal open-

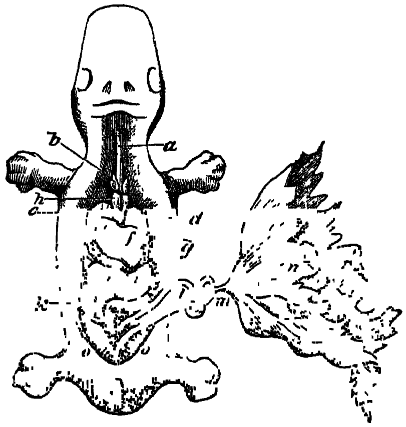

Fig. 28.

ing, closing in front, leaves only a small aperture, through which the united pedicles of the allantoid and umbilical sacs pass to constitute the umbilical cord. To describe each of these processes at length, or the variation which has been shown to exist in them, among the leading tribes of animals, would lead us too far. It will suffice to say, that from the serous layer is principally formed the nervous centres and the organs of sense; from the vascular layer for the most part is produced the voluntary and non-voluntary muscles, the bones, and the blood-vessels; and from the mucous layer, the mucous surfaces and chief portion of the glands.

Besides the changes which occur within the ovum, and

Fig. 27.—An Embryo older than the last, seen in front. *a.* Nasal Apertures—*b.* Eyes—*c.* First Visceral Arch, now the Under Jaw—*d.* Second Visceral Arch—*e.* Right, and *f.* Left Auricle—*g.* Right, and *h.* Left Ventricle—*i.* Aorta—*k.* Liver; between its two lobes is seen the cut *Vena Omphalo-Mesenterica*—*l.* Stomach—*m.* Intestinal Canal, terminating in the Umbilical Vesicle—*n, o.* Wolffian Bodies—*p* Allantois—*q.* Upper, and *r.* Under Extremity. (5. *diam.*)

which result in the formation of the embryo, there are others which seem external to it, and which are indirectly very necessary to its formation. As the impregnated ovum descends the Fallopian tube towards the uterus, it becomes covered with an albuminous layer, called the *chorion;* and on passing into that organ, encounters another which lines it, called the *decidua.* When the allantoid sac becomes developed, it sends vessels into a portion of these membranes to form the *placenta,* the relations of which to the various sinuses of the uterus are of a kind that enable the mother to furnish blood to the fœtus by transudation of its fluid substance through a double membrane. The uterus also becomes greatly enlarged and thickened; numerous non-voluntary contractile fusiform cells are formed in it; and at length, the fœtus having arrived at maturity, these commence to contract, and, by a series of expulsive efforts, finally expel the infant. The mammary glands also gradually enlarge, so that about the period of birth they are fitted to furnish a copious supply of milk, under the stimulating action of suction, to which the infant is instinctively impelled for the sake of nourishment.

Such is a general sketch of the various stages of the function of reproduction, a study of which in the different classes of animals has led to the formation of various ingenious hypotheses, whereby it has been sought to bring the order of evolution within the operation of certain laws. One of these, which has excited great attention, is, that the human fœtus passes through transition periods resembling in turn the different inferior beings of the animal scale: that is to say, it at first resembles a zoophyte, then a mollusc, then a worm, a fish, a reptile, and so on. Thus the monads found among the inferior animals have been supposed to be represented by the germinal vesicle. The yolk, when divided, has been thought to resemble a gonium or a volvox. When the primitive groove closes, it has been likened to a worm; afterwards to a molluscous animal; and when the visceral arches appear, to a fish; and so on. This method of viewing the phases of development has led to a generalization thus expressed by Serres,—viz., that "Human organogenesis is a transitory comparative anatomy, as in its turn comparative anatomy is a fixed and permanent state of the organogenesis of man." But that the human embryo ever resembles a worm, a mollusc, reptile, fish, or bird, can on careful examination nowhere be recognised. It is true, that at one period all ova resemble each other; but it is equally certain that from the first moment of their formation they are impressed with a power of developing themselves only in one direction, so that the ovum of a reptile, fish, or bird will always be developed into similar animals, and by no concurrence of circumstances will ever be transformed into different ones. Neither is there any anatomical or structural relation between them, for the visceral arches in the human fœtus are in no way, as has been supposed, analogous with the branchiæ or lungs of the fish, for the former are transformed into the bones of the face, while the lungs originate in inflexions of the mucous layer. The theory, then, may be considered as more fanciful than real, and founded upon loose analogies, which, instead of being strengthened, are weakened as development proceeds, and the true types of such analogies become more evident.

In recent times another theory has been brought forward, denominated *alternate generation* by Steenstrup, but more correctly *parthenogenesis* by Owen. Many of the facts described by the former refer not so much to an alternate as to a continuous development. Thus, many insects spend part of their lives as a worm, and part as a moth. The moth produces the worm, and the worm produces the moth; but this is not an alternate, but a different phase of the same generation. So a correct knowledge of the development of the *Medusa aurita* has shown that what naturalists had considered to be four distinct animals are in fact only different stages in the development of one animal. The formation of the Aphis is especially alluded to by Steenstrup, several of which insects are produced from the mother, and each of which may produce others, although it is only certain of them which become transformed into a fly. But the generation of a plant may be called alternate in the same sense as it is used in the case of the Medusa or the Aphis, inasmuch as the seed produces a leaf and a root, which proceeds to develop other leaves before it finally produces the flowers with the seed like that from which the plant originated. The term *parthenogenesis* (παρθενεία, *virginity*), as expressive of the power of reproduction in various forms without the act of fecundation, is therefore the more correct one.

This doctrine has now led to many important results, among which the discovery of the origin and mode of reproduction of tape-worms, and the manner in which the three kinds of bees are produced, are good examples. It is now known that certain Entozoa are partly developed in one animal and partly in another. Thus, the minute eggs of certain Tœniæ, or tape-worms, enter the body of the mouse, and are converted into cystic worms, which have been considered as distinct creatures. In this stage they would remain in that animal; but the mouse being eaten by the cat, the cystic worm of the former is converted into a tape-worm in the body of the latter. In the same way, the *Cysticercus pisiformis,* found in hares and rabbits, is converted into the *Tœnia pisiformis,* so common in the fox, which feeds on those animals; and the *C. cellulosæ,* so frequent in the flesh of pork and of mutton, is transformed into the *Tœnia Solium* of man. Thus the mystery as to the origin of tape-worm has been cleared up; and the practical result, that if we desire to cure the disease, besides giving anthelmintics and purgatives, we must also prevent the eating of flesh underdone, or game and fish out of season, when it is likely to be infected with *Cysticerci.* So, among bees it has been shown by Dzierzon and Siebold that the queen-bee, during her nuptial flight, receives the semen of the male into a receptacle communicating with the oviducts, but from which it can be shut off at will. The workers having prepared three kinds of cells,—namely, drone-cells, worker-cells, and royal-cells, each of which has its own peculiar form and size,—the queen deposits an egg in each. In doing this, she takes care to bring every one of those destined for the royal and the worker cells into contact with the seminal fluid, but takes equal care to keep free from such contact every one of those destined for the drone-cells. It has also been shown that a worker-bee can be transformed into a queen by feeding it on a peculiar kind of food. It follows that male animals in insects may be produced independent of the union of the ova with spermatozoids, in the same way that buds are thrown out in trees, or polype heads formed without fecundation. The queen-bee in this respect is like a tree, uniting two kinds of development, oviparous and gemmiparous. Her ovary resembles a *gemmarium,* the products of which she fertilizes at will, by shedding on the ovum the semen stored up in her receptacle.

The modern researches into reproduction, therefore, indicate that the tribes of animals hitherto described by naturalists are not so numerous as was once thought, and that many of them are only the metamorphic changes of one creature. They show that animals as well as plants can propagate in two ways—by buds and by germs; the individual developed from the bud being capable of producing an ovum from which another individual may spring that may produce a bud. Thus much of the mystery that has shrouded the origin of many animals has been dissipated, and the arguments by which it has been sought to esta-

blish a spontaneous or equivocal generation overthrown. They also confirm the instinctive convictions, so long established among the human race, which point to the male as being not merely the head and proper representative of the species, but the real reproducer of it also. The man being the head of the woman; she merging in him, and having no right apart from him; their joint offspring, not hers, but truly his; born indeed of her, but begotten by him. Hence the truth of the long-confirmed notion of descent in the male line, which, coupled with the instinct of power, has given rise to the law of primogeniture. Science, jurisprudence, and religion, therefore, unite in proving that the wife is part of the husband; the two being, in the language of Scripture, "no more twain, but one flesh." (A. Harvey.)

PART III.—PATHOLOGICAL PHYSIOLOGY.

Every animated being has a limited period of existence, during which it is constantly undergoing a change. So long, however, as this change takes place uniformly in the different parts of which it is composed, its physiological or healthy condition is preserved. But immediately the action of one organ becomes excessive or weak in proportion to the others, disease, or a pathological state, is occasioned. This state may be induced by direct mechanical violence, but may also occur from the continued or irregular influence of several physical agents, such as temperature, moisture or dryness, quality of the atmosphere, kind of food, &c., &c. These are always acting upon the vital powers of the individual as a whole, as well as incessantly stimulating the various organs to perform their functions. We have previously seen that life may be defined in the words of Béclard—"Organization in action." Health is the regular or normal, and disease the disturbed or abnormal condition of that action.

While such may be assumed to be our notion of disease in the abstract, what constitutes disease in particular has been much disputed. From the time of Hippocrates to that of Cullen and his followers, the external manifestation or symptoms constituted the only method of recognising diseased action, and gradually came to be regarded as the disease itself. Then these symptoms were arranged into groups, divided, subdivided, and named, according to the predominance of one or more of them, or the mode in which they presented themselves. These artificial arrangements are the nosologies of former writers. All philosophical physicians, however, have recognised that the true end of medical inquiry is, if possible, to determine rather the altered condition of the organs which produces the disordered function, than to be contented with the study of the effects they occasion. But the difficulty of this inquiry has been so great, and a knowledge of the means of prosecuting it so limited, that it is only within the last thirty years medicine has been enabled to build up for herself anything like a solid scientific foundation. What has hitherto been accomplished in this way has been brought about by the conjoined cultivation of morbid anatomy, pathology, and clinical observation, greatly assisted, however, by the advance of numerous collateral branches of science, and especially in recent times by chemical and histological investigation. The result has been a complete overthrow of nosological systems, and an attempt to trace all maladies to their organic cause; and doubtless in proportion as this has been successfully accomplished, medicine has become less empirical and more exact. The organic changes, however, which produce or accompany many diseases have not yet been discovered, and consequently a classification of all maladies on this basis cannot be strictly carried out. The organic cause of epilepsy, hydrophobia, and of many fevers, for example, is as yet unknown. When, therefore, the morbid change in an organ is unequivocally the origin of the symptoms, we employ the name of the lesion to designate the disease; but when there is disturbance of function, without any obvious lesion of a part, we still make use of the principal derangement to characterize the malady. Thus, as regards the stomach, we say a cancer or an ulcer of that viscus, and thereby express all the phenomena occasioned. But if we are unable to detect such cancer or ulcer, we denominate the affection after its leading symptom,—dyspepsia, or difficulty of digestion.

In endeavouring to carry out this distinction, however, modern pathologists have fallen into a great error, inasmuch as they have continued to employ the nomenclature of our forefathers, and use words which were simply expressive of the presence of symptoms to indicate the altered condition of organs, the cause of those symptoms. Formerly inflammation meant the existence of pain, heat, redness, and swelling; it now means certain changes in the nervous, vascular, and parenchymatous tissues of a part. Formerly apoplexy meant sudden unconsciousness originating in the brain; now it is frequently used to express hæmorrhage into an organ; and hence the terms apoplexy of the lung and of the spinal cord. The two ideas are essentially distinct, and bear no reference to each other, because the same word may be, and often is, employed under circumstances where its original meaning is altogether inapplicable, and even when the symptoms it was intended to express are altogether absent. Hence it is incumbent on every one who gives to organic changes terms which have been long employed in medicine, to define exactly what he means by them. In this way, old indefinite expressions, though still retained, will have a more precise meaning attached to them.

But notwithstanding the confusion which has necessarily resulted from the rapid advance of medicine in late years, and from the frequent change of ideas with regard to the nature of morbid actions, it still is correct to say that disease is only an alteration in the healthy function of organs. Hence all scientific classification of maladies must be founded on physiology, which teaches us the laws that regulate those functions; and they may be divided, like the functions themselves, into—1*st*, Diseases of Nutrition; 2*d*, Diseases of Innervation; and 3*d*, Diseases of Reproduction.

DISEASES OF NUTRITION.

The various modes in which nutrition becomes impaired can only be understood by knowing the different steps of the nutritive process. For ages medical men have been in the habit of considering the blood to be the primary source of numerous maladies. But our previous description of the process of nutrition must show that the changes in this fluid, and the diseases which accompany them, are for the most part not primary, but secondary; that is to say, they are dependent on previously existing circumstances, to the removal of which the medical practitioner must look for the means of curing his patient. This will become apparent, not so much by analysing the individual disorders to which the various organs and tissues of the body are liable, as by describing the fundamental pathological processes which are common to all parts of the frame. An enumeration and definition of these appear necessary in the first place.

Classification of Diseases of Nutrition.

Congestion, or Excess of Blood in a Part.—This is an over-distension of the blood-vessels, but more especially of the capillaries, with blood. It may be caused by excite-

ment of the nervous system, by mechanical impediments which obstruct the return of venous blood, or by irritation of the textures. However produced, congestion may be temporary, and disappear without producing much disturbance, or, if long continued, it may give rise to one or more of the following conditions:—

FEVER.—When congestion is caused or accompanied by general excitement of the nervous system, it produces fever, a morbid condition characterized by hot skin, accelerated pulse, furred tongue, thirst, and headache,—phenomena usually preceded by a sensation of cold, or rigor. If caused by some poison introduced through the blood, it is called *primary*, the principal forms being *intermittent, remittent*, and *continued.* If produced by injuries to texture, either directly from violence, or indirectly from reflex action causing internal inflammations, it is denominated *secondary* or *symptomatic*.

DROPSY, OR EFFUSION OF SERUM.—When congestion is *passive*, or caused by mechanical obstruction to the flow of blood through the veins, serum transudes through the walls of the capillary vessels, and collects in various places, causing dropsy. If generally diffused, especially through the subcutaneous tissue, it is called *anasarca;* if limited to the peritoneal cavity, *ascites;* if local, *œdema.*

HÆMORRHAGE, OR EXTRAVASATION OF BLOOD.—This may arise from direct injury to a blood-vessel, from a wound, or from disease of its coats. Under such circumstances it may be *arterial* or *venous*, the former distinguished by the blood being of a bright florid, and the latter by its being of claret colour. The capillaries are frequently ruptured from over-distension with blood, which is *capillary* or *congestive* hœmorrhage, causing dropsical effusions or inflammatory exudations to assume a sanguinolent character.

INFLAMMATION, OR EXUDATION OF LIQUOR SANGUINIS.—When congestion is *active*, or arises from irritation of the textures, it may, if excessive, terminate in the exudation through its coats of the *liquor sanguinis.* This is inflammation; an expression still used very vaguely by some pathologists, but which, thus defined, separates the morbid state accurately from congestion or fever on the one hand, and from dropsy, or the processes of growth, on the other. The exudation thrown out undergoes a variety of changes, producing various morbid conditions, according as it lives or dies.

SIMPLE OR INFLAMMATORY EXUDATION consists of the normal *liquor sanguinis*, which infiltrates the neighbouring tissues or collects in serous cavities. It then coagulates, and may undergo the following vital transformations: 1*st*, Into cells and fibres, forming *adhesive lymph*, as on the surface of serous membranes; 2*d*, Into pus-cells, constituting *suppuration*, as in mucous surfaces or in areolar texture; 3*d*, Into granule-cells, forming *inflammatory softening;* and 4*th*, Into various elementary tissues, such as the fibrous, vascular, cartilaginous, bony, &c. In this manner, the exudation may be (1.) absorbed, or undergo *resolution;* (2.) evacuated externally by discharge; or (3.) assimilated to the body. It is the agent which forms abscesses, causes the healing of wounds, and the union of divided tendons, bones, &c.

TUBERCLE, OR TUBERCULAR EXUDATION.—When an exudation, instead of undergoing the vital changes just referred to, assumes a yellow or grayish aspect and cheesy consistence, it is called *tubercle.* It consists of solid irregularly-formed bodies, called *tubercle corpuscles*, more or less associated with molecules and granules. If disseminated in small grains, it is called *miliary;* if in considerable patches or masses, it is *infiltrated tubercle.* When chronic, it may be *encysted*, or present the form of *cretaceous* or *calcareous masses.*

CANCER, OR CANCEROUS EXUDATION.—When an exudation, instead of undergoing the vital transformations previously described, passes into cells and fibres, the former increasing endogenously, it is called *cancer.* If hard, and principally formed of fibres from associated morbid growth, it is called *scirrhus;* if soft, often yielding a milky juice on pressure, it is *encephaloma;* if having a fibrous basis, this is so arranged as to form areolæ or loculi, containing a gelatinous gum or glue-like matter; then it is called *colloid cancer.*

MORTIFICATION, OR MOIST GANGRENE.—When the exudation is poured out rapidly in such quantity as to paralyse the nerves, obstruct the blood-vessels, and prevent the return of circulation in them, it dies, and undergoes chemical putrefactive changes, and is said to be mortified, or to be affected with moist gangrene. It differs from dry gangrene, which is slow death of pre-existing texture from want of nourishment. Sometimes it is epidemic, from external or unknown causes, resembling the blight which affects vegetables.

ULCERATION.—When an exudation does not pass into the vital transformations formerly described, but presses upon the surrounding parts, obstructing the flow of blood in them, death of such parts takes place. Under these circumstances, the whole slowly disintegrates; loss of texture is occasioned, with breach of continuity; and an *ulcer* is formed. Ulceration may also be produced by the direct pressure of a foreign body, continued weight of depending parts, &c.

MORBID GROWTHS OF TEXTURE.—Increased growth of tissues may assume various forms: the organ or structure may be enlarged in whole or in part, still maintaining more or less of its original texture, shape, and function—constituting *hypertrophy.* Membranes may become preternaturally thickened, causing more or less *induration*, whereby the movements of parts may be affected; or the calibres of tubes and ducts may be diminished, producing *stricture.* The vital transformations of an exudation into pus, granule, or other cells, must be regarded as a form of morbid growth, as must the results of the healing process, which give rise to new tissues exactly resembling those previously existing in other parts of the body,—as in cicatrices, callus, &c. Lastly, such growths may assume the form of *tumour.* Morbid growths may be classified into—1*st*, *Fibroma*, or fibrous growths; 2*d*, *Lipoma*, or fatty growths; 3*d*, *Angionoma*, or vascular growths; 4*th*, *Cystoma*, or cystic growths; 5*th*, *Adenoma*, or glandular growths; 6*th*, *Epithelioma*, or epithelial growths; 7*th*, *Echondroma*, or cartilaginous growths; 8*th*, *Osteoma*, or osseous growths; and 9*th*, *Carcinoma*, or cancerous growths.

MORBID DEGENERATIONS OF TEXTURES.—This also may assume various forms. The organ or structure may be diminished in whole or in part, constituting *atrophy*, still, however, retaining its normal shape and function; or the structure of the parts themselves may have undergone alterations, whereby their functions are impaired or destroyed. Such degenerations are of four kinds:—1*st*, They may, in a variety of ways, become indurated and shrivelled up, or converted into a waxy or glue-like material, apparently from an excess of one or more of the albuminous or gelatinous compounds. This is *albuminous degeneration.* 2*d*, They become softer, from an accumulation of fatty granules, either within cells or among the minute elements of the texture. This is *fatty degeneration.* 3*d*, In the same manner, pigment of various kinds is deposited in or replaces the tissue, which may be red, yellow, brown, green, blue, purple, or black, owing to chemical changes ascribable to extravasated blood or bile, or to some peculiar secretion. This is *pigmentary degeneration.* *Lastly*, the tissues may become infiltrated with mineral matter of various kinds,

but generally with salts of lime in solution, which subsequently becoming solidified, impede or destroy function. Such is *mineral degeneration*.

CONCRETIONS.—These are non-organized and non-vascular productions, formed by the mechanical deposition and aggregation of various kinds of matter, generally in the ducts or cavities of the hollow viscera. They may be composed of albuminous, fatty, pigmentary, or mineral substances, but are separable from degenerations from their never being formed out of an organic structure. *Urinary concretions*, or calculi, are composed of the salts which are too predominant in the urine, and which have been precipitated round a central body or nucleus, formed within or introduced from without. *Intestinal concretions* are usually composed of hair or vegetable fibres, which have been swallowed and accumulated also round a central nucleus. *Mineral concretions*, composed of carbonates and phosphates of lime, are common in the mucous passages of various organs, especially the salivary, bronchial, pancreatic, hepatic, and renal. They also occur in the veins, when they are called *phlebolites*. Occasionally they resemble starch grains, and are called *amyloid;* and not unfrequently concretions are found really composed of aggregated or isolated starch corpuscles, which may be called *amylaceous*.

PARASITIC GROWTHS.—These are of two kinds, vegetable and animal. The vegetable parasitic growths may be divided into such as grow on the surface (*Epiphyta*), or those that have been formed in the interior of the body, chiefly on the mucous surfaces (*Entophyta*). The animal parasites may also be divided into such as infest the surface (*Epizoa*), and such as are found in the interior of the body (*Entozoa*). To the former belong the several species of *Pediculus*, or louse; the *Acarus Scabiei*, or itch-insect; the *Entozoon folliculorum*, which inhabits the follicles of the skin; and the *Pulex penetrans*, or guinea-worm. The Entozoa are numerous, and may be divided into—1*st*, *Cystica*, or saccular worms; 2*d*, *Cestoidea*, or chain-worms; 3*d*, *Trematoda*, or flat worms; and 4*th*, *Nematoda*, or thread-worms.

Such is an enumeration and definition of the organic diseases of textures and organs. What are called *functional disorders* of the same parts are such as leave no traces of their existence after death, and are for the most part simple excess or diminution of normal actions. It is only when these last lead to congestions and exudations, terminating in fever or vital transformations, and chemical changes producing degenerations, that a true structural lesion can be said to exist. The causes of these organic alterations of texture are to be sought—1*st*, In increased or diminished stimulation acting directly on the tissues themselves; 2*d*, In increased or diminished excitability of the nervous system operating upon them indirectly; 3*d*, In an altered condition of the blood; and 4*th*, In chemical transformations of texture. These may act separately or combined, and one may occasion the other. We shall treat of these causes under the following heads:—

I.—*Theory of Active Congestion.*

When we irritate the web of a frog's foot, it may be seen under the microscope that—1*st*, The capillary vessels are narrowed, and that the blood flows through them with greater rapidity. 2*d*, The same vessels become enlarged, and the current of blood is slower, although even. 3*d*, The flow of blood becomes irregular. 4*th*, All motion of the blood ceases, and the vessel appears fully distended. 5*th* and *lastly*, The *liquor sanguinis* is exuded through the walls of the vessel, sometimes accompanied by extravasation of blood corpuscles, owing to the rupture of the capillaries.

The first step in the process,—viz., narrowing of the capillaries,—is readily demonstrated on the application of acetic acid to the web of the frog's foot. If the acid be weak, the capillary contraction occurs more slowly and gradually. If it be very concentrated, the phenomenon is not observed, or it passes so quickly into complete stoppage of blood, as to be imperceptible. Although we cannot see these changes in man under the microscope, certain appearances indicate that the same phenomena occur. The operations of the mind, for instance, as fear and fright, and the application of cold, produce paleness of the skin; an effect which can only arise from contraction of the capillaries, and a diminution of the quantity of blood they contain. In the majority of instances, also, this paleness is succeeded by increased redness, the same result as follows from direct experiment on the web of the frog's foot, constituting the second step of the process. In other cases, the redness may arise primarily from certain mental emotions, or from the application of heat. In either case, it depends on the enlargement of the capillaries, and the greater quantity of blood they contain.

It has been asserted that, instead of contraction of the capillaries, the first changes observable are enlargement, with an increased flow of blood. To determine positively the question of contraction or dilatation, Professor Bennett has made a series of careful observations on the web of a frog's foot. Having fixed the animal in such a way that it could not move, he carefully measured with Oberheuser's eye micrometer the diameter of various vessels before, during, and after the application of stimuli. The results were, that immediately hot water was applied, a vessel that measured thirteen spaces of the eye micrometer contracted to 10; another that measured 10 contracted to 7; a third that measured 7 contracted to 5; a fourth, which was a capillary carrying blood globules in single file, and measured 5, was contracted to 4; and another, one of the smallest size, which measured 4, was contracted to 3. With regard to the ultimate capillaries, it was frequently observed that if filled with corpuscles, they contracted little, but if empty, the contraction took place from 4 to 2; so that no more corpuscles entered them, and they appeared obliterated. This was especially seen after the addition of acetic acid. It was also observed that minute vessels that contracted from 4 to 3 afterwards became dilated to 6 before congestion and stagnation occurred. The smaller veins were seen to contract as much as the arteries of the same size.

The variation in the size of, and amount of blood in, the capillaries is conjoined with changes in the movement of that fluid. Whilst the vessels are contracted the blood may be seen to be flowing with increased velocity. After a time the blood flows more and more slowly, without, however, the vessel being obstructed: it then oscillates,—that is, moves forwards and backwards, or makes a pause, evidently synchronous with the ventricular diastole of the heart. At length the vessel appears quite distended with coloured corpuscles, and all movement ceases.

Again, these changes in the movement of the blood induce variations in the relation which the blood corpuscles bear to each other, and to the wall of the vessel. In the natural circulation of the frog's foot, the yellow corpuscles may be seen rolling forward in the centre of the tube, whilst on each side a clear space is left, only filled with *liquor sanguinis* and a few lymph corpuscles. There are evidently two currents, the centre one very rapid, that at the sides (in the lymph spaces, as they are called) much slower. The coloured corpuscles are hurried forward in the first, occasionally mixed with some lymph corpuscles. These latter, however, may frequently be seen clinging to the sides of the vessel, or slowly proceeding a short distance down the tube in the lymph space, and then again stopping. Occasionally they get into the central torrent,

when they start off with great velocity, and accompany the yellow corpuscles. It has been said that these corpuscles augment in number, accumulate in the lymph spaces, and obstruct the flow of blood. In young frogs their number is very great; but then they constitute a normal part of the blood, and in no way impede the circulation. In old frogs, on the other hand, all these, and subsequent changes, may be observed, without the presence of colourless corpuscles. When the capillaries enlarge, however, the central coloured column in the smaller vessels may be seen to enlarge also, and gradually approach the sides of the tube, thus encroaching on the lymph spaces. The slower the motion of the blood, the closer it comes, until at length the coloured corpuscles come in contact with the sides of the vessel, and are more or less compressed and changed in form. At length the vessel is completely distended with coloured corpuscles, the original form of which can no longer be discovered, and the tube appears to be filled with a homogeneous deep crimson fluid. This is congestion. Such a congestion may be temporary: it is

An exact copy of a portion of the Web in the Foot of a Young Frog after a drop of strong alcohol had been placed upon it.

The view exhibits a deep-seated artery and vein, somewhat out of focus; the intermediate or capillary plexus running over them, and pigment cells of various sizes scattered over the whole. At the top of the figure the circulation is still active and natural. About the middle it is more slow, the column of blood is oscillating, and the corpuscles crowded together. At the bottom, congestion, followed by exudation, has taken place.—*a*. A deep-seated Vein, partially out of focus. The current of blood is of a deeper colour, and not so rapid as that in the artery. It is running in the opposite direction. The lymph space on each side, filled with slightly yellowish blood plasma, is very apparent, containing a number of colourless corpuscles, clinging to or slowly moving along the sides of the vessel.—*b*. A deep-seated Artery, out of focus, the rapid current of blood allowing nothing to be perceived but a reddish-yellow broad streak, with lighter spaces at the sides.—Opposite *c*, laceration of a capillary vessel has produced an extravasation of blood, which resembled a brownish-red spot.—At *d* congestion has occurred, and the blood corpuscles are apparently merged into one semi-transparent, reddish mass, entirely filling the vessels. The spaces of the web, between the capillaries, are rendered thicker and less transparent, partly by the action of the alcohol, partly by the exudation. This latter entirely fills up the spaces, or only coats the vessel. (200 *diam.*)

only when, as we have seen, it leads to effusion, extravasation, or exudation, that true organic lesion is apparent. The different changes leading to congestion may be explained as follows:—

1. The contraction and dilatation of the capillaries are explicable by supposing them to be endowed with a power of contractility analogous to that existing in non-voluntary muscles. John Hunter thought they were muscular, from the results of his observations and experiments; and they may be shown by the histologist to consist of a delicate membrane in which permanent nuclei are imbedded. In structure, then, they closely resemble the muscular fibres of the intestine, and we know that, like them, they may be contracted or dilated by emotions of the mind—that is, through the nerves; or by local applications—that is, directly. The narrowing of these tubes, therefore, may be considered, as Cullen thought it was, analogous to spasm; while their dilatation is similar either to the relaxation which follows such spasm or to muscular paralysis. The recent observations of Cl. Bernard and others as to the effects produced by dividing the large nervous trunk of the sympathetic in the neck have singularly confirmed this theory, and shown how the modification of nutrition which characterizes *fevers* is probably owing to a morbid condition of the ganglionic nervous system.

2. The rapid and slow movement of the blood is explicable on the hydraulic principle, that when a certain quantity of fluid is driven forward with a certain force through a pervious tube, and the tube is narrowed or widened, while the propelling force remains the same, the fluid must necessarily flow quicker in the first case and slower in the second. It has been supposed, from the throbbing of large vessels leading to congested parts, that they pump a larger quantity of blood than usual into them. This was called "determination of blood" by the older pathologists, and is now known not to be a cause, but a result, of the changes going on in the capillary vessels and tissues of the affected part. The oscillatory movement, seen later in the transparent parts of small animals, has not been observed in man, and probably depends, in the former, on a weakened power of the heart.

3. It is the stoppage of the blood, and exudation of the *liquor sanguinis*, however, which it is most difficult to explain; for why, so long as there is no mechanical obstruction (and during this process none has ever been seen), should the circulation through the capillaries of a part cease? It has been endeavoured, indeed, of late years, to establish a mechanical obstruction, by supposing the formation of colourless corpuscles in large numbers, which cling to the sides of the capillaries, and so cause interruption of the stream. But this hypothesis is negatived by the following facts:—1*st*, In young frogs the vessels may be seen to be crowded with colourless corpuscles, while the circulation is in no way affected. 2*d*, In old frogs, oscillation and gradual stoppage of the stream may be seen, without any colourless corpuscles being present. 3*d*, The colourless corpuscles, as shown by Remak, are increased, after large venesections, in the horse, without causing active congestion. And 4*th*, In leucocythemia, or white cell-blood, all the vessels are crowded with colourless corpuscles, and yet no active congestion in these vessels, nor exudation of and kind, has been occasioned.

We cannot ascribe the stoppage of the circulation in the capillaries to venous obstruction, or to mechanical pressure of any kind, because all observation proves that such causes, while they induce effusion of serum, never occasion exudation of *liquor sanguinis*. Neither can we suppose it to depend on endosmose, nor on a *vis à tergo*, as such physical causes cannot be shown to apply in all cases. We are compelled, therefore, to attribute the vital force producing these changes, not to anything residing in the blood or in the vessels, but in the tissues which lie outside the vessels. That these do possess a power attractive and selective, whereby matters are drawn from the blood to carry on nutrition and secretion, is now generally admitted in physiology. A modification of this power, whereby the attractive property is augmented, and the selective one diminished,

Physiology

at least offers us an explanation consistent with all known facts, and seems to be the only active agency to which we can ascribe the approach of the coloured particles to the capillary walls, and the passage through them of the exudation.

Theory of the Exudations.

The true cause of exudation, therefore, is irritation of texture, so modifying its vital properties that, instead of selecting and attracting from the blood simply what is necessary to keep up the nutritive processes, it draws out the entire *liquor sanguinis.* This is the exudation which, if it do not die to produce mortification or ulceration, undergoes vital transformations, constituting what have been called the *terminations*, or *resulting phenomena* of inflammation in healthy persons, or tubercle and cancer in certain constitutional states of the system. In the first case, the transformations materially depend on the rapidity with which the exudations are thrown out, or the situation where they occur, and on the vital powers of the body. But in tubercular and cancerous exudations we observe no distinctions from these causes, although it has been remarked that situation so far influences cancer that scirrhus is most common in fibrous, and encephaloma in cellular organs. The more important characters of the three kinds of exudation may be shortly stated as follows :—

We observe in a simple or inflammatory exudation, that it may occur at all epochs in life ; that it may attack all tissues, and most commonly those which are very vascular ; that it may be poured out in large or small quantities ; and that it may occur with greater or less rapidity ; hence the terms *acute* and *chronic.* We further observe, that the acute exudations are generally attended with symptoms of a peculiar character (inflammatory), and have a great tendency to cell or temporary formations, which rapidly break down, are absorbed, and excreted by the emunctories ; that the chronic exudations, on the other hand, have a tendency to fibrous or permanent formations, producing adhesions, strictures, indurations, &c.

We observe in a cancerous exudation that it occurs for the most part in persons of adult or advanced life ; that it may also occur in every tissue, but is by far most common in glandular or fatty organs, such as the liver or female mamma, and is very apt to attack the lymphatic glands *secondarily ;* that its progress, although sometimes slow when very fibrous, becomes rapid when corpuscles abound in it ; that there is a great tendency to the formation of the most perfect forms of cell life, which have the power of self-development, and thereby of spreading to neighbouring tissues ; and lastly, that when by pressure ulceration is produced on free surfaces, it bursts through these in exuberant fungoid excrescences.

We observe in a tubercular exudation that it occurs for the most part in young subjects, between the periods of dentition and of adult age ; that it may also occur in all tissues, but is by far most common *primarily* in the lymphatic glands, and afterwards in fibrous or albuminous textures, as the lungs and serous surfaces ; that its progress is in general exceedingly slow ; that there is no disposition to the formation of perfect cell formation, but rather to abortive corpuscles, which form slowly, and slowly break down ; that there is little tendency to absorption, but great liability to disintegration and ulceration ; and finally, that the local changes are almost always preceded by derangement of the *primæ viæ*, and a group of symptoms known under the name of *dyspepsia.*

Taking, then, the products of simple exudation (say pus) as a standard, we cannot fail to remark, that whilst the cell-development of tubercle is below, that of cancer is above this standard. Of the three kinds of exudation, tubercle is the lowest, and cancer the highest, in the scale.

Of the ultimate cause producing this difference in the formative power of the exudation we are ignorant, but every kind of reasoning must lead us to the conclusion, that these changes and effects depend, not upon the vascular system, which is the mere apparatus for the production of exudation ; not upon the nervous system, which conducts impressions to or from this apparatus ; and not on the texture, which is the seat of the exudation, as that varies, whilst the cancerous or tubercular formation is the same ; but in the inherent composition or constitution of the exudation itself. On this point most pathologists are agreed ; and hence the supposed existence of various kinds of *dyscrasiæ* originating in the blood, which it is imagined explain the different results produced. But here pathologists pause : once traced back to the blood, they are content ; and they have not sufficiently taken into consideration that the blood itself is dependent for its constitution on the results of the primary digestion in the alimentary canal on the one hand, and the secondary digestion in the tissues on the other. Yet it must be evident to every physiologist that if it be the constitution of the blood which determines the nature of the exudation, the causes which produce this must be sought in those circumstances which operate on the composition of the former fluid.

Now, numerous facts render it probable that, while the blood is normal in simple exudation, it contains an excess of nutritive materials in cancerous, and a deficiency of them in tubercular exudation. These are points, however, which can only be established after examining instances of such exudations in detail. But it must not be forgotten, in the meantime, that as the blood is continually undergoing changes, is receiving and giving off new matters, it can scarcely happen that it remains the same for many hours together. An exudation at one time may be very different from that at another. At one period it may abound in elements which do not exist in it at the next. Hence it often happens that a concurrence of circumstances is necessary to occasion a certain result. A cancer, once formed, may remain local until such a series of events arises, comprising, first, the phenomena leading to and producing an exudation ; secondly, the occurrence of this exudation in some other tissue or organ sufficiently predisposed for the purpose ; and thirdly, a peculiar constitution of the blood. Hence why the histologist is continually finding all kinds of intermediate formations between the three leading kinds of exudation, and why, even when the constitution is thoroughly cancerous or tubercular, simple exudations may be poured into tissues as the result of recent wounds or injuries. But, whilst a recent cancerous or a tubercular exudation may be found to accompany, or alternate with, a simple exudation, the two former are seldom met with together ; a circumstance which still further points out the wide difference between the constitutional causes producing them.

The final termination of either kind of exudation may be the same, only each has its peculiarities. We have noticed the tendencies of simple exudation to be transformed into pus or fibres, according to its seat. In the former case, the pus cells break down, and are re-absorbed in a disintegrated and fluid condition into the blood ; in the latter, permanent fibrous tissue is produced, constituting chronic adhesions or cicatrices. The cells of a cancerous growth may also degenerate or decay, but this rarely takes place throughout the whole structure. But it is not uncommon to find in certain encephalomatous tumours yellow matter, either in masses or reticulated through its substance (*cancer reticulare* of Müller). This is generally owing to fatty degeneration of the cancer cells. (See "Fatty Degeneration," in this article). The fibrous structure of cancer may also increase, and occa-

sionally produce cicatrization. Tubercle possesses no such fibrous stroma; but is infiltrated among the elements of various organs, the vascularity of which it tends to destroy. This, indeed, is the reason why a cancerous tumour increases by growth, which tubercle cannot be said to do; the former is vascular, the latter is not: in the one, cells are formed which have the power of re-development; in the other, no reproductive cells are produced. In cancer, the morbid matter circulating in the blood (whatever that is) is concentrated or attracted to the cancerous part, and should none afterwards be present, the healthy blood is made subservient to the purpose of nourishing a foreign growth. In tubercle, successive fresh exudations only are made, which, by their accumulation, augment the volume or amount of the morbid product.

All three forms of exudations may be rendered abortive by the animal matter being broken down and absorbed, while the mineral matter remains, constituting a cretaceous or calcareous concretion. This is not unfrequently seen as the result of simple exudation; is rare in cancerous, but very common in tubercular exudation.

During the disintegration of simple, cancerous, and tubercular exudations, the animal matter broken down is again rendered fluid, re-passes into the blood, and then constitutes that excess of fibrin detected by chemists. The quantity of this will of course vary according to the amount of the exudation and the activity of the disintegrating process. In the blood this effete matter undergoes a series of chemical changes, preparatory to its excretion by the different emunctories, but more especially by the kidneys, in the form of various sediments. The resolution of simple exudation is generally accompanied by the presence of such urinary sediments, which indicate pretty clearly in what way, after it has passed through the phases of development described, it is at length discharged from the body. In the same manner, the amount of these sediments frequently points out the extent of absorption going on in cancerous and tubercular exudations.

Another theory has been advanced regarding the various products of exudation as we have described them—viz., that instead of being new formations in an exuded blood plasma, they are only modifications of pre-existing texture. According to this view, pus-cells are only altered epithelial ones, cancer-cells are an increased development of gland or other cells, and tubercle corpuscles are a degeneration or "necrosis" of these. This theory, though it has many facts for its support, is opposed by others; so that its fallacy is easily demonstrated. For instance, pus-cells may occur in tissues where no epithelial cells exist, as among muscles, while cancer and tubercle are both found in the white substance of the brain, where there are no cells to develop themselves in the one case, or to degenerate in the other.

Theory of Morbid Growths.

This comprehends a consideration of the origin, development, propagation, and decline of morbid growths. Doubtless many facts are yet to be discovered as to the structure, chemical composition, and mode of formation of morbid growths; but enough has been ascertained of late years, from combined histological and clinical research, to necessitate great modifications in the views previously held regarding them. The following account, it is only right to say, is derived not only from careful study of what has been written by others, but from a large amount of original investigation.

Origin of Morbid Growths.—All morbid growths consist—1*st*, In augmented development of pre-existing textures (so-called *homologous* or *homeomorphous* growths); 2*d*, Of new elements which have no previous existence in the economy (so-called *heterologous* or *heteromorphous* growths); and, 3*d*, Of these two sorts of growth mingled together. The causes which induce them are of two kinds,—1*st*, Local irritation, excited directly or indirectly; and, 2*d*, Constitutional or unknown changes, supposed to operate through the blood. Thus the direct stimulus of a blow may so irritate the tissue of a part as to excite increased nutritive action, so causing hypertrophy, or it may give rise to an exudation; and irritation at a distance may, through the nervous system, produce like effects, as when the female mamma is influenced by the state of the uterus. If, on the other hand, the constitution be affected, such local changes may assume peculiar characters. In this manner, age, sex, hereditary predisposition, and concomitant disorders, as syphilis and cancer, not only modify, but give rise to morbid growths.

It has been a favourite idea with pathologists that morbid growths have fixed tendencies from the beginning, such as are impressed upon the ova of various animals, in virtue of which they are necessarily developed in certain directions. If so, this is not traceable to any peculiarity of structure or chemical composition. In this respect morbid growths are like healthy ones, which, however different in ultimate composition, all originate in a finely molecular blastema. A careful observation of the subsequent development of these growths, however, seems to indicate that specific differences are not impressed upon them from the first—that one does not, as a matter of course, exclude the other, and that any of the classes into which they have been divided may supervene upon pre-existing ones. For instance, persons may have a fibrous or glandular growth, and after a time its blood-vessels may pour into it a cancerous exudation, or this latter may undergo a fibrous or fatty transformation. It is only in this manner we can explain numerous cases, which are daily observable in practice, where indolent fibrous tumours suddenly assume increased power of development, and become cancers, or where these last slough out, and subsequently cicatrize.

Besides these constitutional causes, locality and the nature of pre-existing textures have a considerable influence on the formation of morbid growths. Thus, as a general rule, fibrous growths are common in fibrous textures, cartilaginous and bony growths in osseous ones, epithelial growths on epidermic and mucous membranes, and so on. Yet even here the system generally occasions differences. For example, osseous growths in rheumatic constitutions occur at the extremities of long bones; but in syphilitic ones, choose in preference their shafts. In youth, epithelioma occurs in the form of warts on the hands; in syphilitic people it occurs in the genitals; in chimney-sweeps, on the scrotum; in smokers, on the lips, &c. This conjoined influence of constitution and locality indicate the complex causes necessary to produce the results, a study of which is of the greatest moment to the physician, who is desirous, through the former, of operating on the latter, or the contrary, as previously explained in the sketch of the function of nutrition.

Development of Morbid Growths.—All morbid growths, once formed, continue to grow according to the histological laws which regulate development in the textures generally; that is to say, after arriving at a certain point, they attract from the blood-vessels in the neighbourhood, or from such new ones as are formed within themselves, the nutritive materials whereby they augment in bulk. In voluntary muscular fibre, this appears to be accomplished by the fasciculi multiplying fissiparously. In non-voluntary contractile fibre, also, the individual fusiform cells multiply, enlarge, and elongate; a change well observed in the pregnant uterus, in which organ many of the small non-contractile spindle-shaped fibres enlarge, become contractile, and then undergo the fatty degeneration, break down, and

ultimately disappear. In the same manner, the elementary parts in hypertrophies of other textures augment fissiparously or endogenously, as in bone and cartilage.

Other forms of morbid growth, especially tumours, are very variable as to rapidity of increase and volume; but the manner in which the development is accomplished is of three distinct kinds:—*1st*, The elementary textures are produced in the same manner as they are in adult tissues. They are either more numerous or larger, but preserve their normal relation and mode of arrangement (*lipoma, adenoma, angionoma*). *2d*, A matter is thrown out from the blood, which serves as a blastema for the formation of cells, which may be detected in various stages of development, undergoing the same changes that similar textures are seen to present in the embryo (*fibroma, osteoma*). *3d*, The cells, whether pre-existing or newly formed, assume such a property of self-multiplication that their normal relation and mode of arrangement is destroyed (*epithelioma, enchondroma, carcinoma*). These three modes of increase may occur singly or united. Any one or two of them may be superadded to the third, and their occurrence at different times, and in various proportions, accounts to a great extent for the apparent anomalies exhibited in the progress of individual growths.

The third mode of development just alluded to deserves special consideration. It consists of the same kind of endogenous multiplication of cells, with this difference, that sometimes these cells previously existed, whilst at others they have been newly formed in an exudation. Thus the cells in softened cartilage or brain, and those in encephaloma, may be identical; yet the one takes its origin in pre-existing normal cells, whilst the other must arise in the new cells of an exudation, as the white substance of the brain contains no corpuscles from which they could be developed. In the cornea and epithelium similar changes occur, as well as in the bones and mesenteric glands. Yet this lesion, so closely allied in its essential nature, has in these different textures been called by different names, and widely separated pathologically. In the non-vascular cornea and cartilage it has been called *inflammation*, but in the equally non-vascular epithelium it has been named *cancer*. Again, in the vascular bones and glands it has received various names, such as *osteo*, or *medullary sarcoma, enlarged glands*, &c.; whilst in the brain and other localities it has been called *encephaloma*, or *soft cancer*. It seems to us that in all these cases the lesion is the same, and that an advanced knowledge of their nature should lead us to group them together. Calling some of them inflammation, and others cancer, supposing the first to be innocent, and the last malignant, is, we contend, incorrect pathology. True theory points out that all these lesions are equally destructive, in consequence of increased endogenous cell growth, and practical experience has long determined the question of their being alike difficult to control.

As a general rule, the greater the number of cells any growth contains, the more rapidly it extends. Hence why a tumour is subject to the laws which govern development and multiplication of cells in addition to those connected with locality and the general powers of the constitution. Thus, room for expansion and the amount of temperature and moisture exercise undoubted influence over morbid growths. We see the influence of room for expansion in the cases of adenoma and carcinoma. In adenoma the cells are confined within pouches or ducts. They become crowded on each other; and thus, by means of compression, tend to atrophy and breaking down, rather than to self-multiplication. This is assisted if the distension from within so irritates the fibrous stroma of the gland that it becomes hypertrophied, and occasions a further obstacle to expansion around the seat of cell increase. In carcinoma, we observe that the growth takes place in extent and rapidity proportionally to the number and power of expansion in the cells. If compressed by much fibrous or hard tissue, they multiply slowly; but if an ulceration occurs, say in the skin, then they become developed rapidly, and constitute the so-called soft fungoid excrescences. Heat and moisture, as they are essential to cell growth throughout the animal and vegetable worlds (increased temperature with fluidity favouring—cold, and dryness checking it, within certain limits), so the influence of these physical agents may be observed to be equally powerful in morbid growths. Rapid augmentation of a tumour is generally accompanied by increased heat and softening of the parts, whilst colder and harder swellings develop themselves slowly.

Propagation of Morbid Growths.—It has seemed to most pathologists that, while some morbid growths are local, and if removed by the surgeon, do not return, others are constitutional or general, and if cut away, exhibit a great tendency to come back. The former have been called *innocent* or *benignant*, and the latter *malignant*. So far has the notion of malignancy in certain growths been carried, that surgeons have refused to remove them, not because they are inaccessible, or so connected with anatomical parts as to render the operation directly dangerous to life, but simply because they thought the disease was in the blood, and that cutting away the local swelling would either be useless, or give increased activity to the lesion.

But modern research has demonstrated that every kind of morbid growth may be malignant in whatever sense that term be employed, whether used to signify a growth incurable; recurring after the operation or primary lesion; as infiltrating neighbouring or distant tissues and organs; or as continuing its progress and destroying life in spite of all the resources of art. On the other hand, it is easy to prove that all these forms of growth may either disappear spontaneously, or be cured successfully by operation. While, however, we contend that there is no growth which may not be malignant, and none which may not be innocent, it is not denied that some have a greater tendency to spread and affect the system than others. In reference to treatment, therefore, it becomes of the greatest importance to determine the laws which apparently govern the propagation and multiplication of morbid growths, or the circumstances which render—say carcinoma and epithelioma—more susceptible of being communicated to neighbouring and internal organs than purely fibrous or osseous ones.

There is one circumstance which has been overlooked by pathologists, viz., that certain growths abounding in cells have a great disposition to infiltrate themselves among muscles and neighbouring parts, and may be detected there by the microscope, although invisible to the naked eye. In many cases where the surgeon thinks he has removed a morbid growth, he really leaves multitudes of germs behind, which continue to propagate the disease. Hence one of the chief causes of propagation among growths is, that the cells in the process of development become infiltrated among neighbouring tissues. But how do they accomplish this? Van der Kolk suggests that the fluids which they contain mingle with the juice of the parenchymatous substance around them, and that in the latter there are deposited molecules and granules, which, having received from the former certain tendencies to evolution, are ultimately transformed into similar structures. This view is not only exceedingly ingenious but very probable, and will serve to explain how the blood and distant organs are secondarily affected. The notion of solid germs floating in the blood has no facts in its support, but the idea of a fluid secreted by cells being absorbed is consonant with every known law of nutrition.

The fluid, then, of a morbid growth, elaborated in the

process of its development, and the result of cell or other formation, would seem to be the most probable material whereby secondary growths are produced. We have seen that many tumours which have no cells may be recurrent, and attack tissues secondarily. Still, they all contain a parenchymatous juice, and as a general rule those that are most soft and pulpy are most liable to return. Many facts, therefore, show that constitutional tendencies do exist for the reproduction of morbid growths similar to those which have previously been formed. A recurrence of all diseases, and especially of apoplexy, epilepsy, rheumatism, bronchitis, &c., is equally common, and appear to follow the same law. But the idea, that *because* they do so they should be separated under the name of "malignant," appears to us unpathological. Multiplying the numbers of cancers seems equally faulty. We may just as correctly talk of a rheumatism being innocent or malignant, as apply those terms in different cases to fibrous, cartilaginous, osseous, or other kinds of morbid growth, for no other reason than because sometimes they are local, and at others more general.

Decline or Degeneration of Morbid Growths.—In their decline, as in their development, the various kinds of morbid growths follow the laws which regulate degeneration of texture. Some, as lipoma and adenoma, have been known to be gradually absorbed and disappear. Others undergo the albuminous, fatty, mineral, or pigmentary transformations to be subsequently described. To enter into the peculiarities of each morbid growth in this respect would lead us too far. All that need be said here is, that every kind of morbid growth may degenerate, and prove abortive in one way or another. Cancer especially has been known to slough out, and heal by cicatrix, besides having been checked in its development and rendered abortive in every known mode of retrograde transformation.

Theory of Degeneration of Texture.

Degenerations of texture, as previously stated, may be classified into four groups,—viz., the Albuminous, Fatty, Pigmentary, and Mineral degenerations.

Albuminous Degeneration.—It has been previously pointed out that albumen is essential to nutrition, and that it forms the basis of the blood and of the tissues. The flesh which constitutes the food of Carnivora, and the albumen which comprises so large a portion of the fodder of Graminivora, are alike, by the solvent action of the digestive juices, reduced to a fluid state. In this condition it passes into the blood, forming the walls of the blood corpuscles, besides entering largely into the constitution of the *liquor sanguinis* as serum,—that is, albumen dissolved in water. During the building up process of the former it undergoes various transformations, among which those of its conversion into the fibrin of flesh and the gelatine of bones are perhaps the most important. By its association with the other proximate principles also, it enters into the composition of every texture and organ in the body, and again joins the blood as albumen, mixed with a minute portion of effete matter as fibrin. There can be no doubt, as we shall subsequently see, that under certain circumstances it may be changed into fat; and the multitudinous transformations this important element is susceptible of making well merits the term which, in its pure state, Mulder bestowed upon it, namely, that of "proteine."

As albumen, we have seen how it may produce abnormal states of the tissues in various forms. The essential conditions for this kind of degeneration appear to be—1*st*, Extreme slowness of effusion from the blood-vessels, as in cases of chronic tubercle and fibroid transformation; and 2*d*, Mechanical obstruction of the veins in some part of the circulation, giving rise to dropsy. In the former case, it is favoured by excess of acidity in the primæ viæ, which, by its power of dissolving the albuminous compounds, must assist in adding this element to the blood in undue proportion. Why, on the other hand, muscles, cartilage, and the exudations should sometimes pass into the albuminous fibroid degeneration, under pretty much the same circumstances that at others they become fatty, is a point in pathology which is still involved in the utmost obscurity.

Fatty Degeneration.—The causes of fatty degeneration are to be sought in all those circumstances which, while they weaken the vital action of a part, do not interfere materially with the assimilation of hydro-carburets. Yet the disease is not purely local, as it may frequently be observed that the kidneys, liver, heart, and other textures are prone to undergo the fatty change in the same person. Hence everything that increases fatty matter in the blood, such as its introduction by means of assimilation, or its not passing off in consequence of diminished excretion, tends to its production. Thus indulgence in rich food, and alcoholic liquors abounding in carbon, especially if there be little exercise, occasion it. Whether the fatty matter be deposited directly from the blood, or whether it be the subsequent result of a chemical transformation of tissue or exudation, has excited great discussion. Dr Quain supports the latter view, and has performed experiments, whereby it would seem that healthy muscular fibrin may be rendered fatty artificially by digesting it for a fortnight in water. We have repeatedly seen muscles and bones converted into adipocere during the maceration in water necessary to clean the latter, and frequently examined the former during the process, so as to be satisfied that the fibrinous material of flesh undergoes a chemical transformation into fat. We believe with Quain that the same thing occurs in the living body, not only when dead tissues are inclosed in it, as in the experiments of Wagner, but slowly in living texture, until its vigour is at length so impaired that it is incapable of performing its function. This view in no way excludes the probability that in certain cases fatty matter may transude occasionally through the vessels in a fluid state, and collect outside, or be infiltrated to a certain extent among neighbouring textures in a molecular form. Further, we have seen that it may occur within cells as a secretion; and by its accumulation not only may cause atrophy of the nucleus, but obstruction of tubes, and an endless variety of organic and functional derangements in the economy, according to the extent and seat of the degeneration.

Pigmentary Degeneration.—The formation and modifications of pigment, as observed in plants and animals, is a subject which has been little studied, and opens up a wide field of inquiry for the chemical histologist. But in endeavouring to ascertain the causes which give rise to change of colour in the textures, we may attend to the following circumstances :—

1*st*, Colouring matter bears a certain relation to the non-nitrogenous and oily constituents both in plants and animals. Thus, vegetable oils and resins are seen to form where starch or chlorophyle is collected, and these substances disappear in the cells, as the quantity of oil in them increases. In animals we almost always find pigment associated with fat. The brilliant colours of the Invertebrata are so many coloured fats, and the pink fat of the salmon, and green fat of the turtle, indicate the same relation in animals higher in the scale. The epidermic appendages, which are generally coloured, are always covered with fat, secreted by a special apparatus—the sebaceous glands. The blood corpuscles are intimately associated with the chyle, which is an oily emulsion; and the bile is rich in fat. In diseased conditions of the liver, the hepatic cells often contain oil, to the exclusion of the yellow pigment.

2*d*, It would appear that light, heat, and exposure to atmospheric air are connected with the production of pigment. The young leaves of plants are much lighter than

those which are older, and the hair of young animals is not so dark as that of the adult. In autumn, the leaves fade, and become brown, reddish, or yellow; and in man, we observe that the pigment of the hair ceases to be formed in advanced age, which at length becomes white. Young fruit is green, and as it ripens the part exposed to the sun is most coloured. Exposure of the skin of man, as is well known, renders it darker, and the fairest skinned individuals (whose integuments are well loaded with fat) are those who are most subject to freckles. Then it must be remembered that while light evolves colour in living, it destroys pigment in dead textures.

Now, the decomposition of the atmosphere is carried on in vegetables by the leaves, under the stimulus of light, and in animals by the lungs and skin. In plants the leaves fix the carbon and give off the oxygen; in animals the lungs receive oxygen, while carbon is separated in the form of carbonic acid by the same organs, and oxygen in combination with water, in the form of exhalation, is given off both by the lungs and skin. That the skin is connected with respiration is proved by the fact, that if its functions are interrupted, pulmonary diseases, and even asphyxia, are the common results. Carbon is also separated in the form of oily matter largely by the skin and by the liver, an organ also connected with respiration. Hence why Europeans in tropical climates, by breathing a rare atmosphere, eating well, and taking little exercise, are liable to hepatic diseases. Thus the lungs, skin, and liver are intimately associated in the function of excreting carbon; and it is curious that these are the three organs in which pigment is formed. The blood must be brought to the lungs to receive fresh oxygen and give off its carbonic acid, and it is then the white corpuscles of the chyle become coloured, while the blood itself is rendered bright scarlet. On the other hand, the accumulation of carbonic acid in the capillaries communicates the darker tint characteristic of venous blood.

3*d*, There seems to be a certain connection between the materials introduced into the structure of the plant or animal by means of the soil and of food. Some plants are rich in acids, others in alkalies, or various salts originally derived from the soil, and we have seen that these re-agents operate on colouring matter. Although this subject has been very slightly investigated, we can still perceive how, by the evolution of chemical products acting on different pigments, the various shades of colour may be occasioned which we observe in most plants and some animals at certain seasons. Thus green chlorophyle may be changed in one place into a yellow resin, and in another, by the formation of ulmic or other acids, be transformed to reddish or brown. In animals, the influence of nutrition is traced with more difficulty; but even here we may discern that at certain seasons (such as that of breeding) new products are evolved, which, by operating on the blood or the vital properties of cells, may eliminate more or less colour. According to Hensinger, carbonaceous food used in excess tends to the production of pigment, and hence he explains how the Greenlanders, notwithstanding the cold, are dark coloured from their constant consumption of fat.

Mineral Degeneration.—We have already seen that sometimes this takes place in such a regular manner as to form bone, which replaces the pre-existing texture,—as in muscle, membrane, or certain exudations and tumours. But at others it enters into the constitution of a texture dissolved in fluid, and is thus deposited in or throughout its substance, changing its physical and destroying its vital characters. In this way we separate mineral degenerations from concretions, which are accidental collections in hollow viscera, although undoubtedly they insensibly pass into one another. There is scarcely perhaps any tissue, whether elementary or compound, that may not undergo the mineral degeneration. But it is frequently observed in the coats of blood-vessels more or less associated with atheroma, in exudations, in certain morbid growths—rarely in nervous texture.

All these forms of degeneration may pass into concretions, but are separated from them essentially by being transformations of tissue; while concretions, for the most part, are primary precipitations from fluids.

Theory of Parasitic Growths.

Vegetable Parasites.—It was the demonstration by Bassi in 1837 of the vegetable nature of the disease named *muscardine* in silk-worms, which causes so great a mortality among those animals, which opened up to pathologists a new field for observation, and led to the discovery that certain disorders in the higher animals, and even in man himself, were connected with the growth of parasitic plants of a low type. Schönlein of Berlin was the first to detect them in favus-crusts; and since then they have been found in mentagra, pityriasis, and other diseases of the skin, in various exudations on mucous surfaces, in the stomach of dyspeptics, and in tubercular cavities of the lungs. They belong to the lowest forms of vegetable life, never reaching an organization higher than the Algæ and Fungi. They grow in such portions of diseased animal matter as present certain conditions necessary for their germination, and seldom, if ever, spring from the healthy tissues. Such growths in living animals indicate impairment of the nutritive functions, or diminished vital power in the economy. Hence why they are commonly found in young or scrofulous persons with skin eruptions, and in such as are labouring under prostrating diseases,—as typhus, dysentery, or other epidemic disorders. Numerous efforts to propagate these vegetations in healthy tissues have failed, but if inflammation be excited, or abrasions and sores occasioned, then, by fastening down portions of the fungus, it may be made to grow on the unhealthy parts. Boys at school frequently propagate the disease by wearing each other's caps, or using the same combs. Hence why *favus*, or ringworm, is so difficult to eradicate from charity institutions and extensive schools. The mode of development of these growths is the same essentially as that of most cryptogamic plants, and may be easily seen in any well characterized specimen of favus-crust. This consists of branched thalli, with variable-sized elongated cells, separated by partitions, the terminal ones forming mycelia, with sporules forming within them. Occasionally they present round clusters or chains at the extremity of the branches. The square masses of Sarcina are developed fissiparously.

Animal Parasites enter the body by the food or drink; others as ova, or in some stage of transformation. The mystery which so long enveloped the origin and development of tape-worms is now removed by the labours of modern helminthologists, as has been previously explained under the head of "Reproduction."

DISEASES OF INNERVATION.

The manner in which the different parts of the nervous system have their functions deranged or suspended is only to be understood by paying attention—1*st*, To the pathological laws which seem to govern morbid actions in them; and 2*d*, To the definition of what constitute special nervous diseases, and the general causes producing them. It should be remembered that the encephalon, spinal cord, and nerves consist of an aggregation of organs more or less connected together, the functions of which, especially as regards the different parts of the encephalon, are by no means determined. In health these act in harmony, but in disease they are so irregularly disordered that, while the action of one is excited, that of another may be perverted or annihilated. These

derangements of the nervous system are capable of assuming at various times every conceivable disorder of intelligence, sensation, and motion; so that not only may all kinds of diseases which have received names be simulated, but the symptoms may be so curiously combined as to set all arbitrary nosological classifications at defiance. If it be farther remembered that through the brain, spinal cord, and nerves the functions of every organ in the body may be more or less influenced, the endless variety of local as well as of general derangements may perhaps be imagined. Then nothing is more common than to observe some of the most fatal nervous diseases, such as hydrophobia, leaving after death no lesion detectable by the most careful histological examination, whilst on other occasions tumours and extensive destruction of the cerebral mass may exist, without producing any effects whatever. Notwithstanding these difficulties, careful observation, conjoined with a knowledge of physiology, will enable us to approximate closely towards, if not actually reach, a correct view of the disease in the great majority of cases.

GENERAL PATHOLOGY OF THE NERVOUS SYSTEM.

The following are the pathological laws which seem to regulate diseased action of the nervous centre.

1. *The amount of fluids within the cranium must always be the same so long as its osseous walls are capable of resisting the pressure of the atmosphere.*—That the circulation within the cranium is different from that in other parts of the body was first pointed out by the second Monro. It was tested experimentally by Dr Kellie of Leith, ably illustrated by Dr Abercrombie, and successfully defended by Dr John Reid. The views adopted by these distinguished men were, that the cranium forms a spherical bony case capable of resisting the atmospheric pressure, the only openings into it being the different foramina by which the vessels, nerves, and spinal cord pass. The encephalon, its membranes and blood-vessels, with perhaps a small portion of the cerebro-spinal fluid, completely fill up the interior of the cranium, so that no substance can be dislodged from it without some equivalent in bulk taking its place. Dr Monro used to point out that a jar or other vessel similar to the cranium, with unyielding walls, if filled with any substance, cannot be emptied without air or some substance taking its place. To use the illustration of Dr Watson, the contents of the cranium are like beer in a barrel, which will not flow out of one opening unless provision be made at the same time that air rushes in. The same kind of reasoning applies to the spinal canal, which, with the interior of the cranium, may be said to constitute one large cavity, incompressible by the atmospheric air.

Before proceeding further, we must draw a distinction between pressure on, and compression of, an organ. Many bodies are capable of sustaining a great amount of pressure without undergoing any sensible decrease in bulk. By compression must be understood that a substance occupies less space from the application of external force, as when we squeeze a sponge, or compress a bladder filled with air. Fluids generally are not absolutely incompressible, yet it requires the weight of one atmosphere, or 15 lb. on the square inch, to produce a diminution equal to $\frac{1}{20000}$th part of the whole. Now, this is so exceedingly small a change upon a mass equal in bulk to the brain as not to be appreciable to our senses. Besides, the pressure on the internal surface of the blood-vessels never exceeds 10 or 12 lb. on the square inch during the most violent exertion; so that, under no possible circumstances can the contents of the cranium be diminished even the $\frac{1}{20000}$th part. When the brain is taken out of the cranium, it may, like a sponge, be compressed by squeezing fluid out of the blood-vessels; but during life, surrounded as it is by unyielding walls, this is impossible. For let us, with Abercrombie, say that the whole quantity of blood circulating within the cranium is equal to ten,—that is, five in the veins, and five in the arteries; if one of these be increased to six, the other must be diminished to four, so that the same amount, ten, shall always be preserved. It follows, that when fluids are effused, blood extravasated, or tumours grow within the cranium, a corresponding amount of fluid must be pressed out, or of brain absorbed, from the physical impossibility of the cranium holding more matter. At the same time, it must be evident that an increased or diminished amount of pressure may be exerted *on* the brain proportioned to the power of the heart's contraction, the effect of which will be, not to alter the amount of fluids within the cranium, but to cause, using the words of Abercrombie, "a change of circulation" there.

Dr Kellie performed numerous experiments on cats and dogs in order to elucidate this subject. Some of these animals were bled to death by opening the carotid or femoral arteries, others by opening the jugular veins. In some the carotids were first tied, to diminish the quantity of blood sent to the brain, and the jugulars were then opened, with the view of emptying the vessels of the brain to the greatest possible extent; while in others the jugulars were first secured, to prevent as much as possible the return of the blood from the brain, and one of the carotids was then opened. He inferred, from the whole inquiry, which was conducted with extreme care,—"That we cannot, in fact, lessen to any considerable extent the quantity of blood within the cranium by arteriotomy or venesection; and that when, by profuse hæmorrhages destructive of life, we do succeed in draining the vessels within the cranium of any sensible portion of red blood, there is commonly found an equivalent to this spoliation in the increased circulation or effusion of serum, serving to maintain the plenitude of the cranium."

Dr Kellie made other experiments upon the effects of position immediately after death from strangulation or hanging. He also removed a portion of the unyielding walls of the cranium in some animals by means of trephine, and then bled them to death; and the differences between the appearances of the brain in these cases, and in those where the cranium was entire, were very great. One of the most remarkable of these differences was its shrunk appearance in those animals in which a portion of the skull was removed, and the air allowed to gravitate upon its inner surface. He says,—"The brain was sensibly depressed below the cranium, and a space left, which was found capable of containing a teaspoonful of water."

It results from these inquiries that there must always be the same amount of fluids within the cranium so long as it is uninjured. In morbid conditions these fluids may be blood, serum, or pus; but in health, as blood is almost the only fluid present (the cerebro-spinal fluid being very trifling), its quantity can undergo only very slight alterations. There are many circumstances, however, which occasion local congestions in the brain, and consequently unequal pressure on its structure, in which case another portion of its substance must contain less blood, so that the amount of the whole, as to quantity, is always preserved. These circumstances are mental emotions, hæmorrhages, effusions of serum, and morbid growths. Such congestions, or local hyperhemias, in themselves constitute morbid conditions; and nature has to a great extent provided against their occurrence under ordinary circumstances, by the tortuosity of the arteries and the cerebro-spinal fluid, described by Magendie.

Dr Burrows has brought forward several observations and experiments, which he considers opposed to the theory

now advocated. His facts are perfectly correct. We have repeated his experiments on rabbits, and can confirm his descriptions. It is the inferences he draws from them that are erroneous. For the paleness which results from hæmorrhage, and the difference observable in the colour of the brain when animals immediately after death are suspended by their ears or by their heels, is explicable by the diminished number of coloured blood particles in the one case, and by their gravitation downwards in the other. That the amount of fluid within the cranium was in no way affected, is proved by the plump appearance of the brains figured by Dr Burrows, and the total absence of that shrunken appearance so well described by Dr Kellie. Neither does our observation of what occurs in asphyxia or apnœa oppose the doctrine in question, as Dr Burrows imagines, but rather confirms it.

On the whole, whether we adopt the terms of local congestion, of change of circulation within the cranium, or of unequal pressure, our explanation of the *pathological* phenomena may be made equally correct, because each of these modes of expression implies pretty much the same thing. But if we imagine that venesection will enable us to diminish the amount of blood in the cerebral vessels, the theory points out that this is impossible, and that the effects of bleeding are explained by the influence produced on the heart, the altered pressure on the brain exercised by its diminished contractions, and the change of circulation within the cranium thereby occasioned.

2. *All the functions of the nervous system may be increased, perverted, or destroyed, according to the degree of stimulus or disease operating on its various parts.*—Thus, as a general rule, it may be said that a slight stimulus produces increased or perverted action, whilst the same stimulus, long continued or much augmented, causes loss of function. All the various stimuli, whether mechanical, chemical, electrical, or psychical, produce the same effects, and in different degrees. Circumstances influencing the heart's action, stimulating drinks or food, act in a like manner. Thus, if we take the effects of alcoholic drink for the purpose of illustration, we observe that, as regards combined movements, a slight amount causes increased vigour and activity in the muscular system. As the stimulus augments in intensity, we see irregular movements occasioned, staggering, and loss of control over the limbs. Lastly, when the stimulus is excessive, there is complete inability to move, and the power of doing so is temporarily annihilated. With regard to sensibility and sensation, we observe cephalalgia, tingling, and heat of skin, *tinnitus aurium*, confusion of vision, *muscæ volitantes*, double sight, and lastly, complete insensibility and coma. As regards intelligence, we observe at first rapid flow of ideas, then confusion of mind, delirium, and, lastly, sopor and perfect unconsciousness. In the same manner, pressure, mechanical irritation, and the various organic diseases, produce augmented, perverted, or diminished function, according to the intensity of the stimulus applied or amount of structure destroyed.

Then it has been shown that excess or diminution of stimulus, too much or too little blood, very violent or very weak cardiac contractions, and plethora or extreme exhaustion, will, so far as the nervous functions are concerned, produce similar alterations of motion, sensation, and intelligence. Excessive hæmorrhage causes muscular weakness, convulsions, and loss of motor power, perversions of all the sensations, and lastly, unconsciousness from syncope. Hence the general strength of the frame cannot be judged of by the nervous symptoms, although the treatment of these will be altogether different, according as the individual is robust or weak, has a full or small pulse, &c. These similar effects on the nervous centres from apparently such opposite exciting causes, can only be explained by the peculiarity of the circulation previously noticed. A change of circulation within the cranium takes place, and whether arterial or venous congestion occurs, pressure on some portion of the organ is equally the result. The importance of paying attention to this point in the treatment must be obvious.

3. *The seat of the disease in the nervous system influences the nature of the phenomena or symptoms produced.*—As a general rule, it may be stated that disease or injury of one side of the encephalon especially influences the opposite side of the body. It is said that some very striking exceptions have occurred to this rule, but these at any rate are remarkably rare. Besides, it is probable that, inasmuch as extensive organic disease, if occurring slowly, may exist without producing symptoms, whilst it is certain most important symptoms may be occasioned without organic disease, even these few exceptional cases are really not opposed to the general law. Then, as a general rule, it may be said that diseases of the brain proper are more especially connected with perversion and alteration of the intelligence; whilst diseases of the cranial portion of the spinal cord and base of the cranium are more particularly evinced by alterations of sensation and motion. In the vertebral portion of the cord, the intensity of pain and of spasm, or want of conducting power, necessary to sensation and voluntary motion, indicates the amount to which the motor and sensitive fibres are affected. Further than this we can scarcely generalize with prudence.

The fatality of lesions affecting various parts of the nervous centres varies greatly. Thus the hemispheres may be extensively diseased, often without injury to life, or even permanent alteration of function. Convulsions and paralysis are the common results of disease of the ganglia in the cranial portion of the cord. The same results from lesion of the *pons Varolii*. But if the *medulla oblongata*, where the eighth pair originates, be affected, or injury to this centre itself occur, it is almost always immediately fatal.

4. *The rapidity or slowness with which the lesion occurs influences the phenomena or symptoms produced.*—It may be said, as a general rule, that a small lesion—for instance, a small hæmorrhagic extravasation—occurring suddenly, and with force, produces, even in the same situation, more violent effects than a very extensive organic disease which comes on slowly. This, however, will depend much upon the seat of the lesion. Very extraordinary cases are on record where large portions of the nervous centres have been much disorganized without producing anything like such violent symptoms as have been occasioned at other times by a small extravasation in the same place. Here, again, the nature of the circulation within the cranium offers the only explanation, for the encephalon must undergo a certain amount of pressure, if no time be allowed for it to adapt itself to a foreign body; whereas any lesion coming on slowly enables the amount of blood in the vessels to be diminished according to circumstances, whereby pressure is avoided.

5. *The various lesions and injuries of the nervous system produce phenomena similar in kind.*—The injuries which may be inflicted on the nervous system, as well as the morbid appearances discovered after death, are various. For instance, there may be an extravasation of blood, exudation of lymph, a softening, a cancerous tumour, or tubercular deposit, and yet they give rise to the same nervous phenomena, and are modified only by the circumstances formerly mentioned, of degree, seat, suddenness, &c. Certain nervous phenomena also are of a paroxysmal character, whilst the lesions supposed to occasion them are stationary or slowly increasing. It follows that the effects cannot be ascribed to the nature of the lesions, but to something which they all have in common; and this apparently may consist of—1*st*, Pressure, with or without organic

change; 2*d*, More or less destruction or disorganization of nervous texture. Further, when we consider that the same nervous symptoms arise from irregularities in the circulation; from increased as well as diminished action; sometimes when no appreciable change is found, as well as when disorganization has occurred; the theory of local congestions to explain functional alterations of the nervous centres seems the most consistent with known facts. That such local congestions do frequently occur during life without leaving traces detectable after death, is certain; whilst the occurrence of molecular changes, or other hypothetical conditions which have been supposed to exist, have never yet been shown to take place under any circumstances.

SPECIAL PATHOLOGY OF THE NERVOUS SYSTEM.

The special disorders of the nervous system may be classified into—1*st*, Cerebral; 2*d*, Spinal; 3d, Cerebro-spinal; 4*th*, Neural; and 5*th*, Neuro-spinal; according as the brain, spinal cord, or nerves are affected alone, or in combination. Aberrations of intellect always depend on cerebral disturbance, while perversions of motion and sensibility, if extensive, indicate spinal, and if local, neural disorder. Thus, insanity and apoplexy are cerebral; tetanus and chorea, spinal; epilepsy and catalepsy are cerebro-spinal; neuralgia and local paralysis are neural; and all combined spasms, dependent on diastaltic or reflex actions, are neuro-spinal. The following is an enumeration of nervous disorders, with the meanings that ought to be attached to them.

Classification of Diseases of Innervation.

I. *Cerebral Disorders, in which the cerebral lobes (or brain proper) are affected:—*

INSANITY, or mental aberration in its various forms, including *delirium*.

HEADACHE and other uneasy sensations within the cranium, such as lightness, heaviness, vertigo, &c. &c.

APOPLEXY.—Sudden loss of consciousness and of voluntary motion, commencing in the brain. The absence of consciousness necessarily involves that of sensation. The same condition as regards nervous phenomena exists in *syncope* and *asphyxia*, but the first of these commences in the heart, and the second in the lungs. Allied to apoplexy is coma or stupor, arising from various causes affecting the brain, such as pressure, or poisonous agents like alcohol, chloroform, opium, &c. &c.

TRANCE, or prolonged somnolence, either with or without perversion of sensation or motion. To this state is allied *ecstasy*, or unconsciousness with mental excitement.

IRREGULAR MOTIONS, SPASMS, &c., originating in excited or diminished voluntary power, as in certain cases of *dominant ideas, somnambulism, saltatory movements, tremors*, &c.; or, on the other hand, *incapability of movement* from langour, surprise, mental agitation, &c. &c.

II. *Spinal Disorders, in which the cranial and vertebral portions of the spinal cord are affected:—*

SPINAL IRRITATION.—Pain in the spinal column, induced or increased by pressure or percussion, often associated with a variety of neuralgic, convulsive, spasmodic, or paralytic disorders affecting in different cases all the organs and viscera of the body, and so giving rise to an endless number of morbid states.

TETANUS.—Tonic contraction of the voluntary muscles. *Trismus*, if confined to the muscles of the jaw; *Opisthotonos*, if affecting the muscles of the back, so as to draw the body backwards; *Emprosthotonos*, if affecting the muscles of the neck and abdomen, so as to draw the body forwards; and *Pleurosthotonos*, if affecting the muscles of the body laterally, so as to draw the body sideways.

CHOREA.—Irregular action of the voluntary muscles, when stimulated by the will.

HYSTERIA.—Any kind of perverted nervous function, connected with uterine derangement. Nothing can be more vague than this term.

HYDROPHOBIA.—Spasms of the muscles of the pharnyx and chest, with difficulty in drinking and dread of fluids.

SPASMS AND CONVULSIONS.—Tonic and clonic contractions of the muscles of every kind and degree, not included in the above, originating in the cord (centric spinal diseases —Marshall Hall).

HEMIPLEGIA.—Paralysis of a lateral half of the body, generally dependent on disorders of the cranial portion of the spinal cord above the decussation in the *medulla oblongata*.

PARAPLEGIA.—Paralysis on both sides of the body, generally the lower half, in consequence of disorder of the vertebral portion of the spinal cord, below the decussation in the *medulla oblongata*.

III. *Cerebro-Spinal Disorders, in which both cerebral lobes and spinal cord are affected:—*

EPILEPSY.—Loss of consciousness with spasms or convulsions occurring in paroxysms. *Apoplexy with convulsion or paralysis* is also cerebro-spinal.

CATALEPSY.—Loss of consciousness with peculiar rigidity of muscles, so that when the body or a limb is placed in any position it becomes fixed.

ECLAMPSIA.—Tonic spasms with loss of consciousness in infants. The acute epilepsy of some writers.

IV. *Neural Disorders, in which the nerves are affected during their course or at their extremities:—*

NEURALGIA.—Pain in the course of a nerve, although in fact all kind of pain whatever is owing to irritation of the nerves. Thus the sympathetic system of nerves and its ganglia, though ordinarily giving rise to no sensation, may occasionally do so, as in *angina pectoris, colic, irritable testicle and uterus*, and in other agonizing sensations, referred to various organs.

IRRITATION OF THE NERVES OF SPECIAL SENSE.—Of the optic, causing *flashes of light, ocular spectra, muscæ volitantes*, &c.; of the auditory, causing *tinnitus aurium*; of the olfactory, causing unusual *sensitiveness to odour*; and of the gustatory, causing *perverted tastes* in the mouth. Itching, formication, and other sensations referable to the peripheral nerves, also belong to this class.

IRRITATION OF SPECIAL NERVES OF MOTION, as in local spasms of one or more muscles, or of the hollow viscera.

LOCAL PARALYSIS.—Loss of motion or sensibility in a limited part of the body, or confined to a special sense, as in *lead palsy*, or in *amaurosis, cophosis, anosmia, ageustia*, and *anæsthesia*.

V. *Neuro-Spinal Disorders, in which both the nerves and spinal cord are affected.*

DIASTALTIC OR REFLEX ACTIONS.—To this class belong all those diseases depending on irritation of the extremity of a sensitive nerve, acting *through* the cord and motor nerves on the muscular system, and producing a variety of spasmodic disorders, local or general, far too numerous to mention,—which can only be understood by a thorough knowledge of the physiology of the diastaltic or excito-motory system of nerves.

All these disorders may be the result of structural disease of the nervous system, or of what is called *functional derangement*, understanding by this a disease which, even when it causes death, leaves no trace of altered structure detectable with the aid of the microscope. Thus, tetanic rigidity may depend on a spinal arachnitis, as well as on

the irritation from a wound or poisoning by strychnine; and delirium and coma may be caused by cerebral meningitis, as well as by moral insanity, starvation, or poisoning by chloroform or opium. Whether in these cases there be in fact only one cause common to the whole, it is difficult to say; certainly it cannot be demonstrated. It might be contended that in every instance there is a certain amount of congestion producing unaccustomed pressure, or that a peculiar state of nutrition of the part is momentarily produced here or there in the nervous mass. But as neither theory appears to us applicable to all cases, we shall consider the pathological causes of nervous disorders as of four kinds,—1*st*, Congestive; 2*d*, Structural; 3*d*, Diastaltic; 4*th*, Toxic.

1. *Congestive Derangements of the Nervous System.*—The peculiar nature of the circulation within the cranium and vertebral canal has been previously pointed out, and we have seen that, although well defended under ordinary circumstances against any mischievous change, still, when such change does occur, it operates in a peculiar manner. In other words, so long as the bones are capable of resisting atmospheric pressure, although the amount of fluid within these cavities cannot change as a whole, yet the distribution of that amount may vary infinitely. Thus, by its being accumulated sometimes in the arteries, at other times in the veins, or now in one place and then in another, unaccustomed pressure may be exercised on different parts of the nervous centres. This, according to its amount, may either irritate or suspend the functions of the parts; a fact proved by direct experiment, as well as by innumerable instances where depression of bone has caused nervous phenomena which have disappeared on removal of the exciting cause. That congestion does frequently occur in the brain and spinal cord there can be no doubt, although it cannot always be demonstrated after death. The tonic contraction of the arteries is alone sufficient to empty them of their contents, and turgidity of the veins may or may not remain according to the symptoms immediately preceding death, and the position in which the body is placed. But it is observable that those causes which excite or diminish the action of the heart and general powers of the body are at the same time those which induce nervous disturbance, as well as occasion a change of circulation in the cerebro-spinal centres—such as the emotions and passions, plethora and anæmia, unaccustomed stimuli, uterine derangement, &c.

It is only by this theory that we can understand how such various results occasionally occur from apparently the same cause, and again how what appear to be different causes produce similar effects. Thus, violent anger, or an unaccustomed stimulus may, in a healthy person, induce a flushed countenance, increased action of the heart, a bounding pulse, and sudden loss of consciousness. Again, fear or exhaustion may occasion a pallid face, depressed or scarcely perceptible heart action, feeble pulse, and also loss of consciousness. In the first case, or *coma*, there is an accumulation of blood in the arteries and arterial capillaries, and a corresponding compression of the veins; in the second case, or *syncope*, there is distension of the veins and venous capillaries, with proportionate diminution of the calibre of the arteries. In either case, owing to the peculiarity of the circulation within the cranium, pressure is exerted on the brain. Hence syncope differs from coma only in the extreme feebleness of the heart's action,—the cause, producing loss of consciousness, sensation, and voluntary motion, being the same in both. Indeed it is sometimes difficult to distinguish these states from each other; and that they have frequently been confounded, does not admit of doubt.

In the same manner, partial congestion from either cause may occur in one hemisphere, or part of a hemisphere, in the brain, or in any particular portion or segment of the spinal cord. The pressure so occasioned may irritate and excite function, or may paralyse or suspend it; nay, it may so operate as to suspend the function of one part of the nervous system, while it exalts that of another. Thus all the phenomena of epilepsy are eminently congestive, the individual frequently enjoying the most perfect health in the intervals of the attack, although the effects are for the time terrible, causing such pressure that, while the cerebral functions are for the time annihilated, the spinal ones are violently excited. In the same manner are explained all the varied phenomena of hysteria and spinal irritation, for inasmuch as the spinal cord furnishes, directly or indirectly, nerves to every organ of the body, so congestion of this or that portion of it may increase, pervert, or diminish the functions of the nerves it gives off, and the organs which they supply. Congestion, therefore, we conceive to be the chief cause of functional nervous disorders originating in the great cerebro-spinal centre.

2. *Structural Derangements of the Nervous System.*—The various parts of the nervous system, being furnished with blood-vessels, are subject to most of the diseases of nutrition. The brain and spinal cord are especially liable to those lesions which produce effusion, extravasation, exudation, morbid growths, and degenerations of texture. The effects these occasion are identically the same in kind as those caused by simple pressure, or from the other circumstances to be referred to. In their mode of onset, however, they exhibit a difference. Thus, as a general rule, hæmorrhage is indicated by suddenness of attack, acute exudations, by local pain, with fever, chronic exudations and tumours, by gradual perversion of the mental, sensitive, and motor functions in various ways and degrees, according to the part affected. Intelligence suffers in proportion to the extent and nearness of the disease to the hemispherical ganglion, and motion according as the cerebral and vertebral portions of the spinal cord are influenced. Occasionally, after more or less impairment of intellect, sudden paralysis appears; a result attributable to the rupture or deliquescence of tubes which have been already softened, but not sufficiently so to interrupt their power as conductors of the nervous force. Instances, indeed, have been recorded where complete destruction of one half of the brain, or of the whole thickness of the spinal cord, is said to have occurred, in which no paralysis or other symptom has been caused; but it is certain that numerous tubes in such cases were intact during life, and capable of transmitting impressions.

3. *Diastaltic or Reflex Derangements of the Nervous System.*—We have previously seen that recent researches render it probable that the actions hitherto denominated *reflex* are in fact direct; only that the impression which is conveyed commences in the circumference of the body, instead of in the nervous centres. There is every reason to believe that such impressions pass *through* the cord by means of conducting nerve fibres, which cross from one side of that organ to the other, and that histology will yet demonstrate that all these apparently confused actions are dependent on the existence of certain uniform conducting media. Indeed, already we can judge with tolerable exactitude from the effects, what are the particular nerves and segments of the cord which are influenced during a variety of actions; and notwithstanding the immense difficulties of the inquiry, we have every hope that the period is not distant when the diagnosis of many more reflex acts will also be rendered certain. The principle involved in all these acts is, that the irritation which produces them is to be sought for in the nervous extremities rather than in lesions of the centres; and the great importance of this principle in pathology and in practice cannot be too highly estimated, although, for the numerous details which illus-

trate it, we must refer to a previous part of this article, and especially to the works of Dr Marshall Hall. We would point to traumatic tetanus, and to the convulsions resulting from teething and gastric derangements in children, as good examples of diastaltic functional disorders. Numerous symptoms which accompany organic changes belong to the same category. In other words, the structural lesion constitutes the irritant, or cause, while the effect is functional.

4. *Toxic Derangements of the Nervous System.*—The influence exercised by certain drugs is of a kind which causes a close resemblance to various diseases of the nervous system. These influences, if carried to excess, are toxic, and dangerous to life; if employed moderately, and with caution, they constitute the basis of our therapeutic knowledge in a vast variety of diseases. Why one drug should possess one power, and another a different one; or why some should influence the brain, and others the spinal cord or nerves, we are ignorant. Such facts are as much ultimate facts in therapeutics as are the separate endowments of contractility and sensibility in physiology. As pathological causes of functional disorders of the nervous system, their power is undoubted. By their means the five classes of nervous disorders may be occasioned in different ways, producing altogether distinct and peculiar effects. Thus—

Toxic Cerebral Derangements are occasioned by opium and most of the pure narcotics, which first excite and then depress or destroy the mental faculties. According to Flourens, opium acts on the cerebral lobes, while belladonna operates on the *corpora quadrigemina*. The first causes contraction, and the last dilatation of the pupils. *Tea* and *coffee* are pure exciters of the cerebral functions, and cause sleeplessness. *Alcoholic drinks*, *æther*, *chloroform*, and similar stimulants, first excite and then suspend the mental faculties, like opium. The modern practice of depriving persons of consciousness, in order for a time to destroy sensation, has been very much misunderstood in consequence of such remedies having been erroneously and unscientifically denominated anæsthetics. The fact is, they in no way influence local sensibility, or the sense of touch. Their action is altogether cerebral; and hence the danger which has frequently attended their action.

Toxic Spinal Derangements.—*Strychnine* acts especially as an exciter of the motor filaments of the spinal cord, causing tonic muscular contractions, as in tetanus from spinal arachnitis, or from the diastaltic action of a wound. *Woorari* produces exactly an opposite effect, causing paralysis and resolution of the same parts. *Conium* paralyses the motor and sensitive spinal nerves, producing paraplegia, commencing at the feet, and creeping upwards. *Picrotoxine*, according to Dr Mortimer Glover, causes the animal to stagger backwards, as in the experiments of Magendie on the *crura cerebelli*.

Toxic Cerebro-Spinal Derangements.—Of these, the poisonous effects of hydrocyanic acid offer a good example. All the animals we have seen killed by this agent utter a scream, lose their consciousness, and are convulsed. These are the symptoms of epilepsy. *Cold* is at first an exciter of the spinal functions, and is a strong stimulant to diastaltic activity, but if long continued, produces drowsiness and stupor.

Toxic Neural and Neuro-Spinal Derangements are especially occasioned by the action of certain metallic poisons, such as *mercury*, which occasions irregular muscular action, with weakness; and *lead*, which causes numbness and palsy, most common in the hands. On the other hand, *cantharides* stimulates the contractions of the neck of the urinary bladder, and *secale Sornutum* those of the pregnant uterus. *Stramonium* acts as a sedative to the nerves of the bronchi; while *aconite* operates powerfully in paralysing the action of the heart.

DISEASES OF REPRODUCTION.

These consist in the various alterations which may occur in the different stages of the generative functions, and include,—1*st*, Diseases which arrest or modify ovulation; 2*d*, Diseases, nutritive or nervous, which impede fecundation, and occasion barrenness in the female, or impotence in the male; 3*d*, Diseases of the embryo, causing various kinds of monsters, from arrest or excess of development in one or more of its parts. This last subject is now generally studied under the name of *teratology* (τέρας, *monster*), and has in recent times become a very extensive one. Congenital malformations of the fœtus were formerly considered as indicative of some misfortune,—as the effect of witchcraft, or as offsprings of the evil spirit. They are now not only recognised to originate in natural derangements of embryonal development, but the laws which govern such derangements have to a great extent been determined. From these it has become evident that monstrosities are not the result of chance, but are always governed by alterations in the known processes which regulate reproduction, and the evolution of the ovum and its contents. Hence in this, as in every other disordered condition, the real source of the abnormality is to be sought for, not only in the investigation of that condition itself, but in the knowledge, first, of the healthy or physiological state; and secondly, of the manner in which it has become deranged. In all our inquiries, it must be apparent that disease is morbid physiology; and such is the aspect in which we have endeavoured to place it before the reader.

ON DEATH.

Death is the permanent cessation of those properties and functions which constitute life. In this wide sense, it must be apparent that the textures are continually dying, in the same manner that they are continually being generated. What we have described as the fourth stage of nutrition essentially consists in the removal of the particles of the body which have been worn out,—fulfilled their functions, and died. Thus, death is molecular, cellular, fibrous, or tubular, in proportion as these various organic elements become degenerated, and disappear to make way for others which enjoy activity or life, and in their turn die, enter into new chemical combinations, and are excreted like their predecessors. In the more common acceptation of the term, however, death may be considered as *partial* or *general*. Partial death of the animal body is caused by those diseases or injuries which produce mortification, and ulceration in soft, and necrosis and caries in the hard parts, to a greater or less extent. Of this we have already spoken, and therefore need only treat of general death of the system. This has been variously considered as *natural* or *unnatural;* by the former meaning death from old age or gradual decay, and by the latter, death from diseases or violence. In this latter case, death may be gradual or sudden, and be induced by a great variety of agents. It may be said, however, that all the modes of death are reducible to three, viz.,—1*st*, Death by syncope,—that is, beginning at the heart; 2*d*, Death by asphyxia, beginning at the lungs; and 3*d*, Death by coma, beginning at the brain.

Death by Syncope.—All causes which arrest the action of the heart occasion stoppage of the circulation; a circumstance which interferes with the due performance of the vital functions; and death is the consequence. It may occur through the nervous system, through feebleness of the muscular walls of the heart itself, or through loss of blood. As examples of the first method of causing syncope, may be cited concussion, or all sudden shocks to the system,—as from violent blows or injuries, extensive lesions, violent mental emotions, a stroke of lightning, exposure to the sun

(or *coup de soleil*), and certain poisons which, acting especially on nerves going to the heart, paralyse its rhythmical motions, as aconite, digitalis, &c. Syncope from feebleness of the muscular walls is illustrated by the effects of long-continued violent exertion, starvation, and disease of its textures, especially that now recognised as fatty degeneration, one of the most common causes of sudden death. Lastly, excessive loss of blood, whether from direct external injury to a large vessel, sudden bursting of an internal vascular tumour or aneurism, disease of the coats of an artery or vein, leading to sudden or to long-continued loss of blood, are among the frequent causes of syncope.

Death by Asphyxia.—This is produced by all causes which interrupt the act of respiration, or the access of oxygen, so necessary for carrying on the nutritive functions, and has been previously referred to. It is now ascertained that mere obstruction of air does not immediately act upon the heart, which not only continues to contract for a time, but even sends venous blood through the arterial system. From the numerous investigations which have been made to determine in what manner the vital actions are arrested in asphyxia, it would appear that at first non-aërated or venous blood passes freely through the lungs to the heart, from whence it goes to all parts of the system. It operates on the brain, however, as a poison, rapidly suspending the sensorial functions. The capillaries of the lung next refuse to transmit non-oxygenated blood, in consequence of which it is not returned to the right side of the heart, and thus the vital actions cease. These effects are produced with greater or less rapidity, according as the occlusion of air is more perfect, as in cases of drowning and strangulation. In diseases of the heart and lungs, the same results are produced more slowly. The only poisons which operate upon the lungs directly causing asphyxia are certain so-called poisonous gases, such as carbonic acid gas, the fatal effects of which, however, are not so much to be ascribed to any noxious properties it possesses, as to the absence of free oxygen.

Death by Coma.—This is caused by all circumstances which suspend the sensorial functions by first operating on the brain. We observe it produced from the long-continued action of cold, from the influence of narcotic poisons, especially opium and chloroform, and from such injuries of the brain, from without or within, as are not necessarily connected with shock. If a violent blow be given to the head of an animal, it may be observed to suffer from shock or syncope; the heart flutters, and the pulse is weak. But if it recover from this, the heart's action may be restored, whilst sensation is suspended, and it dies comatose. If shock be avoided during the operation, the brain of an animal may be removed, producing coma or stupefaction, which will ultimately kill, although for some time the circulation and respiration continue. In apoplexies, fevers, and other diseases, similar effects are observable.

It should not be overlooked that death in many cases is produced by a conjunction, or by the rapidly-following results of two or all three of these modes. Thus chloroform may kill from the conjoined stupefying action on the brain, as well as from difficulty of respiration. Coma, from pressure on the brain, may, by influencing the *medulla oblongata*, affect the pneumo-gastric nerves, which send branches to the heart and lungs. In this case, death is the most rapid—occurring in all three ways. Hence the humane effort of the hangman not only to produce strangulation, but by dislocation of the bones of the neck to crush the upper part of the spinal cord.

The preceding observations evidently indicate that, in our endeavours to produce recovery from either of these states, much will depend upon the correct information we derive as to the causes producing them. In syncope, our efforts will be directed to restore the action of the heart by stimuli, a proper position, checking hæmorrhage, &c.; in asphyxia, to reproduce respiration; and in coma, to remove any cause which, by pressure on the brain from without or within, interferes with its functions. (J. H. B—T.)

PIACENZA (anc. *Placentia*, Fr. *Plaisance*), a town of Italy, capital of a province of the same name in the duchy of Parma, stands about half a mile from the S. bank of the Po, 2 miles below its confluence with the Trebbia, 37 miles W.N.W. of Parma, and about as far S.E. of Milan. It is of an oblong form, surrounded by ancient walls and ditches, and defended by a citadel which is garrisoned, according to a provision of the Congress of Vienna, with Austrian troops. The streets are in general broad and straight, but dull and deserted; and the grass that grows in many of the thoroughfares shows that the town is much too large for its present population. The most busy part is near the principal square, called *Piazza de Cavalli*, from the equestrian statues in bronze of Allessandro and Ranuccio Farnese, dukes of Parma. In this square is the ducal palace and the town-house, an edifice built by the merchants of Piacenza in 1281, in a mixed style of architecture, and considered one of the finest buildings of the kind of that century. The cathedral of Piacenza, consecrated in 1132, is a fine building in the ancient Lombard style. In the interior, which is adorned with massive pillars supporting wide-spreading arches, there are many fine paintings by various artists. Of the numerous other churches of Piacenza, many are very fine, both from their architecture and the paintings with which they are adorned. The Farnese palace, designed by Vignola, was once a most splendid edifice, but it is incomplete; and is now used for barracks. Among the other public buildings are the governor's house, the custom-house, and the court-house. Piacenza contains a college with a library of 30,000 volumes, an episcopal seminary, several schools, two theatres, a hospital, orphan asylums, and many other charitable institutions. It is the see of a bishop, and the seat of a court of appeal and inferior tribunals. The manufactures of the town consist of woollen and cotton cloth, silk, hosiery, hats, and earthenware. Some trade is carried on in cattle and agricultural produce. The ramparts are now partly used as a public walk, and from them may be obtained some fine views,—with the Alps and the Apennines in the distance; the city, with its magnificent buildings, in the foreground; and the broad stream of the Po appearing here and there, with its numerous willow-covered islands. The origin of the ancient *Placentia* is doubtful, being ascribed by some to the Gauls, and by others to the Etruscans. It is of no historical importance before 219 B.C., when it became a Roman colony. It remained faithful to Rome during the second Punic war, which was then raging, and resisted an attack of Hasdrubal. In the year 200 it was taken and plundered by the Gauls, but it soon recovered from this calamity. After the irruptions of the northern barbarians, Placentia was one of the first cities that recovered its prosperity; and it became in the tenth century a place of considerable commerce. It was for some time independent; but after being subject to several lords in succession, it came into the hands of the Visconti of Milan. In 1447 Piacenza revolted from the Milanese, but was retaken in the same year by Francesco Sforza. Under him and his successors it remained until Louis XII. of France took it. It was then retaken by Pope Julius II., and retained by the Papal See, till, along with Parma, of which duchy it has since formed a part, it was transferred to the Farnese family. Pop. 30,500.

PIANO-FORTE, a well-known modern instrument, in which the immediate sonorous bodies are wires of brass

and steel. It has completely usurped the place of the old harpsichord, upon which it is a great improvement. It has undergone many modifications, which are too numerous to be noticed here. The merit of its invention is disputed by the Italians and the Germans. Count G. R. Carli, in his works printed at Milan in 1784–1794, states (in vol. xiv., p. 405), that the piano-forte was invented in 1718, by Bartolommeo Cristofori of Padua, during his stay in Florence. The count speaks indignantly of the forgetfulness of the Italians regarding their own inventions:—"Della quale inventione ci siamo scordati a segno, che l'abbiam creduta una nuova cosa, allorchè ci venne dalla Germania e dall' Inghilterra, accogliendola come una singolare produzione di quelle felici regioni, destinate ad illuminarci con i lumi presi dagl' Italiani." On the other hand, the Germans assert that it was invented about the year 1717, by C. A. Schrœter, a German organist, and that it was afterwards improved by Silbermann, G. A. Stein, and others. To the Rev. William Mason, the English poet, is ascribed the important improvement of detaching the hammer entirely from the key, and giving to them only a momentary connection when the key is struck by the finger. The English makers have gained great repute by their excellent piano-fortes. Those of Broadwood are distinguished by a rich soft tone, well suited for accompanying the voice. Erard's possess a more powerful and brilliant tone, and are better suited for the public performer of piano-forte sonatas, concertos, &c. The horizontal piano-fortes are those most used, as being the best. The origin of the vertical piano-forte may be found in Père Mersenne's *Harmonicorum libri xii.*, 1652, folio; in which there is an engraving of a similarly formed instrument of an ancient date. We consider the modern extreme extension of the compass of the piano-forte, both grave and acute, as detrimental to the best effects of the instrument. (On this subject, and as to the true powers of the pianoforte, see the article MUSIC, vol. xv., pp. 740–741.) An Italian writer informs us, that in the beginning of the present century he had played upon many piano-fortes of a compass of *six octaves and a half*, made by Antonio Gherardi of Parma.

We quote the following interesting remarks by Mr Thalberg, which were printed in the reports by the juries of the Exhibition of 1851, pp. 326–329:—"To give an idea of the degree of perfection attained at the present day in the construction of the piano, we will describe one of the grand pianos in the Exhibition. This instrument is 8¼ feet in length, and 4½ feet in its greatest width; its frame is of enormous strength compared with the instruments of former times, being heavily braced with wood below the strings, having a complete system of metallic bracing above the strings firmly abutted, and consisting of longitudinal bars let into metal at each end, and having the curved side formed of a number of separate pieces glued together in a mould, to insure durability and fixedness of form. Its sounding-board extends to the frame on all sides, except the space left for the action. The strings are made entirely of steel, and of wire so thick that the tension necessary to bring them to the proper pitch produces an aggregate strain equal to at least 12 tons weight, while they are passed through studs drilled into the metal-wrest plank, thus giving the strings an upbearing position, which prevents the slightest displacement of the point of contact by any force of the hammers; and the system of placing the strings on the instrument, determined by accurate acoustic experiment, causes them to be struck by the hammer at that precise nodical point which produces the freest and clearest tone. The compass is extended to seven octaves from *A* to *A*. The action of this piano is described by Dr Lardner, in a work just published on Mechanics, as a beautiful example of complex leverage in the mechanism which connects the key and hammer. In this instrument the object is, to convey from the point where the fingers act upon the key to that at which the hammer acts upon the string, all the delicacy of action of the finger; so that the piano may participate to a certain extent in that sensibility of touch which is observable in the harp, and which is the consequence of the finger acting immediately on the string in that instrument, without the intervention of any other mechanism. The power of this instrument, depending on the quantity of matter brought into vibration; the resonance, or the perfection of that vibration, depending on the correct proportions of its parts; and the accuracy of intonation, depending on the nature of the bridging, the proportions of the strings, and their arrangement with regard to the blow of the hammer,—are all most admirable; while the action, depending on the peculiar mechanism employed, far surpasses everything else of the kind, for it enables the player to communicate to the strings all that the finest-formed and most skilful hand can express; and becomes as it were a part of himself, reflecting every shade of his feelings from the most powerful to the softest and most delicate sounds. This action is indeed so perfect, particularly in its power of delicate repetition, that if any note is missed in execution upon it, it is the fault of the player and not of the instrument. Many persons have a very meagre notion of the power of expression possessed by the piano-forte. The fact is, however, that it really possesses almost all those elements of expression which belong to any other instrument, and several which are peculiar to itself, from the circumstance of the various parts of music adapted to the instrument being brought out by the same hand and same feeling. An immense difference of volume of tone and of effect is produced by the manner of touching the keys and by the use of the pedals, especially upon an instrument of great power, fine quality of tone, and delicate mechanism in the action. The manufacture of the piano as a branch of trade is of very great importance, from the superior character of the principal workmen, and the vast numbers employed, directly and indirectly, in connection with it. In all the cities of the civilized world there are numerous makers of this instrument, with immense numbers of workmen; and in most secondary towns throughout Europe there are small makers; whilst the increase of the number of pianos, compared with the population, is every year more rapid, a circumstance which is not observed in regard to other musical instruments. This is corroborated by the fact, that some years ago piano-forte music constituted only a very modest portion of a music-seller's stock; whereas now it fills more than three-quarters of his shelves, and makes his chief business. The number of teachers is something wonderful; many are reduced ladies, who find in this exercise of their acquirements the most available means of support. Every professional pianist has often had occasion to exercise his kindly and generous feelings in recommending and assisting accomplished women, whose helpless families would otherwise have been utterly destitute. The social importance of the piano is, beyond all question, far greater than that of any other instrument of music. One of the most marked changes in the habits of society, as civilization advances, is with respect to the character of its amusements. Formerly nearly all such amusements were away from home and in public; now with the more educated portion of society the greater part is at home, and within the family circle; music on the piano contributing the principal portion of it. In the more fashionable circles of cities, private concerts increase year by year, and in them the piano is the principal feature. Many a man engaged in commercial and other active pursuits finds the chief charm of his drawing-room in the intellectual enjoyment afforded by the piano. In many parts of Europe this instrument is the greatest solace of the studious and solitary. Even steam and sailing vessels for

passengers on long voyages are now obliged, by the fixed habits of society, to be furnished with piano-fortes; thus transferring to the ocean itself something of the character of home enjoyments. By the use of the piano many who never visit the opera or concerts become thoroughly acquainted with the choicest dramatic and orchestral compositions. This influence of the piano is not confined to them, but extends to all classes; and while considerable towns have often no orchestras, families possess the best possible substitute, making them familiar with the finest compositions. The study of such compositions, and the application necessary for their proper execution, may be, and ought to be, made the means of greatly improving the general educational habits and tastes of piano students, and thus exerting an elevating influence, in addition to that refined and elegant pleasure which it directly dispenses." (G. F. G.)

PIANOSA, an island in the Mediterranean, belonging to Tuscany, lies about 10 miles S.S.W. of Elba, and nearly 40 from the nearest point of the mainland. It is 3 miles long by 2½ broad, and is about 10 miles in circuit. The surface is low; but it is fertile and well wooded, and is chiefly inhabited by fishermen. In the island are granite quarries, probably worked in the time of the Romans, when it was called *Planasia*. It was here that Postumus Agrippa was banished by Augustus, and afterwards put to death by order of Tiberius. Pianosa was annexed to Elba and granted to Napoleon after his first abdication.

PIAUHI, or PIAUHY, a province of Brazil, bounded on the N. by the Atlantic, E. by the provinces of Ceara and Pernambuco, S. by those of Bahia and Goyaz, and W. by that of Maranhao, lies between S. Lat. 2. 42. and 11. 20., W. Long. 40. 30. and 47. The length of the coast-line is little more than 60 miles; but the province stretches inland for about 400 miles, and has a very considerable breadth in the interior. Its area is 109,668 square miles. On the E. and S. frontiers it is bounded by mountain ranges; the Serra Habiapaba separating it from Ceara, and the Cordillera de Borborema from Pernambuco. From these mountains the country gradually slopes towards the bed of the Parnahiba, the only large river in the province, which it separates from that of Maranhao. The river Piauhi, from which the province derives its name, originates in the southern frontier, and, running northward through pasture lands, enters the Caninde, an affluent of the Parnahiba, 50 miles below Oeiras, the capital, after a course of 140 miles. There are no serras of any consequence, nor any large forests, in this province. It consists of vast grassy plains, little wooded, but in which numerous tall herbs attest the bounty of the sun. Originally the province was explored and subdued on account of its pastures, and not for the sake of slaves or from its possessing mines of the precious minerals or metals, for in these it appears to be deficient. Iron, lead, silver, and other minerals are found, but very little worked. Horses and cattle still form the chief riches of the country. It is to Piauhi that the neighbouring provinces of Pernambuco, Maranhao, Bahia, and Minas Geraes look chiefly for their supply of cattle. Piauhi occasionally suffers greatly from drought; but the evils consequent thereupon are much ameliorated by the presence of several trees which yield abundance of grateful and wholesome juices. The climate is warm and dry; and the soil, being generally flat and fertile, is well adapted for cultivation. Rice, tobacco, and sugar are raised near the rivers and lakes, where abundance of water can be obtained; and in the more arid regions millet, mandioc, and cotton are grown. The only seaport in the province is Parnahiba, on a branch of the river of the same name, where some trade is carried on in hides and cotton. Oeiras, the capital, stands on a small tributary of the Caninde, 320 miles S.S.E. of Maranhao. It is small, with broad but unpaved streets, and neat whitewashed houses, and contains several churches and schools. It is the seat of the provincial legislature, of the governor of Piauhi, and other officials. Some trade is carried on in cattle and agricultural produce. Pop. (with the surrounding district) 6000. Piauhi is divided into six *comarcas*. It has a provincial assembly of twenty-eight members, and appoints to the general legislature of Brazil one senator and two deputies. Pop. (1856) 150,400.

PIAZZA, a town of Sicily, in the province of Caltanisetta, stands on an isolated hill, 18 miles N. of Terranova, and as far E.S.E. of Caltanisetta. It is the see of a bishop; and contains a cathedral and many other churches, several convents, a school, hospital, &c. Woollen cloth and caps are manufactured; and some trade is carried on in grain, oil, fruits, &c. Pop. 13,000.

PIAZZETTA, GIOVANNI BATISTA, an Italian painter, was born at Venice in 1682. His first lessons in art were received from his father, a statuary in wood. But it was not until he had studied the works of Guercino at Bologna that his characteristic style was formed. In spite of a mannered and monotonous colouring and a hasty execution, his pictures there became notable for a strong contrast of light and shadow, and a boldness of relief. He produced pleasing altar-pieces; he succeeded admirably in several caricatures; and he was especially excellent in painting busts and heads. The consequence was, that he rose into high repute. Many followers gathered around him. Pitteri, Pelli, and Monaco engraved several of his pictures. He was also appointed director of the Academy of Painting in his native city, a post which he held till his death in 1754.

PIAZZI, GIUSEPPI. See ASTRONOMY, *History of*.

PICA. See MIRANDOLA.

PICARD, JEAN, an eminent French astronomer, was born at Flèche in 1620, and became priest and prior of Rillé in Anjou. His knowledge of astronomy early attracted notice. On the 25th of August 1645 he was employed, along with Gassendi, in observing the solar eclipse; in 1655 he was appointed to the astronomical chair in the College of France; and in 1666 he was selected by Colbert to assist in founding the Academy of Sciences. Picard, however, was destined to become still better known for his improvements in practical geometry. In 1667, along with Auzout, he was the first to apply a telescope to the quadrant in the measurement of angles. It was his good fortune, shortly afterwards, to introduce the modern method of determining the right ascension of the stars by employing a pendulum to note the instant of their meridional passages. He brought this list of improvements to a close in 1669, by making the first exact measurement of a degree of the meridian. So great indeed were his services to science, that by the time of his death in 1682 he was worthy of being considered the father of French astronomy. The principal works of Picard are *La Mesure de la Terre*, Paris, 1671; *Voyage d'Uranibourg*, Paris, 1680; *Observations Astronomiques faites en divers Endroits du Royaume*; *Observations faites à Baïonne, Bordeaux, et Royan pendant l'Année* 1680; and *La Connaissance des Temps*. There are also several contributions by him in the sixth and seventh volumes of the Memoirs of the Academy of Sciences. (See Delambre's *Histoire de l'Astronomie*, and his article "Jean Picard" in the *Biographie Universelle*.)

PICARD, *Louis-Benoit*, a celebrated French comic dramatist, was born in Paris in July 1769. Although educated for the law, he soon abandoned every pursuit to give himself up entirely to writing for the stage. His ready activity in this new profession was almost unparalleled. He brought into play a fertile brain, a happy skill in sketching manners, a lively wit, a great knowledge of scenic effect, and an abundant flow of diction. Prose comedies, poetical comedies, comic operas, were produced in rapid succession to delight the theatres. The business

of actor, which he undertook in 1797, and that of theatrical manager, which he began not long afterwards, did not withdraw him from the literature of the stage. He continued to write until he had produced more than seventy dramas. Death only put an end to his industry in 1828. The best, though still incomplete, collection of Picard's plays, was that published in 10 vols. 8vo, 1821–23. A supplementary volume, in 8vo, was issued in 1832. He was also the author of *Le Gil-Blas de la Révolution* and other novels.

PICARDS, a religious sect which arose in Bohemia in the thirteenth century. (See ADAMITES.)

PICARDY, an ancient province of France, was founded on the N. and E. by the Strait of Dover, and the provinces of Artois, Flanders, and Champagne; S. by that of Isle of France; and W. by that of Normandy. It is now included in the departments of Aisne, Ardennes, Oise, Pas-de-Calais, and Somme.

PICCINI, NICOLO, a celebrated composer of music, was born in 1728, at Bari, in the kingdom of Naples. In May 1742 he was placed under Leo, in th conservatory of Sant' Onofrio, at Naples. Leo dying soon afterwards, his successor Durante took charge of Piccini as a favourite pupil. In 1754 Piccini left the conservatory, and began to compose operas for the Teatro Fiorentino. His success was so great that he was engaged to write for the San Carlo theatre; and in 1758 was called to Rome to compose the music of *Alessandro nelle Indie*, an opera which he re-composed in 1775 at Naples. He revisited Rome in 1760, and composed *La Cecchina, ossia la buona figliuola*, which was received with rapture, and was soon after heard in every theatre of Italy, to the exclusion of all other operas. In 1756 he married Vincenza Sibilla, formerly one of his pupils in singing. She bore him several children. Induced by promises held out to him by the Neapolitan ambassador at Paris, Piccini went thither at the close of 1776. Not knowing a word of French, he had infinite difficulty in setting to music the opera of *Roland*; and, to add to his annoyances, Gluck raised a violent cabal against him, and endeavoured to prevent *Roland* from being performed. Nevertheless, *Roland* was performed in 1778, and received with great applause. He then composed *Phaon*, *Atys*, *Iphigénie en Tauride*, and *Adèle de Ponthieu*. Sacchini's arrival in Paris led to the forming of another party against Piccini. The court ordered a grand opera from each of the composers. Piccini produced his *Didon*, and Sacchini his *Chimène*. Both were admired, but especially the *Didon*, which is Piccini's best French opera. In 1784 he was appointed singing-master in the royal school of music and declamation. He wrote fifteen operas for the French theatre; but at last, suffering from injustice and neglect, and from the loss of a large sum due to him by the banker La Borde, he left France with his family in July 1791, and reached Naples in September. There he composed, in 1792, his oratorio of *Jonathan*, the best of his serious works. The marriage of one of his daughters with a young Frenchman settled at Naples exposed him to persecution. Two of his old pupils denounced him as a Jacobin, and the minister ordered him to remain shut up in his house. At the same time, he learned that everything he had left at Paris, including his Scores, was lost. He remained for four years in neglect and poverty. His friends in Paris encouraged him to return thither; and accordingly he arrived there on 3d December 1798. The French government granted him 7400 francs a year, and apartments in the Hôtel d'Angivilliers, where part of his family soon rejoined him. Through the good offices of the First Consul Bonaparte, he was appointed inspector of the Conservatory of Music; but the boon arrived too late—he was dying. He expired at Passy on the 7th May 1800, and was interred in the common burying-ground. Only those who have studied the operas of Piccini, Sacchini, Gluck, and Mozart, know how much the latter composer was indebted to the other three. The musical wars carried on in Paris by the partizans of Gluck, Piccini, and Sacchini, are narrated in various publications, such as Marmontel's *Memoires*, &c.; Ginguené's *Lettres*, &c., 1783, 8vo; and his *Notice sur la Vie et les Ouvrages de Piccini*, 1800, 8vo. Piccini composed seventy-nine operas, comic and serious; several oratorios, of which the best are *Jonathan* and *Sara*; a number of pieces of church music; romances and canzonets, published at Paris in Desormery and Bouffet's *Journal de Chant et de Piano*, 1799. (G. F. G.)

PICCOLOMINI, ALESSANDRO, Archbishop of Patras, was a native of Siena, where he was born about the year 1508, being descended of an ancient and illustrious family, which came originally from Rome. He composed with success for the theatre; but he was more distinguished for his genius than for the purity of his manners and his regard to virtue. His charity was great, and chiefly exerted in relieving the necessities of men of letters. He left behind him a number of works in Italian, the most remarkable of which are,—various *Opere Dramatiche*, which laid the first foundation of his character as a writer; *Un Traité della Sphera*; *Una Theoria delle Planète*; a translation of Aristotle's *Art of Rhetoric and Poetry*, in 4to; and *Institutione Morale*, published at Venice, 1575, in 4to, translated into French by Pierre de Larivey, and printed at Paris, 1581, in 4to. These, with a variety of other works, prove his extensive knowledge in natural philosophy, mathematics, and theology. He was the first who made use of the Italian language in writing upon philosophical subjects. He died at Siena on the 12th of March 1578, at the age of seventy.

PICCOLOMINI, *Francesco*, of the same family with the preceding, was born in the year 1520, and taught philosophy with success for the space of twenty-two years, at Siena, Pérugia, and Padua. He afterwards retired to Siena, where he died in 1604, at the age of eighty-four. This city went into mourning on the occasion of his death. His works are,—*Some Commentaries upon Aristotle*, printed at Mayence, 1608, in 4to; and *Universa Philosophia de Moribus*, printed at Venice, 1583, in folio. The latter is his principal work. He laboured to revive the doctrines of Plato, and endeavoured also to imitate the manners of that philosopher. He had as his principal rival the famous Zabarella, whom he excelled in facility of expression and neatness of discourse, but to whom he was much inferior in point of argument.

PICENUM, an ancient province of Italy, was bounded on the N. by the Galli Senones, on the W. by the Umbrians and Sabines, on the S. by the Vestini, and on the E. by the Adriatic Sea. It was a country of romantic beauty. The line of the Apennines ran along the western frontier. A series of heights, shooting off from the eastern side of this central branch, and undulating gradually downwards to the sea-shore, occupied the entire district. Extensive forests waved on the ridges, fruitful orchards and olive-yards basked on the slopes, and fertilizing mountain streams meandered through the valleys. In that delightful region the Picentes seem, during the early periods of their recorded history, to have enjoyed considerable prosperity. They remained long in undisturbed tranquillity, while the neighbouring tribes were vainly struggling against the all-usurping ambition of Rome. That power condescended in 299 B.C. to enter into an alliance with them. Even when they were at length obliged, in 268 B.C., to bow before the resistless destinies of the Romans, they suffered little injury. It was not until the outbreak of the Social War, in 90 B.C., that the Picentes appear to have experienced the toils and calamities of a great struggle. Then they assumed an active and zealous part in the general revolt against Rome. Their capital city, Asculum, gave the signal of in-

surrection by assassinating the Roman proconsul. Their armies kept the Roman general Cn. Pompeius Strabo for a long time at bay. Nor when the tide of battle began to turn against them did their courage waver. They continued to fight until in 89 B.C. they were put down by sheer force. The history of Picenum after this period contains little else than an account of the frequent changing of boundaries of the country.

The most important towns of the Picentes were Ancona, on the sea-coast, and Auximum (*Osimo*), Asculum (*Ascoli*), and Hadria (*Atri*), in the interior.

PICERNO, a town of Naples, province of Basilicata, 8 miles W. of Potenza. It contains a church and a convent; and has manufactures of silk and woollen goods. Pop. 4000.

PICHEGRU, CHARLES, a famous general of the French republic, was the son of humble parents, and was born in 1761 at Arbois in Franche-Comté. His education was favourable for the development of his talents. He received his elementary instruction at the monastery of the Minims. After that he studied mathematics at the college of Brienne, the seminary which the young Napoleon Bonaparte was at that time attending. Then entering a regiment of artillery, he acquired, as he passed through the several gradations from a common soldier up to a serjeant-major, a practical knowledge of military tactics. Thus thoroughly trained, Pichegru only wanted some great opportunity to rise into notice. Accordingly, no sooner had the French revolution broken out, and the army of the Rhine received him within its ranks, than a career of distinction opened up before him. He rapidly rose by the several steps of promotion to the post of general of division. His growing fame then recommended him, in 1793, as a fit person for the chief command of the expedition. Undertaking the precarious task, he set himself to improve the adverse state of affairs. Discipline was enforced, a new system of tactics was introduced, and the self-confidence of the troops was restored. He led them on to the victory of Haguenau, the relief of Landau, and the capture of Lauterburg. Still greater was his success after he had been appointed in 1794 to the command of the army of the north. His firmness and decision soon turned the tide of success against the invaders of his country. The enemies fled before him at Cassel, Courtrai, and Menin, and left all West Flanders in his power. Bruges, Bois-le-Duc, and Nimeguen were compelled to open their gates to his advancing troops. The waters of the Wahl only checked his victorious career for a short time. Taking advantage of an intense frost which froze up the rivers, he crossed on the ice, pressed forward with forced marches, drove the retreating enemy beyond the Yesel, took possession of Amsterdam on the 16th January 1795, and thus effected the conquest of Holland. This was the close of Pichegru's military successes, and the remainder of his life was occupied in endeavouring to effect the restoration of the Bourbons. Appointed to the command of the army of the Rhine, he entered into negotiations with the Prince Condé for the purpose of overthrowing the republic. Having retired in 1796 from military life, and having been chosen in 1797 to be president of the Council of Five Hundred, he still continued to plot. A discovery, a trial, and a banishment to Cayenne did not divert him from his designs. Escaping from his prescribed place of exile, he repaired to England only to involve himself in a desperate conspiracy which was destined to end in his own ruin. In course of time he planned a scheme, along with George Cadoudal, for the destruction of the government of the First Consul; and in January 1804 repaired to Paris, like the other accomplices, to carry it into execution. The plot was discovered; his person was seized, and lodged in the Temple; and on the 6th April 1804 he was found strangled in his cell. For a long time afterwards it was supposed that Pichegru had been murdered by order of Napoleon. It is now, however, generally agreed that he had committed suicide. (For an account of the evidence belonging to the case, see FRANCE.)

PICKERING, a market-town of England, in the North Riding of Yorkshire, 26 miles N.N.E. of York, and 18 S.S.W. of Whitby. It is a long, straggling town; and contains a large old parish church with a tall spire, and an ancient castle. The Independents, Quakers, Swedenborgians, and Primitive and Wesleyan Methodists have places of worship here. The town has also a court-house, several schools, and a savings-bank. The manufacture of brooms is largely carried on, the materials being obtained from the surrounding moors. In the vicinity some Roman remains have been discovered. Pop. (1851) 2511.

PICO. See AZORES.

PICTOR, FABIUS. See FABIUS PICTOR.

PICTOU, a town of Nova Scotia, capital of the county of the same name, stands on the harbour of Pictou, about 3 miles from its entrance, and 72 miles N.E. of Halifax. It is well built of stone; and contains, besides other public buildings, an academy, library, and grammar-school. An extensive and increasing trade is carried on in coal, timber, and fish; the annual value of the exports being about L.100,000.

PICTS. See CALEDONIA, and SCOTLAND.

PICTURE. See PAINTING.

PICTURESQUE literally signifies that which is capable of, or fitted for, pictorial delineation. (For the various theories of the picturesque, see BEAUTY.)

PIEDIMONTE, a town of Naples, in the province of Terra di Lavoro, 21 miles S.W. of Campobasso. It stands in a lofty and commanding position, and is in general well-built. It is the seat of a bishop, and contains a feudal castle, and a palace belonging to the Duke of Laurenzana. There are numerous manufactories in the town, including cotton, paper, flour, fulling, and copper mills. The water-power for these mills is supplied by a torrent supposed to flow by a subterranean channel from Lake Matese. The inhabitants are largely employed in the cultivation of vines and olives in the neighbourhood; and the wine and oils produced are excellent, and contribute in a great degree to the support of the people. Pop. about 7000.

PIEDMONT, PRINCIPALITY OF (Ital. *Piemonte*, or *Pie di Monte*, meaning "foot of the mountain"), a district of the continental portion of the Sardinian States, now forming the divisions of Turin, Coni, Alessandria, Aosta, and Novara. On three sides it is inclosed by mountains; by the Alps on the N. and W., and by the Apennines on the S.; while towards the E. it stretches into the great plain of Lombardy. Its length from N. to S. is 120 miles, its breadth nearly 100; area 15,913 square miles. It is a distinct physical region shut in by the loftiest chains of the Alps and Apennines, and forming the upper part of the valley of the Po, to which it entirely belongs. The western and larger portion of Piedmont is mountainous, being occupied with branches and offsets from the Alps and Apennines, with numerous upland valleys among them; and from these high lands the ground gradually descends in beautifully-waving slopes to the rich level plains which occupy the east of the principality. The Po, which rises in this country, receives within its limits many tributaries. These, though few of them are navigable, are all of the highest importance to the country, as an extensive and skilful system of irrigation is carried on by their means. The soil is thus enabled to produce the richest crops. Wheat, maize, rice, and beans are the principal articles raised. Wine and fruits are also produced; and excellent timber is obtained from the forests. Besides agriculture, the people are largely employed in pastoral pursuits, and great numbers of cattle are reared. The corn produced in Piedmont is more than sufficient for the

wants of the people, and supplies also the adjacent country along the Mediterranean as far as Toulon. Some minerals are obtained in this country; the principal being iron, marble, copper, and argentiferous lead. Manufactures are actively carried on; hosiery, linen, woollen, and silken goods, brandy, glass, and iron, being the chief articles made here. Besides corn and cattle, silk, wine, wool, iron, &c., are exported. The Alpine valleys of Piedmont are celebrated as the country of the Waldenses, who have from time immemorial stood out against the corruptions of the Romish Church, notwithstanding the persecutions to which they have been exposed. They now enjoy toleration. With this exception, the people of Piedmont all profess the Roman Catholic religion. The population of the country is more than 3,000,000. (See SARDINIA.)

PIERIDES, a surname of the Muses, derived from Mount Pieris, near Mount Olympus, where they were first worshipped. Others derive the name from Pierus, an ancient king of Macedon, who migrated from Thrace into Bœotia, where he established their worship.

PIERRE, JACQUES HENRI BERNARDIN DE ST, the author of *Paul and Virginia*, was born at Havre in 1737, of a family which claimed kindred with Eustache de St Pierre of Calais. He seems to have received little regular education, to have shown as a child a passion for animals, and a remarkable power of living in a visionary yet methodical world of his own. The event of his early life was the reading of *Robinson Crusoe*, which awakened in him the fixed idea of founding a colony where nature was to be all beauty and man was to be all virtue. After making some progress in mathematics, St Pierre was admitted as a pupil at the school of the Ponts et Chaussées, and afterwards entered the corps of engineers. He served one campaign in Hesse in 1760, but having quarrelled with his superior officers, he left France, and offered his services to Catherine of Russia, and subsequently to the King of Poland. But his vain and irascible temper led him to regard every post as unworthy of him; and, returning to France in 1766, he succeeded, by dint of importunity, in receiving the appointment of chief engineer of the Isle of France. Disappointed also with this undertaking, St Pierre returned to France in disgust in 1771, and began to form some valuable literary friendships. He was on terms of intimacy with Condorcet, Rousseau, and D'Alembert, and resolved to enrol himself among this literary fraternity, and make letters his vocation. He accordingly set to work; and in 1784 published the first portion of the *Etudes de la Nature*, which instantly brought him both fame and fortune. These *Studies* came recommended to that age by their true sensibility, their gentle and vague piety, their pensive melancholy, and their keen sympathy with solitude. Just four years had elapsed when St Pierre published his fourth volume of these *Etudes* containing the celebrated idyl of *Paul et Virginie*, on which his fame now chiefly rests. The remainder of his life was highly prosperous. He was made intendant of the Jardin-du-Roi, and was subsequently installed professor of morals in the École Normale. He died in 1814, leaving his *Harmonies de la Nature* ready for publication. St Pierre's second wife survived him, and afterwards married his idolizing biographer Aimé Martin, who collected and published *Les Œuvres de J. H. Bernardin de St Pierre, mises en ordre*, par L. Aimé Martin, 12 vols. 8vo, Paris, 1818–20.

PIERRE D'OLERON, a town of France, in the department of Charente-Inférieure, stands near the centre of the island of Oleron. It contains a distillery, vinegar manufactory, and tile-work. Excellent salt is obtained here; and some trade is carried on in wine. A tribunal of commerce is held in the town. Pop. 4769.

PIERRE-LÈS-CALAIS, a town of France, in the department of Pas de Calais, forms one of the suburbs of Calais. It has manufactures of cotton, lace, leather, buttons, hats, salt, and beet-root sugar. The railway to Lille traverses the town. Pop. 11,524.

PIERRE, ST, a town in the West Indies, on the N.W. coast of Martinique; N. Lat. 14. 44., W. Long. 61. 18. It is the largest town not only in the island, but in the whole of the French possessions in the West Indies, and it is said to be the finest of all the towns in the West Indies. Built on a narrow strip of level ground, along the shore of a semicircular bay, it consists of three broad streets parallel to the shore, crossed by several others. The principal streets are traversed by streams of water, which produce a delightful coolness and freshness in the hot climate. The town is fortified, and contains many handsome churches and a botanic garden. The anchorage in front of the town is good, but very much exposed. A considerable trade is carried on. Pop. about 30,000.

PIERRE, ST, a small island belonging to France, off the south coast of Newfoundland. Its area is about 8 square miles. It is occupied with rocky heights about 500 feet above the sea, and with ponds and marshes in the lower ground. Stunted pines and birches are almost the only vegetation; and the people live chiefly by fishing. A village of the same name, with a roadstead and fort, stands on the S.E. coast. Pop. about 1200.

PIETISTS, the name given to a sect of reformers which sprung up in the Lutheran Church in Germany towards the end of the seventeenth century. (See SPENER, *Philip Jacob*.)

PIETRA DE FUSI, a town of Naples, in the province of Principato Ultra, stands on a hill 1½ mile N.E. of Montefusco. It contains several churches and chapels. Pop. 5000.

PIETRAPERZIA, a town of Sicily, in the province and 5 miles S.E. of Caltanisetta. Sulphur, gypsum, and other minerals are obtained in the vicinity; and an active trade is carried on in corn. Pop. 8500.

PIGALLE, JEAN BAPTISTE, an eminent French sculptor, was the son of a carpenter, and was born in Paris in 1714. His first efforts in sculpture were rather unpromising. In the school of Lorraine he showed little or no aptitude for the art. Under the tuition of Lemoyne, he was an unsuccessful competitor for the prize of the Academy; and it was only after he had studied for three years the master-pieces of Italy, and had returned to his native city, that he took a high place in his profession. The career of Pigalle then began to be prosperous. A statue of Mercury in 1744 gained for him admittance into the Academy; and an image of the Virgin not long afterwards introduced him to the patronage of Madame de Pompadour. A series of high commissions was the consequence. He was employed by Louis XV. to execute that group of "Mercury and Venus" which was presented to the King of Prussia in 1748, and which is still at Sans Souci. He set up that great master-work, the allegorical tomb of Marshal Saxe, in the church of St Thomas at Strasbourg. He executed a bronze statue of Louis XV., which continued to adorn the town of Rheims till it was destroyed by the republican fury of the Revolution. He was also intrusted with the erection of a tomb to the Duc d'Harcourt in one of the chapels in the church of Notre Dame at Paris. Meanwhile Pigalle had been rising to a high place in the Academy. The office of professor had been conferred upon him in 1752, and that of rector in 1777. He had just attained to the highest dignity, the chancellorship, when he died in 1785.

PIGEON. See ORNITHOLOGY.

PIGHIUS, ALBERT, one of the opponents of Calvin, was born at Kempen, in the province of Overyssel, in 1490, and was educated at the university of Louvain. He entered upon the field of religious controversy about 1523

with no small reputation. His mathematical knowledge had been shown in several works; his theological attainments had been proved in several of the principal chairs in the Netherlands; and his fame as an orator was so great that Pope Adrian VI. had sent for him to Rome. The position which he now assumed in the great contest of the Reformation was not unworthy of such a reputation. The Supreme Pontiff despatched him to defend the cause of the Church of Rome in Germany. It was his privilege shortly afterwards, in 1524, to take part in the discussions and decisions of the diet of Ratisbon. He attained his greatest notoriety when he entered the lists against Calvin, and published his pamphlet *De Libero Hominis Arbitrio et Divina Gratia, adversus Lutherum, Calvinum, et Alios*. Cologne, 1542. Pighius died in 1542, in the possession of the provostship of St John in Utrecht.

PIGHIUS, *Stephanus Vinand*, a laborious antiquary, and the nephew of the preceding, was born at Kempen, in the province of Overyssel, in 1520, and completed his education at Cologne. Although a churchman, he gave himself up to antiquarian pursuits. Eight years in the early part of his life were devoted to the study of the ancient remains at Rome. During the rest of his career his attention was chiefly occupied in arranging and digesting the information he had collected. He had just published the first volume of his researches, under the title of *Annales Romanorum*, when he died in 1604. The two remaining volumes were entrusted to the editorial care of Andreas Schott, and the entire work appeared at Antwerp in 1615, in 3 vols. folio.

PIGNOTTI, LORENZO, an Italian historian and fabulist, was born in 1739 at Figlini, a small town between Florence and Arezzo. His life was characterized throughout by a genial attachment to literature. At the school of Arezzo and the university of Pisa he was distinguished for his devotion to poetry and the classics. While practising as a medical man at Florence, he continued the study of polite learning. At length, after his appointment, in 1774, to the chair of physics at Pisa, his literary zeal vented itself in authorship. With agreeable and well-selected incidents, and in a simple and natural style, he wrote many fables, which soon became known in other countries. A more laborious, though not more successful, undertaking was his *History of Tuscany*. Commencing at the time of the early Etruscans, he availed himself throughout of all the materials collected by his predecessors. At intervals, his own well-informed mind supplied a fresh and original chapter on such topics as the origin of the Italian language, the revival of letters and arts, and the condition of science at the end of the fifteenth century. He had just brought the entire work to a conclusion, when he died in 1812. It was published under the title of *Storia della Toscana sino al Principato con diversi Saggi sulle Scienze, Lettere, ed Arti*, in 9 vols. 8vo, Pisa, 1813. An edition of Pignotti's Fables and Poems appeared in 1820.

PIKE. See ICHTHYOLOGY.

PILAO-ARCADO, a town of Brazil, in the province of Bahia, stands on the river San Francisco, S. Lat. 14. 15., W. Long. 42. 40., 65 miles W. of Jacobina. It has a church, a school, and large salt-works. Numbers of cattle are reared at this place. Pop. 5000.

PILATE, PONTIUS, was the sixth Roman procurator of Judæa (Matt. xxvii. 2; Mark xv. 1; Luke iii. 1; John xviii. xix.), and the one under whom Jesus Christ taught, suffered, and died (Acts iii. 13; iv. 27; xiii. 28; 1 Tim. vi. 13; Tacitus, *Annal.* xv. 44). Pilate succeeded Valerius Gratus as governor of Judæa, and held office for ten years during the reign of Tiberius. His character, as indicated by Philo-Judæus, by Josephus, and in the New Testament, is, without exception, stubborn, cruel, and avaricious. His imperious cruelty at last cost him his office. Josephus informs us (*Antiq.* xviii. 4, 2) that the Samaritans, having been treated by Pilate in a barbarous manner, complained to Vitellius, governor of Syria, who ordered him to Rome to give an account of his conduct to the emperor. Tiberius was dead before Pilate arrived; but Eusebius relates that the guilty procurator was banished to Vienne in Gaul, where he committed suicide about the year A.D. 38.

PILATRE DE ROZIER, JEAN FRANÇOIS. See AERONAUTICS.

PILCHARD. See ICHTHYOLOGY.

PILCOMAYO, or ARAQUA-GUAZI, a river of South America, in Bolivia and the Plata Confederation, rises in the former country on the eastern slope of the Andes, near Chuquisaca, and flows S.E. through Bolivia and Plata, till it falls into the Paraguay nearly opposite Assumption; total length estimated at 1000 miles. It is navigable for boats nearly the whole of its length; but it is very shallow in the dry season, and where it is narrow the current runs with great force. The only city on its banks is Chuquisaca. Its chief affluents are the Pilaya and Paspaya. About 150 miles from the Paraguay it divides itself into two arms, inclosing a marshy island.

PILES, ROGER DE, an historian and critic of art, was born of a noble family at Clameci in 1635. His love for painting appeared early, and was never lost amid the public business which engrossed his life. Travelling as tutor, and then as secretary, to the son of President Amelot, he sedulously increased and matured his knowledge of pictures. Sent as a spy of the French king to the Hague, he practised the profession of a painter in order to conceal his real character. Nor could a Dutch prison damp his enthusiasm for art. During his confinement he wrote his principal work, the *Lives of the Painters*. Piles died at Paris 1709. A collection of the works of this author was published in 5 vols. 12mo, 1767.

PILEUS and PILEUM (πῖλος and πιλίον), were terms applied by the Greeks and Romans to any piece of *felt*, and particularly to a felt cap, a hat made to fit close to the head, and without any brim. The pileus was usually of a half-egg shape, but was frequently more elevated. The Greeks, who bequeathed the art of felting to the Romans, doubtless derived it themselves from Asia. The Phrygian cap or bonnet, which was of a similar shape and texture to the pileus, seems to have been peculiar to the inhabitants of Asia Minor generally, as we find it continually introduced by artists as the symbol of Asiatic life. The felt cap was the emblem of liberty among the Romans. When a slave obtained his freedom, he exchanged the hair of his head for an undyed pileus.

In contradistinction to the brimless pileus, the Greeks and Romans wore the *petasus* (πέτασος), a species of hat also made of felt, and consisting of a great variety of forms, from that of a mere circular disk to shapes closely resembling our "wide-awakes."

PILLAR. See *Glossary* to ARCHITECTURE.

PILLAU, a town of Prussia, in the government of Königsberg, stands at the entrance of the Frische Haff, 25 miles W. of Königsberg, of which it is the port. It is defended by a fort, and has a good harbour, a lighthouse, a Protestant church, and a school of navigation. Ship-building and fishing are actively carried on here. The entrance to the Frische Haff is very narrow and shallow, so that large vessels have to discharge their cargoes here, which gives the town a considerable trade. Pop. 3491.

PILLEEBHEET, a town of British India, capital of a pergunnah of the same name, in the district of Bareilly, N.W. Provinces, stands on the left bank of the Gurrah, 802 miles N.W. of Calcutta. The river, which is here 250 yards broad, is crossed during the dry season, from December to June, by a ford, and at other times by a ferry. The town is extensive, and is the seat of an active com-

merce. Timber, pitch, honey, wax, wool, various metals, and other goods, are brought hither from Kumaon and Chinese Tartary, and are exchanged for the produce of the plains. The rice of Pilleebheet, which is valued in India for its fine flavour, is grown in the valley of the Kosilla, in the south of Kumaon, and brought to market here. Pop. (1853) 26,760.

PILLORY (Fr. *pilori*, probably from Lat. *pila*, a pillar), a mode of punishment by a public exposure of the offender long used in most countries of Europe. No punishment has been inflicted in so many different ways as that of the pillory. Sometimes the machine was constructed so that several criminals might be pilloried at the same time; but it was commonly capable of holding but one at once. Francis Douce, in his *Illustrations of Shakspeare*, vol. i., p. 146, gives six representations of distinct varieties of this instrument. These varieties are all reducible, however, to the simplest form of the pillory. It consisted of a wooden frame or screen raised on a pillar or post several feet from the ground, and behind which the culprit stood supported on a platform, his head and hands being thrust through holes in the screen, so as to be exposed in front. This screen, in the more complicated forms of the instrument, consisted of a perforated iron circle or *carcan* (hence the name given to the pillory in French), which secured the hands and heads of several persons at the same time. The pillory was abolished in Britain in 1837, by the statute 1 Vict., c. 23; and in France in 1832.

PILOT, in many maritime countries, is the name applied to a particular officer in a ship who has the charge of the helm and the ship's course. The term is usually applied in this country, however, to a person taken on board at any particular place, to conduct the vessel into or out of particular harbours, or along certain coasts. Charters of incorporation were formerly granted to pilots of this class, such as those of the Trinity House. Deptford, Strond, and those of the Cinque Ports, &c. For the present state of the law respecting "pilotage," see the Merchant Shipping Act 1854, entitled "An Act to amend and consolidate the Acts relating to Merchant Shipping," 17 and 18 Vict., c. 104, in which will be found various enactments respecting the license, regulation, and guidance of pilots belonging to the United Kingdom only.

PILSEN (Bohem. *Plzen*, Lat. *Pilsna*), a town of Bohemia, capital of a circle of the same name, stands at the confluence of the Mies and Radbusa, which form the Beraun, 53 miles W.S.W. of Prague, and about the same distance S.E. of Eger. It is well built, for the most part of stone, and fortified. Among the public buildings are numerous churches, the most remarkable of which is that of St Bartholomew, a fine Gothic structure, built in 1292. The town-hall and the hall of the Teutonic knights are also in the Gothic style. Pilsen contains two convents, a theatre, a philosophical institution with a library and museum, a grammar school, other educational establishments, two hospitals, and an infirmary. Manufactures are carried on of cloth, leather, and musical instruments. Standing on the high road from Prague to the middle and south of Germany, Pilsen is a place of considerable trade, and its weekly and yearly markets are of some importance. Rich coal-pits and iron mines are worked in the vicinity. Pop. (1851), exclusive of the military, 11,486.

PILUM, a missive weapon used by the Roman soldiers. (See ARMY, § *Roman Army*.)

PIMENTO, ALLSPICE, or JAMAICA PEPPER, is the unripe fruit of *Eugenia Pimenta* (Nat. Ord. *Myrtaceæ*), dried in the sun. (See BOTANY.) It receives the name *allspice*, from its resemblance in flavour to a mixture of cloves, cinnamon, and nutmeg. The tree is a native of the West Indies, but is cultivated almost exclusively in Jamaica; thence the produce is called *Jamaica pepper*. It is formed into plantations, intersected with broad walks, known as *pimento walks*. The berries are gathered in an unripe state, when the essential oil which they contain is most abundant; they are then spread out, and dried by frequent turning in the sun, when their colour changes from green to a fine clove-brown. The flavour resides within the shell of the pimento, which is, when dried, about twice the size of a pepper-corn, and incloses two seeds. The consumption of allspice in the United Kingdom has very greatly increased during the past ten years. It is occasionally used in medicine, but chiefly as an article of cookery. It yields an essential oil, known as "oil of pimento," used in perfumery and confectionary. (See OILS.) The importations of pimento for 1857 amounted to 31,014 cwts., of which 4035 cwts. were entered for home consumption, yielding, at the rate of 5s. per cwt., a total duty of L.1009.

PIMLICO, a suburb of London, in the county of Middlesex, and liberty of Westminster, lies to the W. of St James's and the Green parks, about 2½ miles W.S.W. of St Paul's. It has many handsome streets and squares, and includes within its limits Buckingham Palace.

PINCHBECK. See BRASS.

PIND-DADUN-KHAN, a town of British India, in the Punjab, stands about 4 miles from the W. bank of the Jhelum, from which it is separated by a green plain; N. Lat. 33. 11., E. Long. 74. 25. It consists of three small groups of houses, not far apart, built of mud, with a framework of cedar, which is got from the mountains to the N., and floated down the river. Salt is obtained in abundance in the vicinity, so as to supply a great part of the Punjab. Pop. 13,588.

PINDAR, the greatest of the Greek lyric poets, was a native of Bœotia, and was born either in Thebes, the capital of that country, or at Cynoscephalæ, a little village between Thebes and Thespia. His father's name is variously given as Daiphantus, Pagondas, or Scopelinus, and his mother's as Cleidice or Myrto. He was born, as he himself mentions (*Fragm. Incert.*, 102), at the time of the Pythian games, which fell in the beginning of July. Clinton fixes the year as Ol. 65.3, or B.C. 518; Böckh as Ol. 64.3, or B.C. 522. Both of these dates are uncertain; but Böckh's computation is now regarded as more probably the correct one. The time of his death is equally doubtful. If it be true, as is commonly believed, that he lived eighty years, Clinton's calculation would give 439 B.C., and Böckh's 442 B.C., as the date of his death. His wife was Megacleia, the daughter of Lysitheus and Callina. Another account gives his wife's name as Timoxena; but it is not unlikely that this Timoxena may have been a second wife, whom he married on the death or divorce of the first. He had one son, named Daiphantus, and two daughters, Eumetis and Protomache.

The family to which Pindar belonged was one of the noblest in Thebes, as is proved by the fact, that the poet wrote the ode which his son Daiphantus sung on his election as *daphnephorus*, an office open to none but members of the highest families in the city. (See DAPHNEPHORIA.) They were famed for their skill in flute-playing, a profession held in much esteem at Thebes. Pindar inherited the family talent, and something more. His father, seeing the bent of his genius, sent him to Athens, where, under the celebrated dithyrambist, Lasos of Hermione, he learned music, dancing, and all the mysteries of the chorus requisite for his training as a lyric poet. He also attended the schools of Agathocles and Apollodorus, and, though a mere lad, was allowed by them to instruct the cyclic chori. How much he owed to these preceptors we do not know. Probably it was not much; at least enough is known of Lasos to show that he had little share in forming Pindar's style. The best part of the young poet's training was probably that which he received on his return from Athens, in his

twentieth year, from his countrywomen, Myrtis and the Tanagrean Corinna. To the instruction and example of the latter, in particular, he was deeply indebted. Corinna was, like Pindar himself, a teacher of choruses. Plutarch relates that she encouraged her pupil to select the themes for his muse from the mythology of his country, and to devote his chief attention to the subject-matter of his song, treating the music and other accessories as of merely secondary importance. On one occasion, when, in compliance with her suggestion, he brought her an ode in which were inwoven all the mythic legends of Thebes, she told him, with a smile, that he "ought to sow with the hand, but not with the whole sack." The pupil became in course of time ambitious enough to enter the lists with his teacher. She accepted the challenge, and, either from her beauty or the superiority of her verse, was five different times declared victor. She was by no means pleased, however, when her rival Myrtis followed her example: "I blame the clear-voiced Myrtis,—I, that she, born a woman, should enter into the contest with Pindar."

Between the age of twenty and twenty-two Pindar began his professional career as a poet. His earliest poem that has come down to us is an Epinician ode (the 10th Pythian) in honour of Hippocles, a noble youth of Pelinna in Thessaly, who had won the prize at the Pythian games. His fame soon grew so great, that he was engaged to compose similar hymns by Hiero, tyrant of Syracuse; Thero, tyrant of Agrigentum; Arcesilaus IV., king of Cyrene; and many other rich and powerful men in Greece and the Greek colonies. About 473 B.C., in compliance with urgent and repeated invitations, Pindar paid a visit to Hiero at Syracuse. It was intended that he should take up his abode permanently with that "tyrannus;" but the arts of court-life soon became distasteful to his independent spirit, and he returned home after an absence of four years. Among his most active patrons was Alexander, son of Amyntas, king of Macedonia. In the praises which he bestowed on this potentate may be found the reasons why, a century and a half later, at the capture of Thebes,

> "The great Emathian conqueror bade spare
> The house of Pindarus, when temple and tower
> Went to the ground."

Nor were the free states of Greece backward in doing honour to his merits. Foremost in the number was Athens, which, in allusion to her heroism during the Persian wars, he had celebrated in one of his dithyrambs as "the pillar of Greece, glorious Athens, the divine city." The Athenians gave him, though a Theban, the *proxenia*, or complimentary franchise of their town, and on one occasion a present of 10,000 drachmæ. After his death they erected a statue in his honour. Similar compliments were paid him by Opus and Ægina, and a still more delicate one by the inhabitants of Ceos, who once employed him, in preference to their own illustrious poets Simonides and Bacchylides, to write a procession-ode for them. The Rhodians inscribed his 7th Olympian ode in characters of gold on the temple of Minerva at Lindus.

In the great events that took place in Greece during his time, Pindar, unlike his contemporary Æschylus, seems to have taken no share. He watched with keen interest the struggle of Athens against Persia, and his countrymen, whose conduct in that struggle was not actively patriotic, were far from pleased with the praises which he lavished on the Athenian victors. The story, that they fined him, and that the Athenians paid the fine, rests on no good foundation. The most marked feature of the poet's personal character was his veneration for the gods. His profession, indeed, demanded that he should show great reverence for their worship and religious observances. That these were not to him mere vain ceremonies we may safely infer. He not only consecrated a temple to the Great Mother and Pan near his own house in Thebes, and statues to Jupiter Ammon in Libya, and to Mercury of the Agora in his native city, but he also rejected or toned down in his odes such myths as represented gods or heroes in undignified or immoral situations.

The poems of Pindar that have descended to us entire belong, with one exception, to the class of Epinician or triumphal odes. That exception is the 11th Nemean, in which the bard celebrates the installation of Aristagoras as prytanis at Tenedos. His extant remains, however, prove him to have excelled in many other departments of lyric poetry; and the ancients themselves do not seem to have attached any special importance to those of his works by which alone we can rightly estimate his powers. Horace no doubt spoke the opinion of antiquity when he attributed to Pindar an unrivalled skill in the kinds of verse specified in the well-known lines;—

> "Seu per audaces nova dithyrambos
> Verba devolvit, numerisque fertur
> Lege solutis,
>
> Seu deos regesque canit deorum
> Sanguinem, per quos cecidere justâ
> Morte centauri, cecidit tremendæ
> Flamma Chimæræ;
>
> Sive quos Elea domum reducit
> Palma cœlestes, pugilemve equumve
> Dicit et centum potiore signis
> Munere donat;
>
> Flebili sponsæ juvenemve raptum
> Plorat."

In the first of these stanzas are mentioned the dithyrambs, or cyclic chorus; in the second, the hymns and pæans; in the third, the *Epinikia*, or songs of triumph; and in the last, the *threnoi*, or dirges; in all of which styles alike Pindar's eminence was unquestioned. The Epinikia, on which we mainly form our estimate of Pindar, are divided into four books. To value them aright it is necessary to appreciate duly the occasions which called them forth. They were written in honour of a victory gained at one of the four great national festivals of Greece—the Olympic, Isthmian, Pythian, and Nemean games. A victory in any of the great contests at these games shed a lustre not only on the conqueror himself, but also on the family and state to which he belonged. On the evening of the day of victory, the conqueror walked in state to the altar of the god of the games, attended by the festive train, which sang his praises. On his return home, a solemn reception was prepared for him by his native town; sacrifices and thanksgivings were offered in his behalf to some god; and the whole proceedings ended in a public banquet and a comus. Hence arises the apparent incongruity of the Epinician odes, in which outpourings of the deepest devotion are found side by side with the wildest utterances of frantic revelry. The victory itself is seldom described; sometimes it is not even mentioned. The glory of the conqueror; his valour,—for none of the contests were without danger; and even his wealth,—for none but persons of at least considerable means could afford the time and money required for the training as fixed by law,—were the themes on which the poet enlarged. The birth of the conqueror is also praised, and, where possible, a parallel drawn between his exploits and those of the mythic founder of the state or city to which he belonged. Indeed the mythic element is a leading feature of the Pindaric odes. Far from being merely ornamental or digressional, it is closely inwoven with the general texture and design of the poems, though its purport is sometimes difficult enough to trace. The structure and distribution of the Epinikia were very intricate; and the chorus which performed them had to be taught their parts either by the bard himself or by some master of the lyric art. The personality of the poet appears in all his odes; he speaks through the mouths of

the chorus as if in his own proper person. It may be questioned how far such a license is consistent with true art; but it gave Pindar what he wanted, an opportunity, namely, of criticising and denouncing his rivals, of defending himself from their attacks, and now and then of sounding his own praises. This latter practice, as in Ol. ii. 83, he occasionally indulges in to an extent scarcely reconcileable with modesty. It is to be remembered, however, that these touches of strong personal feeling, and the sometimes seeming extravagance of his mirth, were by no means inconsistent with the wild revelry of the banquets at which his odes were intended to be sung. The style of Pindar is wonderfully vivid and picturesque. His best English expositor, J. W. Donaldson (in his essay *De Stylo ac Dictione Pindari*), declares that in this quality Pindar had no rival among his own countrymen, and no equal or superior till the age of Dante: "Vivido vigore ingenî fere omnes Græcos superat, atque in ea facultate, quæ res non visas depingit, et quasi sensibus subjicit, neminem cum eo contenderem, præter Durantem illum Aligerum." The general morale of his writings, too, is high and pure. In the moments of his wildest hilarity he uses no improper word or phrase: "Vates deorum ac sacerdos, sic ut oraculum loquebatur." No evil deed is by him once defended; no divinity scoffed at or denounced.

The editions of Pindar are numerous. The *princeps* was published at Venice at the Aldine press in 1513; another by Calliergi appeared at Rome two years later, with the Scholia. The first critical edition is that of Erasmus Schmidius, Wittemberg, 1616. The other editions of the seventeenth century are that of Joannes Benedictus, Salmurii, 1620; and the Oxford edition of 1697. Heyne's celebrated first edition was published at Göttingen in 1773; a second version of this work, with a valuable essay on the Pindaric metres by Hermann, appeared at the same place in 1798. The best German edition of Pindar is that of August Böckh, Leipsic, 1811–21, in 3 vols. 4to, which has thrown an entirely new light on the music of the Greeks, and the artistic construction of their lyric poetry. Dissen's edition, published in the *Bibliotheca Græca*, Gotha, 1830, 2 vols. 8vo, is nothing more than a rather masterly abridgment of Böckh's great work. The illustrative matter is exceedingly good; but as the fragments are not given complete, it cannot be said to supersede its immediate predecessor. Thiersch's Pindar, Leipsic, 2 vols. 8vo, 1820, has a valuable introduction; and the text of the poet, as given in Bergk's *Poetæ Lyrici Græci*, is very accurate. Of English editions, by far the best is that of the Rev. John William Donaldson, London, 1841, in 1 vol. 8vo. It contains the cream of the best German editions, and besides embodying in the notes the results of great original research and scholarship, possesses a learned and masterly Latin essay, *De Stylo ac Dictione Pindari.* The English translations of Pindar are not numerous. The oldest is that of West, which has little to recommend it; Moore's exhibits much more taste and vigour. Better than either is that of the Rev. H. F. Cary, London, 1833, which, however, has the disadvantage of being founded on Heyne's somewhat antiquated edition of the poet.

PINDEMONTE, Ippolito, a delightful Italian poet, was the younger son of a patrician family, and was born at Verona in 1753. A course of education at Este and Modena, and a tour through Europe, fostered and matured his literary taste. A severe illness, which unfitted him for public life, was the occasion of bringing his accomplishments into exercise. Retiring to a country house in the neighbourhood of Verona, he spent his quiet days in the congenial labour of poetical composition. He translated from his favourite classical poets, recorded the solemn thoughts which sprung up amid the stillness of solitude, and descanted upon the news which came at intervals from the distant world. His *Versi* appeared in 1784, his *Volgarizzamento dell' Inno a Cerere scoperto ultimamente e attribuito ad Omero* in 1785, his *Saggio di Poesie Campestri* in 1788, his *Poesie* in 1798, his *Arminio Tragedia* in 1804, and his *Epistole in Versi* in 1805. He had but recently published a prose work, entitled *Elogi di Letterati*, when he died in 1828. A collection of Pindemonte's works appeared in 8 vols., Milan, 1829.

PINDUS, a long mountain chain in ancient Greece. It began, under the name of *Lacmon* or *Lacmus*, about the 40th degree of N. Lat. among the Macedonian and Illyrian ranges. Running southward, it sent off in different directions the rivers Peneus, Aous, Aracthus, and Achelous, and formed the boundary between Thessaly and Epirus. When it reached the 39th degree of latitude it assumed the name of *Tymphrestus*, and shot forth the branch of Mount Othrys. A little farther south, its heights were merged into other ranges. Pindus was deemed a favourite haunt of Apollo and the Muses.

PINEROLO, or Pignerol, a town of the kingdom of Sardinia, capital of a province of the same name, in the division of Turin, stands near the foot of the Alps, on the Chisone, 21 miles S.W. of Turin. It is surrounded by a wall of no great strength; and though irregularly and not very well built, contains several squares, one of which, the Piazza d'Armi, is large and handsome. There are here a fine modern cathedral, several other churches, numerous convents, a town-hall, theatre, college, hospital, and barracks. Manufactures of iron, cloth, paper, leather, and silk are carried on; and there is a considerable trade in these articles, as well as in corn, wine, spirits, &c. Pinerolo, along with Fenestrelles, Oulx, Cesana, and the surrounding country, though originally a part of Piedmont, was in the possession of France from 1631 till the peace of Utrecht in 1713. It was once very strongly fortified; but its defences were blown up by the French in 1713. Pop. 14,000.

PINGRÉ, Alexandre-Gui, a French astronomer, was born at Paris in 1711, and was educated at a religious establishment at Senlis. The first part of his career was devoted to theology; but in 1749 the offer of a teachership in an academy at Rouen gave him a motive for applying himself to astronomy; and about 1753 his appointment to the office of librarian in the academy of St Geneviève afforded facilities for carrying out the study. Henceforth all the energies of Pingré were directed to astronomical pursuits. He became an indefatigable observer of transits and eclipses; and contributed many papers to the Memoirs of the Academy of Sciences, of which he was an associate. Especially in the numerical calculations which he made did his unwearied activity appear. He verified Lacaille's table of the eclipses of the first eighteen centuries of the present era, and carried back the computations to the date of 1000 years before Christ. He also calculated the orbits of all the known comets in a work which was published at Paris in 1783, under the title of *Cométographie*, and which was his only important publication. Pingré died at Paris in 1796. (See Delambre's biography of this astronomer in the *Biographie Universelle*.)

PINKAFELD (Magyar *Pinkafö* or *Pinkafej*), a market-town of Hungary, in the county of Eisenburg, stands on the Pinka, not far from the Styrian frontier, 19 miles W. of Güns. It contains a palace belonging to the Batthyani family; and in the vicinity there is an abundant and much-frequented chalybeate spring. Woollen cloth of various kinds is manufactured here, and an active trade in horses is carried on. Pop. 4000.

PINKERTON, John, a voluminous writer, was born in Edinburgh in 1758, and was educated at the grammar school of Lanark. A self-willed devotion to literature began to characterize him at an early period. Before entering into business, he occupied his time with dipping at random into French classics and mathematics. While serving his apprenticeship

with an Edinburgh writer to the signet he persisted in writing and publishing insipid rhymes. On his abandonment of the legal profession, and his removal to London in 1780, this perverse literary ardour took a new direction. His mind now wandered with all its usual laborious eccentricity into the field of antiquarian research. Sometimes he pored over the ancient literature of his native country, forming collections of ballads, and adding imitations by himself. At other times he made historical compilations, boldly distorting every fact that did not accord with his own prejudices, and fiercely denouncing every one who might dare to dissent from his own conclusions. A long series of curious and whimsical publications was the result. There were *Select Scottish Ballads*, in 2 vols., 1783; *Ancient Scottish Poems*, in 2 vols. 8vo, 1786; *Dissertation on the Origin and Progress of the Scythians and Goths*, 8vo, 1787; *An Enquiry into the History of Scotland preceding the Reign of Malcolm III.*, in 2 vols. 8vo, 1789; and *The History of Scotland during the Reign of the Stuarts*, in 2 vols. 4to, 1797. His *Geography*, published in 1802, in 2 vols. 4to, is considered valuable. In spite of these and many other works, the author had great difficulty in securing a maintenance, and died in indigence at Paris in 1826. Pinkerton was intimate with Gibbon and Horace Walpole.

PINION, in *Mechanics*, an arbor or spindle, having in the body of it several notches, which catch the teeth of a wheel that serves to turn it round; or it is a lesser wheel that plays in the teeth of a larger.

PINNACE, a small vessel navigated with oars and sails, and having generally two masts rigged like those of a schooner.

PINNACLE. See *Glossary* to ARCHITECTURE.

PINS. Metal pins are said to have been introduced into this country from France in the year 1543, previous to which ladies were accustomed to fasten their dresses by means of skewers of boxwood, ivory, or bone. For some time after their introduction pins must have been costly, for we find that they were acceptable New-Year's gifts to ladies, and that presents of money were made for buying pins; whence money set apart for the use of ladies received the name of *pin-money*. In the reign of Henry VIII. a law was passed that "no person should put to sale any pin, but only such as shall be double-headed, and have the heads soldered fast to the shanks of the pins, well smoothed, the shanks well shapen, the points well and round filed, canted, and sharpened." The manufacture of pins was introduced into several towns of Great Britain by individuals who, in some cases, are called the inventors of the article. Pins must soon have been made and sold at a very cheap rate, to justify the common remark, "Not worth a pin," and equivalent expressions in some of our early writers, such as Tusser:—

> "His fetch is to flatter, to get what he can;
> His purpose once gotten, a *pin* for thee than."

Pins are made of brass wire, which is furnished to the pin-maker in a thick, close form, and he reduces it to the proper gauge by drawing. The coil of wire thus produced is straightened by being interlaced and pulled between seven strong metal pegs, and thus made to describe a series of zig-zags, until the coil or twist is taken out of it. When a length of from 12 to 20 feet has been thus straightened, it is cut off, and when a number of these lengths have been collected, they are cut up into short lengths, each containing enough wire for about six pins. These lengths are pointed at each end on an iron cylinder or round head of steel, cut with a double row of teeth, which meet obliquely in the middle of the face. This is called a *mill;* and on the same axis with it is a smaller steel mill with finer teeth. The grinder points from fifty to eighty pin wires at one operation, forming the points first at the larger mill, and smoothing them on the finer-cut mill. By a peculiar action of the thumb and finger the grinder gives the required rotatory motion to the wires. The dust given off during the pointing is injurious to health, and should be removed by careful ventilation. The pointed wires are next placed in a small box shorter than themselves, from which one end is removed, and the projecting portions are cut off by means of shears. The same operation being performed on the opposite ends, the intermediate lengths are returned to the pointer. The heads of the pointed portions are in some cases formed by jumping up a portion of the blunt end of the shaft. In Germany the heads have recently been formed in composition metal, cast after the manner of bullets, with a hole in the centre for the insertion of the shaft; but the older and more common method is to form the heads separately with a few coils of wire. In the latter method, a long, close spiral of wire is formed on a piece of stiff wire about 40 inches long, and of the exact thickness of the pin: this wire, called the *mould*, is attached to an ordinary spinning-wheel, and made to rotate rapidly, and the soft heading-wire being held to it, becomes closely coiled round it nearly from end to end. The coil thus formed is slipped off the mould, and is cut into heads by means of a small chisel, to which a quick chopping motion is given. The heads are next annealed by being raised to a red heat in an iron ladle. The shafts are headed by girls, who are seated with a number of pin-heads in their laps, and, taking up a shaft between the finger and thumb, pass it through the heads, and catch up one on the point; if more than one be taken up, it is removed by the fingers. The head is fastened by placing the shaft in a small steel die sunk to half the size of the head, while another die similarly sunk is allowed to drop upon it, the effect of which is to close the coil firmly upon the shaft. The upper die is suspended vertically in a frame, and can be raised by means of a treadle. Under the lower die is a small spring, which raises the pin out of the die as soon as the blow has been struck, and the upper die raised. A skilful workwoman will thus head 1500 pins in an hour. The next operation is *yellowing*, or scouring in a barrel containing wine lees, or a solution of tartar, and made to rotate for half an hour, the effect of which is to make the pins chemically clean. Then comes the *whitening* or tinning, for which purpose about 6 lb. of pins are put into a copper pan, and upon them 7 or 8 lb. of grain tin; then more pins, and upon them more tin; and so on in alternate layers until the copper is filled; water is added, the pan is set on the fire, and when hot, cream of tartar is sprinkled in, and the water is left to boil for an hour. The pins are next taken out, washed in water; and the process is repeated once or twice, until the pins are properly tinned. The pins are then polished in a rotating barrel containing warm bran: the bran is separated by winnowing; and the pins are collected in bowls for *papering*. The papers having been crimped with irons, the folds for one row are gathered up and placed between the jaws of a vice. A girl, with her lap full of pins, takes up a row by passing a pocket-comb among them, and resting the points in grooves in the vice, presses the heads forward with the thumb, which is covered with a leather guard. In this way the pins are quickly papered. Mourning-pins are blackened after the yellowing by being coated with a black varnish; but a neater and sharper mourning-pin is now made by means of steel wire tempered to a deep purple colour.

Pins are of various sizes, from the large blanket-pin 3 inches in length, to the smallest ribbon-pins, of which 300,000 weigh only 1 lb. Insect-pins, used by entomologists, are of finer wire than ordinary pins, and vary in length from 3 inches to a size smaller than ribbon pins. It has been calculated that ten tons of pins are made every week in England alone, requiring from fourteen to fifteen tons of brass wire.

Attempts have been made to produce pins by machinery, the most successful of which is by Mr Wright, patented in

1824. It is stated as an objection to machine-made pins, that as the heads are made by pressure, a soft wire must be used, which renders the pin liable to bend. (C. T.)

PINSK, a town of European Russia, in the government of Minsk, stands in an extensive marshy plain on the Pina, which here falls into the Pripetz, 148 miles S.S.W. of Minsk. It contains Greek and Roman Catholic churches, several convents, and a college formerly belonging to the Jesuits. Manufactures of Russia leather are carried on here; and there is a considerable trade. Annual markets are held at Pinsk. Many of the inhabitants are Jews or Tartars. Pop. (1851) 8716.

PINTELLI, or PONTELLI, BACCIO, a Florentine architect, was constantly employed at Rome by Pope Sixtus IV. between 1471 and 1484. Among other fabrics, he designed the church of Santa Maria del Popolo, and the Ponte Sisto. But his most notable work was the Sistine chapel, an edifice which was destined to be adorned with some of the greatest masterpieces of modern painting. The death of Pintelli is supposed to have taken place at Urbino about 1490 or 1491.

PINTURICCHIO, BERNARDINO, an eminent Italian painter, was born at Perugia in 1454, and studied under Pietro Perugino. His success in art was very considerable. With the occasional aid, as it is supposed, of his friend and fellow-pupil Raphael, he contrived to design naturally and to execute gracefully. The liveliness of his faces, and the magnificence of his architecture, in spite of a vicious habit of gilding his ornaments, completed the general effect, and made his pictures striking and popular. In course of time, popes, cardinals, and other ecclesiastics noticed him, and entrusted him with several important commissions. He was employed to decorate many churches, and other edifices, both at home and throughout Italy. At length he attained the summit of his excellence in the cartoon at Siena, which represents the most memorable events in the life of Pius II., and in the great work at Spello, which consists of pictures of "The Annunciation," "The Nativity," and the "Dispute with the Doctors." Notwithstanding such a fortunate career, Penturicchio is said to have come to a wretched end at Siena in 1513. According to Vasari, he died of chagrin at having narrowly missed an opportunity of discovering a quantity of gold pieces. Another account states that his wife left him on a sick-bed to perish by hunger. (See Vasari's *Lives of Painters*, &c., and Lanzi's *History of Painting in Italy*.)

PINUS, the PINE-TREE. See BOTANY, and PLANTING.

PIOMBINO, a seaport-town of Tuscany, in the province of Pisa, stands on the channel of the same name, 69 miles S.S.W. of Florence. It is surrounded by walls, and has a citadel, three forts, a fine church, a palace, and a small harbour. In the vicinity there are salt-works, and some remains of the ancient town of *Populonia*. Some trade is carried on here. Piombino was at one time the capital of an independent principality, which included the island of Elba. Pop. 4000.

PIOMBO, FRA, SEBASTIANO DEL. See SEBASTIANO.

PIOVE-DI-SACCO, a town of Austrian Italy, in the government of Venice and province of Padua, stands on the Brenta Canal, 12 miles S.E. of Padua. It contains a castle, several churches and chapels, and many country houses belonging to the Venetians. Leather and linen are manufactured here. Pop. (1846) 6596.

PIOZZI, HESTHER LYNCH, who was the daughter of John Salusbury, Esq. of Bodvel in Caernarvonshire, and was born in 1739, is celebrated for her connection with Dr Johnson. In 1764, the year after her marriage with her first husband, the wealthy brewer Thrale, her intimacy with the great moralist began. A turn for literature, a fondness for intelligent conversation, and a smart, lively fancy, enabled her to appreciate his society. Apartments were allotted to him in her house in the city, and in her villa at Streatham; and her hospitable table was the scene of many of his most brilliant nights. She continued to soothe his hypochondria, and study his wayward tastes, until her marriage with the Italian musician Piozzi in 1784 broke off the friendship. Even then the connection between the two names did not cease. In 1786, while living in Florence, she wrote a book narrating, in a flippant, garrulous, and clever style, many of the superstitious whims, the ridiculous oddities, the brow-beating retorts, and the vehement outbursts of the departed lexicographer. Up till her death, too, in 1821, she continued to talk to another generation about the great men of the Johnsonian age. Besides her *Anecdotes of Dr Johnson*, Mrs Piozzi published *A Collection of Letters to and from Dr Johnson*; a popular poem, entitled *The Three Warnings*; and several miscellaneous works. A book entitled *Piozziana*, by a Friend, appeared in 1833.

PIPE, a musical instrument, various in kind. (See MUSIC, and ORGAN.) Without entering into useless details regarding the ancient αὐλοι and *tibiæ*, we may mention that Strutt, in his *Sports and Pastimes of the People of England*, gives representations of the pipe and tabor, as used in England in the fourteenth century to accompany a dancing-dog, a cock on stilts, a horse rearing, &c. From the drawings we cannot ascertain the nature of the pipe represented. We may, however, suppose it to have been similar to the *galoubet* used in France, along with the tabor, from a very remote period. This *galoubet* is a small instrument of the flageolet kind. Its use, for more than the last two centuries, has been confined to Provence. It has only three finger-holes, and is played with the left hand, whilst the right beats the tabor, which is attached to the performer. The compass of the *galoubet* is two octaves and a tone from D on the third line of the treble clef up to E in *altissimo*. Great skill is required to bring out all the sounds of its compass. Some of the players on this small and imperfect instrument are said to be so dexterous as to be able to perform upon it very difficult pieces of music composed for other instruments, such as the violin, &c. It is always accompanied by the tabor, which is a small drum of a cylindrical form, and rather longer and narrower in its relative proportions than the common drum. In the last century several books of instruction were published at Paris by distinguished performers on the *galoubet*. It was upon a very small instrument of this kind that the blind Sardinian peasant Picco performed so wonderfully at London and at Edinburgh in 1856. (G. F. G.)

PIPE-OFFICE is an office in which a person called the *clerk of the pipe*, makes out leases of crown-lands, by warrant from the lord treasurer, or commissioners of the treasury, or the chancellor of the exchequer. The clerk of the pipe also makes out all accounts of sheriffs, &c., and gives the accountants their *quietus est*.

PIPERS, a musical term, now applied to performers on the bagpipe. Thus we have Northumbrian pipers, Irish pipers, Calabrian pipers, Scottish pipers, &c. The bagpipe seems to be one of the most ancient of musical instruments. It had various names in ancient times and in different countries. Boccaccio introduces it as a fashionable instrument in his *Decameron*; and, from the accounts of the household expenses of our British monarchs, we find that the bagpiper was a court musician in the olden time. In Strutt's *Sports and Pastimes of the People of England* we find a bagpipe-player on stilts, from an illuminated manuscript of the thirteenth century, in the reign of Henry III.; and another bagpiper of the same century, with a girl dancing upon his shoulders. Some of the most curious representations of bagpipers and their instruments (*chori* or *cori*) are given by Gerbert *De Cantu et Musica Sacra*, plates 33 and 34 of the second volume. (G. F. G.)

PIR PANJAL (*Saint's Mountain*), a mountain range of India, stretching from N.W. to S.E., between Cashmere and the Punjab. Its length is about 40 miles, from the Baramula pass on the N.W. to the Pir Panjal pass on the S.E.; and its highest point, which is in N. Lat. 33. 40., is about 15,000 feet above the sea. Its structure on the Cashmere side consists of primary rocks, while the summit is basaltic, and transition formations also appear in some places. The pass of Pir Panjal, though 12,000 feet high, is below the snow-line, and remains passable for a great part of the year.

PIRÆUS, in *Ancient Geography*, a celebrated port to the W. of Athens, consisting naturally of three harbours or basins, which lay neglected till Themistocles put the Athenians on making it a commodious port; the Phalerus, a small port, and not far from the city, being what they used before that time. The Piræus, as Athens flourished, became the common emporium of all Greece. Hippodamus, an architect, celebrated as the inventor of many improvements in house-building, besides other monuments of his genius, was employed to lay out the ground. Five porticoes, which, communicating with one another, formed the *Long Portico*, were erected by the ports. Here was an *agora* or market-place, and, farther from the sea, another called *hippodamia*. Beside the vessels were dwellings for the mariners. A theatre was opened, temples were raised, and the Piræus, which surpassed the city in utility, began to equal it in dignity. The cavities and windings of Munychia, natural and artificial, were filled with houses; and the whole settlement, comprehending Phalerus and the ports of the Piræus, with the arsenals, the store-houses, the famous armoury of which Philo was the architect, and the sheds for 300, and afterwards 400 triremes, resembled the city of Rhodes, which had been planned by the same Hippodamus. The ports, on the commencement of the Peloponnesian war, were secured with chains. Sentinels were stationed, and the Piræus was carefully guarded.

The Piræus was reduced with great difficulty by Sylla, who demolished the walls, and set fire to the armoury and the arsenals. In the civil war it was in a defenceless condition. Calenus, lieutenant of Cæsar, seized it, invested Athens, and ravaged the territory of the state. Strabo, who lived under the emperors Augustus and Tiberius, observes that the many wars had destroyed the long walls, with the fortress of Munychia, and had contracted the Piræus into a small settlement by the ports and the temple of Jupiter the Saviour. (See Athens.)

Piræus, the seaport of Athens, stands on an isthmus joining to the mainland a rocky promontory overlooking the gulf of Salamis, 5 miles S.W. of Athens. The modern town has been entirely built since 1834, and contains many fine houses, four churches, six schools, a custom-house, and a lazaretto. The harbour is deep and good, though rather difficult of entrance; and a quay has recently been constructed capable of accommodating numerous vessels. The number of vessels belonging to the port in 1855 was 496, tonnage 18,331; in the same year there entered, exclusive of the coasting trade, 814 ships, tonnage 229,412; and there cleared 595, tonnage 173,736. The commerce of Piræus is great, and rapidly increasing in importance. The value of the imports was in 1854, L.155,840; and in 1855, L.270,280. The chief articles imported are corn from Turkey and Egypt, sugar, coffee, and all kinds of manufactured articles. The export trade is not so great; it amounted in value in 1854 to L.12,520, and in 1855 to L.28,080. Raw silk, wool, and leeches are sent to France; wine, cheese, honey, &c., to Turkey; hides, tobacco, &c., to Austria; and silk to Britain. Pop. (1852) 5526.

PIRANESI, Giovanni Battista, a very eminent Italian engraver, was born in the former half of the eighteenth century, and studied his art at Rome. The sight of the great architectural remains of that city soon kindled within him a flame of enthusiasm, which continued to burn throughout his career. With all the powers of his ardent genius in full play, he began to copy and restore the ruined edifices. His cunning hand faithfully imitated the actual remains of a fabric; his exquisite invention, catching the design of the original architect, supplied the parts that were wanting; his artistic skill introduced groups of vases, altars, tombs; and his scientific distribution of light and shade completed the picture, and threw a striking effect over the whole. One engraving after another was executed with unrivalled brilliancy; and a magnificent vision of the palaces and temples of the ancients continued to rise before the eyes of the public. As the great work went on, the zeal of the artist only waxed stronger. In course of time it was found necessary to call in the aid of all his children, and of several pupils. He did not, in fact, slacken in his exertions until in 1778 his enthusiasm was quenched by death. The plates of Piranesi were collected and preserved by his son and coadjutor Francesco. They were afterwards published, to the number of about 2000, in 29 vols. fol., Paris, 1835–37.

PIRANO, a town of the Austrian empire, in the kingdom of Illyria, and circle of Istria, stands at the extremity of a small peninsula separating the bay of Trieste from that of Largone, 13 miles S.W. of Trieste. It is well built, and contains an old castle and a Gothic cathedral. The harbour is large, but shallow; and there is good anchorage for large vessels in the roads. There are also docks for ship-building. Fishery and trade are actively carried on; the exports consisting of wine, oil, and salt from the works in the neighbourhood, which are the largest in Istria. Pop. 9200.

PIRATE (πειρατής), a sea-robber, or an armed ship which roams the seas without any legal commission, and seizes and plunders every vessel she meets with indiscriminately, whether friends or enemies.

PIRMASENS, or Pirmasenz, a town of Bavaria, in the circle of Palatinate, stands in a hilly and well-wooded country, 22 miles W.S.W. of Landau. It is well built, and surrounded by a wall; and contains several churches, and a palace, formerly the residence of Louis IX. of Hesse-Darmstadt. Shoes, musical instruments, straw-hats, mirrors, and other articles are manufactured here. Pop. 5600.

PIRNA, a town of Saxony, in the circle of Dresden, stands on the left bank of the Elbe, 10 miles S.E. of Dresden. It rises in terraces from the river up to the fortress of Sonnenstein, which is now used as a lunatic asylum. This fortress was stormed by the Swedes in 1639; and in 1758 the Prussians took it, and destroyed the outer works. The town is surrounded by walls, and entered by two gates. It contains a fine Gothic parish church, several other churches, an orphan hospital, and a handsome railway station. It is the seat of a court of law, and of several public offices. Calico, porcelain, beet-root sugar, &c., are manufactured here; and there is a considerable trade and navigation on the Elbe. In the vicinity there are good quarries of sandstone. Pop. 6592.

PIRON, Alexis, a French poet, was born at Dijon in July 1689, where his father was an apothecary, and where he passed more than thirty years in idle and destructive dissipation. He was at length obliged to quit the place of his nativity, in order to avoid the reproaches of his fellow-citizens, on account of an ode which he had written, and which gave them great offence. His relations not being able to give him much assistance, he supported himself at Paris by means of his pen, the strokes of which were as beautiful and fair as those of an engraver. He lived in the house of M. de Belleisle as his secretary, and afterwards with a financier, who, however, did not know that he had a man of genius under his roof. His reputation as a writer commenced with some pieces which he published for the

Pisa.

entertainment of the populace, and which showed strong marks of original invention; but what fully established his character in this way was his comedy entitled *Métromanie*, acted in 1738, and replete with genius, wit, and humour, and which was pronounced the best that had appeared in France since Regnard's *Gamester*. Piron's mischievous ingenuity was partly the cause which excluded him from the French Academy. "I could not," said he, "make thirty-nine people think as I do, and I could less think as thirty-nine do." He called that celebrated society "les invalides du bel esprit," and yet he often endeavoured to become one of those invalids. He died on the 21st of January 1773, at the age of eighty-three. He had prepared for himself the following characteristic epitaph:—

Ci gît Piron, qui ne fut rien,
Pas même académicien.

A collection of his works appeared in 1776, in seven vols. 8vo, and nine vols. 12mo. The principal pieces are,—*L'Ecole des Pères*, a comedy acted in 1728 under the title of *Fils Ingrat; Callisthène*, a tragedy, the subject of which is taken from Justin; *L'Amant Mysterieuse*, a comedy; *Gustave Wasa* and *Ferdinand Cortez*, two tragedies, some scenes of which discover an original genius, but the versification neither pleases the ear nor affects the heart; *Métromanie*, a comedy; *Les Courses de Tempe*, an ingenious pastoral, in which the manners both of the town and country are pleasantly drawn; with some odes, poems, fables, and epigrams. In this last kind of poetry he was very successful, and he may be placed after Marot and Rousseau. Excepting *Métromanie, Gustave Wasa, Les Courses de Tempe*, some odes, about twenty epigrams, three or four fables, and a few epistles, the rest of his works are but indifferent, and have no claim to any extraordinary merit.

PISA, a town of the grand duchy of Tuscany, capital of the province of the same name, in a fertile plain on both sides of the Arno, 8 miles above its mouth, and 45 W. of Florence. It is surrounded by walls and ditches, about 6 miles in circuit, and is entered by six gates. A great part of the area thus inclosed is occupied by gardens, or entirely unoccupied; and this gives the outer part of the town a very dreary and decayed appearance. But the central part has no lack of cheerfulness and animation; its broad though irregular streets are lined with many stately palaces and gorgeous marble buildings. Both sides of the Arno are lined with quays, and with a street called the Lung d'Arno containing many splendid edifices. Three bridges span the river; one of them, of marble, is among the finest structures of the kind in Europe. In a large open grass-grown space, at the N.W. corner, stand the four most remarkable edifices,—the cathedral, baptistery, leaning tower, and *Campo Santo*, or cemetery,—all built of white marble in the same style, beautifully grouped together, apart from the other buildings. The cathedral, whose architect was Buschetto, is a splendid building, founded 1067, and consecrated 1118. It is in the form of a cross, with a nave, 4 aisles, transepts, and choir. Its whole length is 311 feet; breadth of the nave and aisles, 106 feet; length of the transepts, 237 feet; breadth of the western front, 116 feet; height from the pavement to the summit of the roof, 112 feet. In the centre rises an elliptical dome, adorned on the outside with eighty-eight columns, and supported in the interior by four piers. The nave is separated from the aisles by twelve Corinthian columns on each side; and these are surmounted by arches; and these again by a number of smaller shafts. The cornices, as well as the bases and capitals of the columns, have been formed by Buschetto with great skill from various fragments of antiquity brought from different places. The twelve altars in the nave and transepts are said to have been designed by Michael Angelo. They are simple in general design, and have much variety in their details. The high altar is heavy; richly and elaborately ornamented. The church also contains many paintings and painted windows, a fine pulpit, and three magnificent bronze doors. It has suffered much from the sinking of the ground, and was greatly injured by a fire in 1596. In the nave is hung a large bronze lamp, the oscillations of which are said to have suggested to Galileo the theory of the pendulum. Opposite the west front of the cathedral stands the baptistery, a circular building 116 feet in diameter, surmounted by a conical dome 102 feet high. In the interior there is a corridor, raised on three steps, running round the building, for the accommodation of spectators of the rite of baptism, which is administered at a large font in the centre. It is of white marble, carved, and inlaid with coloured stones; and has in the centre an image of St John on a column. The baptistery contains a remarkably beautiful pulpit by Niccola Pisano. The exterior of the building is adorned with sculptures and statues. The famous leaning tower of Pisa stands at the other end of the cathedral, overhanging its base more than 13 feet. In shape it is cylindrical, 53 feet in diameter at the base, and 179 feet high; and it consists of eight tiers of columns supporting semicircular arches, and forming as many galleries round the tower. Its leaning position is probably accidental, owing to the sinking of the soil; but it is quite safe, as the centre of gravity falls considerably within the base, and the walls are strengthened with iron bars. The view from the top is extensive and beautiful. The Campo Santo, which stands to the north of the other edifices, is of an oblong form, 415 feet long by 138 broad, and is surrounded by an arcade 34 feet broad and 46 high. In the centre is a mound of earth, said to have been brought from Mount Calvary, and formerly used as a burial-place for its supposed miraculous qualities. The surrounding arcade contains numerous ancient and modern sculptures, and the walls are covered with frescos, some of which are much admired. Pisa contains numerous other churches, some of them remarkable for the beauty of their architecture, or of the pictures they contain: in that of St Catherine is still preserved the pulpit from which Thomas Aquinas used to preach. There are also numerous fine palaces in Pisa. The university of Pisa, founded in the fourteenth century, was formerly one of the most celebrated in Italy; but its faculties of law and philosophy have recently been transferred to Siena. It has nearly 300 students. In the quadrangle stands a fine marble statue of Galileo, erected in 1839. Attached to the university are a library, a museum of natural history, and a botanic garden. The town contains an academy of fine arts, several schools, hospitals, a theatre, &c. It is defended by a citadel to the north, and a fortress to the south of the Arno. Some remains of antiquity, especially of baths, still exist at Pisa. The manufactures of the town are few and unimportant, consisting of cotton and woollen stuffs, soap, white lead, vitriol, &c. The trade has very much declined since the rise of Leghorn. Of the origin of the ancient *Pisæ*, which occupied the same site as the modern town, several traditions are given, but little is known with certainty: whether founded by Pelasgians; or, as the poets would have us to believe, by Greeks from the Elean Pisa; or, according to a third account, by Etruscans. It was at one time Etruscan; but its early fightings with the Ligurians, and its exploits in piracy and trade, are buried in the dim obscurity of those early times. We do not even know how, nor exactly when, *Pisæ* became subject to the growing power of Rome. It certainly was a dependent ally of the republic before the second Punic war, and its port was used as a place of departure for Spain and Gaul. It was also for a long time the frontier city against the Ligurians; and suffered frequently from the invasions of these people in their protracted wars with Rome. In 180 B.C. a colony was established here, and it soon be-

came one of the most flourishing places in Etruria; but its history again becomes obscure in the decline of the Roman empire. It passed successively under the dominion of the Goths, Lombards, and Franks, when they conquered Italy; and subsequently became virtually an independent state, owning allegiance nominally to the marquises of Tuscany, who were vassals of the emperor. In this condition the city gradually rose to much importance, and maintained a fleet of galleys, which was employed with much success against the Mohammedan pirates on the coasts of the Mediterranean. They even went so far as to conquer, in 1022, the island of Sardinia, with the assistance of the Genoese, and afterwards that of Corsica, which they received in 1091 as a fief from the Papal See. This was the period of their greatest prosperity, when the city was decorated by its magnificent ecclesiastical edifices. For about four centuries Pisa was one of the most powerful maritime powers in the Mediterranean; but this high rank was lost in the course of the long wars with Genoa, which began in 1070, and resulted in the destruction of the harbour of Pisa in 1290. Meanwhile the city was also engaged in the wars between the Guelphs and Ghibelines in Italy. Pisa supported the latter or imperial party, and was attacked by Florence, the head of the opposite side. It was in these contentions that Ugolino, Count Gherardesca, whose story has been rendered famous by Dante, after being for ten years captain-general of Pisa, was displaced by the Pisans for favouring the Guelph party, and died by starvation, with his sons and grandsons, in the Tower of Famine, which is still pointed out in the city. Peace was at last made with Florence in 1293, and with Genoa in 1299; and the city, now shorn of its naval power, afterwards lost by the same unhappy feuds its independence too. War soon after broke out anew, and Pisa had to contend single-handed against the whole power of Tuscany. In 1326 they lost Sardinia, after repeated attempts to retain it. But the city itself long held out against its foes, and was only reduced by domestic feuds and treachery under the power of Florence in 1406; the chief families proudly withdrawing to Sardinia and Sicily. On the French invasion in 1494, Pisa made a last effort for independence, but was a second time conquered by Florence in 1509. Its liberty was now lost for ever; and it has continued since that time subject to Florence, whose fortunes it has shared. Pisa is celebrated as the birthplace of the famous Galileo. Pop. 25,000. The province of Pisa has an area of 1176 square miles. Pop. (1857) 229,730.

PISA, LEONARDO. See ALGEBRA.

PISANO, ANDREA, an eminent Italian sculptor, born at Pisa about 1280, and had the honour at a very early age of introducing a new style of art. Taking as his models the collection of ancient statues which were preserved in the cathedral and the Campo Santo of his native city, and also adopting Giotto's new method in design, he improved immensely upon the coarse and infelicitous manner of his predecessors, and rose to the first place in his profession. As a result of this proficiency, it came to pass that Pisano was summoned by the Florentines to take up his abode amongst them, to adorn their city, and to receive their patronage. He was employed to ornament with statues of the apostles and saints the façade of Santa Maria del Fiore. He was engaged during twenty-two years in executing the great gate of bronze for the church of San Giovanni, a work which still remains a proof of his genius. Many other commissions, both in sculpture and in architecture, continued to be entrusted to him until he died in 1345, surrounded with affluence, and dignified with the titles of citizen and magistrate.

PISANO, *Niccola*, a very celebrated Italian sculptor and architect, was born at Pisa about the beginning of the thirteenth century. The restoration of art was the great task of his life. Studying the ancient sarcophagi in his native place, he acquired a style closely resembling the antique. Then being extensively employed both as a sculptor and an architect, he gave in many different cities of Italy many specimens of a new and improved manner of design, invention, and composition. The urn at Bologna, which procured for him the name of "Niccola of the Urn," and the marble pulpit in the church of San Giovanni at Pisa, which was sculptured over with the "Universal Judgment," were especially instructive to the artists of the day. Architects, sculptors, and even painters, felt themselves stimulated and assisted in their several pursuits. Nor did his influence cease when he died in 1278. The revival in art was continued by his son Giovanni, who died in 1320, leaving many memorials throughout Italy of his excellence in sculpture and architecture.

PISCINA, a large basin in a public place or square, where the Roman youth learned to swim, and which was surrounded with a high wall, to prevent filth from being thrown into it. This word is also used for a lavatory amongst the Turks, placed in the middle court of a mosque or temple, where the Mussulmans wash themselves before they offer their prayers.

PISEK (Lat. *Piseca*), a town of Bohemia, capital of a circle of the same name, stands on the Wottawa, here crossed by a fine bridge, 24 miles W.S.W. of Tabor, and 55 S.S.W. of Prague. It is surrounded by an ancient wall, and contains a castle, several handsome churches, a grammar school, military academy, &c. There are here an iron-wire work, cotton factories, dye-works, and manufactories of musical instruments. Pisek is the seat of law courts for the circle. Pop. (1846) 6092.

PISIDIA, a district of Asia Minor, originally included within Pamphylia or Phrygia, was constituted a separate province in the division of the Roman empire under Constantine the Great. It was bounded on the N. by Phrygia, on the W. by Phrygia and Lycia, on the S. by Pamphylia, and on the E. by Cilicia and Isauria. The physical character of the country was wild and variegated. Offshoots from Mount Taurus extended themselves in all directions; a rich fertile valley occasionally intervened; and a chain of lakes inclosed the landscape. The habits of the inhabitants were in accordance with their mountain home. Under their original name of *Solymi*, they lived a lawless, free-booting life, spurning the advance of civilization, and daring any invader to follow them into their rugged fastnesses. Rome conquered them only to find that their spirit of independence was not broken. They would not brook the establishment of a single garrison or colony. It was only their towns that paid tribute. They carried their invincible disposition down to modern times; and under the appellation of *Karamanians* they still continue to be wild, rapacious, and suspicious of strangers.

The principal towns of Pisidia were Selge, Cremna, Sagalassus and Termessus.

PISISTRATUS, the son of Hippocrates, was descended from one of the most illustrious families of Athens, which claimed to derive their origin from Codrus, and through him traced their pedigree to Nestor and the Pylian kings. At the time that he began to take part in the political affairs of his country, there were three factions struggling for power; those of the lowlands, highlands, and coast. Megacles, chief of the great family of the Alcmæonidæ, took the lead of the coast party, whilst Pisistratus headed the democratical faction of the highlanders. Solon had tried to calm their passions by the wisdom of his laws, but the contending parties had refused to submit; and when he returned, after an absence of several years, he found much confusion, and everything tending towards a state of anarchy. Pisistratus was determined to secure to himself the chief authority in the government; and by pretending to the people that he was in danger of his life, he

obtained a guard for the security of his person, and it was not long before he made himself master of the citadel. He thus became what was afterwards called Tyrant of Athens, B.C. 560; though Herodotus expressly states that all the laws continued in force, and that the constitutional powers of the magistrates were not in the least restricted. Solon used to say that, were it not for his ambition, there would not be a better disposed man, or a more worthy citizen, in Athens. Though Solon was no doubt deeply mortified that his countrymen were unable to maintain the political constitution which he had formed for them, it does not appear that he broke off all connection with Pisistratus. He took the wiser course of trying to direct his measures for the benefit of his country, and assisted him in the administration of the commonwealth. How long Pisistratus continued to maintain himself in power is not stated, but he was at last driven into exile by the two parties of Megacles and Lycurgus uniting their strength. A dispute between the victors induced Megacles to propose an accommodation with Pisistratus, upon condition that he should marry his daughter; and this was at once acceded to. A quarrel, however, with Megacles again took place, and Pisistratus was obliged to retire to Eretria in Eubœa. Here he continued to increase his influence till a favourable opportunity presented itself of regaining his former position. It was in the eleventh year of his second banishment that he returned, when the Athenians flocked to his standard, and, in the words of Herodotus, preferred tyranny to liberty. He defeated the Alcmæonidæ, and entered Athens, promising safety to all who returned quietly to their homes. Some of the leaders were of course banished, but the great body of the people seem to have benefited by the change. He was kind to the poor, and introduced many laws and regulations which were highly advantageous to his country. He was a lover of learning, and is said to have been the first who arranged the poems of Homer as we now have them. Cicero speaks of his eloquence in the highest terms. He continued to direct the administration of Athens till his death, B.C. 527, thirty-three years after his first usurpation, of which time he ruled seventeen years. He left two sons, Hippias and Hipparchus, who succeeded to his power.

PISTICCIO, a town of Naples, in the province of Basilicata, between the Basiento and the Salandrella, 15 miles S. by W. of Matera. It contains several churches, a convent, hospitals, and manufactories of woollen cloth. Pisticcio was nearly destroyed by an earthquake in 1688. Pop. 6200.

PISTOJA, or PISTOIA (anc. *Pistoria*), a town of Tuscany, in the province of Florence, near the Ombrone, not far from the opening of the valley of that river into that of the Arno, 21 miles N.W. of Florence. It is inclosed with lofty ramparts bearing the Medici arms, and covers a large extent of ground; though, as the population is not commensurate with the size of the town, much of the space is occupied with gardens. The streets and squares are broad, and lined with handsome buildings, but they are pervaded with that dulness which characterizes many Italian towns. Many of the public buildings possess much interest. The cathedral has been built at different dates, and the interior modernized in 1838 and 1839. Though not very remarkable for architecture, it contains a great variety of paintings, sculptures, and monuments. Opposite the cathedral is a baptistery in the Italian-Gothic style. The church of St Andrew, which was probably the original cathedral, contains a finely-carved pulpit by Giovanni da Pisa. Several of the other churches in the town are remarkable for their architecture or the paintings they contain. The Palazzo Pretorio and the Palazzo della Communita, Italian-Gothic buildings of the thirteenth century; the episcopal palace, built in 1787; and other similar buildings, are among the ornaments of Pistoja. The town has also several convents, a large hospital founded in 1218, a clerical seminary and other schools, two good public libraries, and a theatre. Pistols are said to have been so named because first made at Pistoja; but they are not now manufactured here. Musket-barrels, cutlery, nails, iron wire, musical instruments, silk fabrics, &c., are produced. Some trade is carried on in silk, straw bonnets, and other articles. *Pistoria* was originally an Etruscan town, but no remains of this period have been preserved. It was a municipal town of small importance under the Romans, and is only historically remarkable for its proximity to the scene of the final defeat and death of Catiline, B.C. 62. Under the Lombards, Pistoja was a place of importance, and was surrounded by walls. After being for some time independent, it became subject to Florence about the middle of the twelfth century. From the dissensions of the Pistojan family of Cancellieri arose in 1296 the factions of the Bianchi and Neri, whose contentions spread to Florence, and involved it, as well as Pistoja, in the greatest calamities. Finally, in 1306, Pistoja was surrendered to the Neri, who destroyed its walls, a blow from which the town never recovered. Pop. 12,387.

PISTON, in pump-work, is a short cylinder of metal or other solid substance, fitted so as to slide air-tight in the cavity of the barrel or body of the pump.

PITCAIRN ISLAND, a solitary island in the Pacific Ocean, S. Lat. 25. 4., E. Long. 130. 8. It is about 7 miles in circumference, and is elevated, and surrounded with steep cliffs. The highest peak on the island is 1046 feet above the sea. The N. coast, where the settlement was, presents a very fine appearance, the ground, which is thickly wooded, rising in the form of an amphitheatre, flanked by steep cliffs. The coasts of the island are for the most part inaccessible to vessels, as they are rocky and exposed to a heavy swell. There are a few small coves, and some traces of coral, but no coral reefs. The island has three landing-places; two having a steep ascent from the beach, and the other, which was generally used by the inhabitants, is very difficult of access. The structure of the island is sandstone, with particles of iron; and volcanic rocks also exist. The soil is deep and rich, consisting of clay mixed with sand. The climate is healthy, and the temperature varies from 59° to 89°. Bananas, plantains, yams, sweet potatoes, cocoa-nut trees, fig trees, mulberry trees, screw pines, and other vegetables are indigenous; while the bread-fruit tree, tobacco, &c., have been introduced. Swine, goats, and domestic fowls are the principal animals. The island was discovered by Carteret in 1767, and named after one of his officers called Pitcairn, who was the first to see it. Its chief interest, however, is connected with the mutineers of the Bounty and their descendants, who lived on it for upwards of sixty years. It was in 1790 that nine of these mutineers landed there, along with six men and twelve women from Tahiti. Although the island was then uninhabited, there is little doubt, from the remains that were subsequently discovered, that it was at one period occupied by natives, who had either become extinct or migrated to some other land. Violent quarrels soon began to break out among the settlers, excited by the use of spirits that were distilled from a root found on the island; and these feuds proved so bloody, that within ten years after the original settlement on the island, the whole of the Tahitian men and all the Englishmen but one, had perished. John Adams, the only surviving mutineer, having a Bible and Prayer-Book that had been saved from the Bounty, was struck on their perusal with remorse for his crimes; and becoming a true Christian, began, with the aid of these books, to instruct the Tahitian women who remained, and their children by the white men. The result of this has been, that a very remarkable community grew up in this lonely isle, distinguished, according to the testimony of all who have visited them, by the kindness and gentleness of their character, and

the virtuous simplicity of their life. As the number of the inhabitants increased, it was feared that the island might not be sufficient for their sustenance; and accordingly, in March 1831, the Pitcairn islanders were conveyed by the British government to Tahiti; but they being dissatisfied with their new position, and having lost several of their number by sickness, returned soon after to their original settlement. In May 1856 the whole community finally left Pitcairn Island, and landed on the 8th of June at Norfolk Island, where land had been allotted to them by the British government. (See NORFOLK ISLAND.)

PITCAIRNE, ARCHIBALD, an eminent physician, was born at Edinburgh on the 25th December 1652. Having taken his master's degree at the university of his native city in 1671, and having spent some time in the study of law, he afterwards turned his attention to medicine. He prosecuted the latter study with great ardour and success for five years in France, and took his medical degree at Rheims on the 13th of August 1680. Returning to Edinburgh, he entered upon a distinguished professional career. On the foundation of the Royal College of Physicians in 1681, Pitcairne was chosen a fellow of that learned body. His publication of *Solutio Problematis de Inventoribus* in 1688 extended his professional reputation, and had the effect of procuring for him the chair of physic at Leyden in 1692. The students of that venerable university—and among them were Boerhaave and Mead—found the Scot too abstract and geometrical in his medical prelections for their tastes, which led to Pitcairne's return to his native city during the following year. He took to his former practice, and soon gained a British reputation as a skilful physician. What leisure he had he contrived to occupy in the composition of satirical verses, which seem to have pleased his friends while they exasperated his enemies. His satirical propensities, combined with his violent prejudices as a Jacobite and an Episcopalian, and a relish for questionable jests, led him into contests, professional and otherwise, both frequent and fierce. The ferocious attack to which he was subjected in the *Apollo Mathematicus*, published in 1695, and ascribed to the pen of Dr Eyzat, was the precursor to a rancorous and disreputable pamphleteering war, conducted by the members of the Royal College of Physicians. At the outset of the squabble Pitcairne rashly unseated himself in the Royal College. He retired in sullen protest, but overtures of reconciliation and pacific resolutions having been duly framed and agreed upon, the breach was got healed, and the suspended doctor resumed his seat after a six years' absence. In 1701 Pitcairne published a volume of eight dissertations at Rotterdam, entitled *Archibaldi Pitcarnii Dissertationes Medicæ*, which he enlarged by the addition of six new discourses in 1713. Of these fourteen dissertations an English translation was soon afterwards published in 8vo, by Drs Sewell and Desaguiliers, under the title of *The Whole Works of Dr Archibald Pitcairne published by himself; wherein are discovered the true Foundation and Principles of the Art of Physic, with Cases and Observations upon Distempers and Medicines.* A tract containing *Epistola Archimedis ad Regem Gelonem, Albæ Græcæ reperta anno æræ Christianæ* 1688, appeared at Amsterdam in 1706. Dr Pitcairne died on the 26th October 1713, in the sixty-first year of his age.

Four years after the author's death appeared a volume made up mainly of notes of his lectures, taken by his pupils. A complete collection of his works in Latin prose, with the addition of a few poems, entitled *Archibaldi Pitcarnii, Medici celeberrimi Scoto-Britanni, Opera Omnia Medica*, appeared at Leyden, 4to, 1737. To Pitcairne also is assigned a share in the composition of *The Assembly, a Comedy by a Scots Gentleman*, London, 1722, and Edinburgh, 1766; a performance characterized more by ribaldry and profanity than by wit or humour. To him also is ascribed the authorship of *Babell, a Satirical Poem on the Proceedings of the General Assembly in the year* 1692, Edinburgh, 1830. His Latin poems, of which an edition was published under the title of *Selecta Poemata*, Edinburgh, 1727, were much esteemed during his own day. They are chiefly to be admired for their point and pungency. Pitcairne belongs to the mathematical and mechanical school of physic; and in the annals of medicine his name is honourably mentioned with those of Borelli, Bellini, and other great masters of the mathematico-medical art. Despite his numerous failings, he seems to have been a man of a highly benevolent disposition; and he is said to have been in the habit of relieving many who knew not their benefactor. "In short," says Dr Sewell, "he was one of the greatest and most useful men in his profession this age has produced; of a free and universal genius, a good orator, poet, and philosopher. He was of a pleasant engaging humour. Life sat very easy upon him in all its circumstances. He despised many, but hated none."

PITCH. See TAR.

PITEA, or NORTH BOTHNIA (Swed. *Norrbotten*), a lân or province of Sweden, lying between N. Lat. 65. and 69., E. Long. 15. 15. and 24. 10., is bounded on the N. and W. by Norway, S. by the lan of Umea, and E. by the Gulf of Bothnia and Russian Lapland; area, 32,934 square miles. A great part of this country, lying to the N., is occupied by the largest plain in Sweden. This extends from the foot of the Kiolen Mountains, which separate it from Norway, to the shore of the Gulf of Bothnia; and, with the exception of a few small hills, it is entirely flat, covered here and there with marshes and small lakes. At the foot of the mountains the land is 1300 feet above the sea; but it gradually slopes downwards, and about midway, between the mountains and the sea, has only an elevation of 400 feet. In the higher portions of this plain dwarf birches are almost the only growth; farther down these appear as trees, and pines also grow; and near the sea the whole country is covered with forests, except the banks of the rivers, where the soil is cultivated. This plain extends from the Russian frontier as far to the S.W. as the Lulea, beyond which river the country consists partly of mountains and partly of plains and valleys. The Kiolen range, which here attains its highest elevation in Mount Sulitelma, sends off numerous ridges towards the E., which are separated by wide valleys. The greater part of this country is covered with wood, except in the more lofty regions. Near the Bothnian Gulf, however, farming is carried on to some extent. The principal rivers of Pitea are,—the Tornea, with its affluent the Muonio, forming the boundary between Sweden and Russia; the Calyx, the Lulea, and the Pitea; all flowing from the mountains into the Gulf of Bothnia, and most of them flowing through numerous lakes. The capital of the lan is Pitea, a town of 1545 inhabitants, which stands on an island at the mouth of the river of the same name, and has a harbour and docks. Lulea and Tornea are the chief other towns. Pop. of the lân (1855), 60,108.

PITHIVIERS, a town of France, capital of an arrondissement in the department of Loiret, on the top and sides of a hill near the Oeuf, 25 miles N.E. of Orleans. It is pretty well built, and contains the ruins of a square castle, erected in the tenth century. Linen, hosiery, farming implements, &c., are made here; and the place is famous for almond cakes and lark pies. Some trade is carried on in saffron, wool, wine, honey, &c. Pop. (1855) 4348.

PITHOU, PIERRE, a Frenchman of great literary eminence, was descended from an ancient and noble family in Normandy, and born at Troyes in 1539. His taste for literature early showed itself, and his father cultivated it to the utmost. He first studied at Troyes, and was subse-

quently sent to Paris, where he became the scholar and friend of Turnèbe. Having finished his pursuits in languages and the belles lettres, he was removed to Bourges, and placed under Cujas to study the civil law. On the removal of Cujas to Valence, Pithou followed him, and continued to profit by his lectures until the year 1560. In 1563 Pithou published his *Adversaria Subcesiva*, a work highly applauded by Turnèbe, Lipsius, and other learned men, and which laid the foundation of that extensive fame which he subsequently acquired. Soon after this, Henri III. advanced him to some considerable posts, in which, as well as at the bar, he acquitted himself most creditably. Pithou, being a Calvinist, narrowly escaped being involved in the massacre of St Bartholomew in 1572; a circumstance which seems to have frightened him out of his religion, which he soon afterwards abjured in favour of the Catholic faith. He died upon his birthday in the year 1596.

Pithou published a great number of works upon law, history, and classical literature; and he gave several new and correct editions of ancient writers. He was the first who made the world acquainted with the *Fables* of Phædrus, and the little anonymous poem entitled *Pervigilium Veneris*, from manuscripts in his possession. He published his master Cujas' *Observations on the Roman Law*, accompanied with remarks and annotations of his own. We are also indebted to him for the discovery of the laws of the Visigoths, which he published in 1579. His principal writings on the canon law are,—*Corpus Juris Canonici*, 1687, 2 vols. folio; *Codex Canonum vetus ecclesiasticum*, in folio; *Gallicæ Ecclesiæ in schismate Status*, in 8vo; and *A Treatise on the Liberties of the Gallican Church.* Pithou also published an edition of the *Capitularies*, a series of French annalists, from the eighth to the thirteenth century; *Memoirs of the Counts de Champagne and de Brie;* the *Historical Fragments of St Hilarius*, containing curious particulars respecting the Council of Rimini; and the writings of several ancient doctors of the Gallican Church, of which several had until then remained inedited. We are likewise indebted to him for editions, from the best manuscripts, of several ancient geographers, the *Itinerary from Bordeaux to Jerusalem*, the works of Salvian, the works of Juvenal and Persius, Petronius, and the moral distichs attributed to Cato.

PITISCUS, SAMUEL, a learned philologist, was born at Zutphen in 1637, and became rector of the college of that city, and afterwards of St Jerome at Utrecht, where he died on the 1st of February 1727. He wrote a *Lexicon Latino-Belgicum*, 1704, in 4to; a *Lexicon Antiquitatum Romanorum, in quo ritus et antiquitates, tum Græcis et Romanis communes, tum Romanis particulares exponuntur*, Leeuwarden, 1713, in 2 vols. folio; and he published good editions, with prefaces and notes, of Quintus Curtius, Polyhistor, Solinus, with the Observations of Salmasius on Pliny, Suetonius, Aurelius Victor, the *Pantheon Mythicum*, and the *Antiquitates Romanæ* of Rosini. In 1685 Pitiscus announced a *Lexicon Catullo-Tibullo-Propertianum*, which unfortunately never appeared.

PITOT, HENRI, descended of a noble family of Languedoc, was born at Aramon, in the diocese of Usez, on the 29th of May 1695. He studied the mathematics without a master; and went to Paris in 1718, where he formed a close friendship with the illustrious Reaumur. In 1724 he was admitted a member of the Royal Academy of Sciences at Paris, and in a few years he rose to the rank of pensioner. Besides a great number of Memoirs printed in the collection of that society, he published in 1731 the *Theory of the Working of Ships*, in one volume 4to, a work of considerable merit, which was translated into English, and caused the author to be admitted into the Royal Society of London. In the year 1740 the States-General of Languedoc made choice of him as their chief engineer, and at the same time gave him the appointment of inspector-general of the canal which unites the two seas. The city of Montpellier being in want of water, Pitot brought from a distance of three leagues the water of two springs, which furnish a plentiful supply of that necessary article. The water is brought to the magnificent Place du Peyron, and thence distributed throughout the city. This work is the admiration of all strangers. In 1754 Pitot was honoured with the Order of St Michael. He died in 1771, aged seventy-six. Pitot was a practical philosopher, and a man of uncommon probity and candour. He was a member of the Royal Society of Sciences of Montpellier, before which his *éloge* was pronounced in 1772 by M. de Ratte, perpetual secretary, in presence of the states of Languedoc; and in the Royal Academy of Sciences of Paris, the same honour was done him by the Abbé de Fouché, who was then secretary.

PITS, or PITSEUS, JOHN, an English biographer, was born in 1560, at Aulton in Hampshire, and educated at Wykeham's school, near Winchester, where he remained until he was about eighteen years of age, when he was sent to New College, Oxford, and admitted a probationer. Having continued in that university not quite two years, he left the kingdom as a voluntary exile, and retired to Douay. He thence proceeded to the English college at Rheims, where he remained about a year, and then went to Rome, where he continued a member of the English college nearly seven years, at the expiration of which he was ordained priest. In 1589 he returned to Rheims, where, during two years, he taught rhetoric and the Greek language. He then quitted Rheims on account of the civil war in France, and retired to Pont-à-Mousson, in Lorraine, where he took the degrees of Master of Arts and Bachelor in Divinity. From this he travelled into Germany, and resided a year and a half at Triers. He then visited several of the principal cities in Germany, and continuing three years at Ingoldstadt in Bavaria, took the degree of Doctor in Divinity. Having made the tour of Italy, he returned once more to Lorraine, where he was patronized by the cardinal of that duchy, who preferred him to a canonry of Verdun; and about two years afterwards he became confessor to the Duchess of Cleves, daughter of the Duke of Lorraine. During the leisure he enjoyed in this employment, he wrote in Latin the *Lives of the Kings, Bishops, Apostolical Men, and Writers of England.* The last of these, commonly known and quoted by the title of *De Illustribus Angliæ Scriptoribus*, was published after his death. The three others still remain in manuscript amongst the archives of the collegiate church of Liverdun. The Duke of Cleves having died about twelve years after Pits had been confessor to the duchess, the latter returned to Lorraine, attended by our author, who was promoted to the deanery of Liverdun, which, with a canonry and officialship, he enjoyed till the close of his life. He died in 1616, and was buried in the collegiate church. Pits was undoubtedly a scholar, and not an inelegant writer; but he is justly accused of ingratitude to Bale, from whom he borrowed his materials, without acknowledgment. He quotes Leland with great familiarity, without ever having seen his book; his errors are innumerable, and his partiality to the Catholic writers is obvious. Pits likewise wrote *De Legibus*, Triers, 1592; *De Beatitudine*, Ingoldst., 1595; *De Peregrinatione*, Dusseld., 1604. (See *Biog. Brit.*)

PITT, CHRISTOPHER, an English poet, celebrated for his translation of Virgil's *Æneid*, was the son of a physician, and was born at Blandford in the year 1699. Having studied four years at New College, Oxford, he was presented to the living of Pimperne in Dorsetshire, which he held during the remainder of his life. He had so poetical a turn, that whilst he was a school-boy he wrote

two large folios of manuscript poems, one of which contained an entire translation of Lucan. He was much esteemed while at the university, particularly by the celebrated Dr Young, who used familiarly to call him his son. Pitt gained very high reputation by his excellent English version of Vida's *Art of Poetry*. This success animated him to another undertaking demanding much greater ability and judgment. This was his metrical translation of Virgil's *Æneid*. He had Dryden as his rival, and he naturally observed his failures and avoided them. On comparing the two versions, that of Dryden leads the reader forward by his general vigour and sprightliness, while that of Pitt frequently stops him to contemplate the excellence of a single couplet; Dryden's faults are forgotten in the hurry of delight, Pitt's beauties are neglected in the langour of a cold and listless perusal. In short, that of Pitt pleases the critics, Dryden the people. He likewise wrote a Miscellany, which appeared in 1727. This amiable poet died in the year 1748, without leaving, it is said, one enemy behind him.

PITT, EARL OF CHATHAM.

Pitt, *William*, first Earl of Chatham, a celebrated British statesman and orator, was born on the 15th of November 1708. He was the youngest son of Mr Robert Pitt of Boconnock in Cornwall, and grandson of Mr Thomas Pitt, governor of Fort St George in the East Indies in the reign of Queen Anne, who sold an extraordinary diamond to the King of France for L.135,000, and thus obtained the name of *Diamond Pitt*. The subject of this notice was educated at Eton, whence, in January 1726, he was removed to Trinity College, Oxford, which he entered as a gentleman commoner. Here the superiority of his mind soon attracted notice, and he was also remarked for his powers of elocution; but at the age of sixteen he experienced the first attacks of an hereditary and incurable gout, which continued at intervals to torment him during the remainder of his life. He quitted the university without taking a degree, and visited France and Italy, whence he returned without having received much benefit from his excursion. His father was now dead, and as he had left very little to the younger children, it became necessary that William should choose a profession. He decided for the army, and a cornet's commission was procured for him in the Blues. But, small as his fortune was, his family had the power and the inclination to serve him. At the general election of 1734 his elder brother Thomas was chosen both for Old Sarum and for Oakhampton. When Parliament met in 1735 Thomas made his election for Oakhampton, and William was returned for Old Sarum. At the time when he obtained a seat in Parliament he was not quite twenty-one years of age. The intention of bringing him thus early into Parliament was to oppose Sir Robert Walpole, who had now been fourteen years at the head of affairs. In fact, his abilities soon attracted notice, and he spoke with great vehemence against the Spanish convention in 1738. It was on the occasion of the bill for registering seamen in 1740, which he opposed as arbitrary and unjustifiable, that he is said to have made his celebrated reply to Walpole, who had taunted him on account of his youth; but the language of that reply, as it now stands, is not the diction of Pitt, who may have said something like what is ascribed to him, but of Dr Johnson, who then reported, or rather wrote, the debates for the *Gentleman's Magazine*. In 1746 Pitt was appointed joint vice-treasurer of Ireland; and in the same year treasurer and paymaster-general of the army, and a privy councillor. The office of paymaster he discharged with such inflexible integrity, even refusing many of the ordinary perquisites of office, that his bitterest enemies could lay nothing to his charge, and he soon became the darling of the people. The old Duchess of Marlborough, who carried to the grave the reputation of being decidedly the best hater of her time, and who most cordially detested Walpole and his associates, left Pitt a legacy of L.10,000, in consideration of "the noble defence he had made for the support of the laws of England, and to prevent the ruin of his country." In the year 1755 Pitt, deeming it necessary to offer a strong opposition to the continental connections then formed by the ministry, resigned his places, and remained some time out of office. But his resignation having alarmed the people, he was, in December 1756, called to fill a higher office, and appointed secretary of state. In this situation, however, he was more successful in obtaining the confidence of the public than in conciliating the favour of the king, some of whose predilections he had conceived himself bound to oppose. The consequence was, that soon afterwards Pitt was removed from office, whilst Legge, with some others of his friends, were at the same time dismissed. But the nation had a mind not to be deprived of his services. The most exalted notion had been formed of him throughout the country; his patriotism was believed to be as pure and disinterested as his adilities and eloquence were confessedly transcendent; and his colleagues shared in the same general favour. In a word, the opinion of the country was so strongly expressed, both directly and indirectly, that the king thought it prudent to yield; and on the 25th of June 1757 Pitt was again appointed secretary of state, Legge became chancellor of the exchequer, and the other arrangements were made conformably to his wishes. Pitt was now in effect prime minister; and the change which soon took place in the aspect of public affairs evinced the ability of his measures, and the vigour of his administration. His spirit animated the whole nation; and his activity pervaded every department of the public service. His plans were ably conceived and promptly executed; and the depression, which had been occasioned by want of energy in the cabinet, and ill success in the field, was followed by exertion, confidence, and triumph. The whole fortune of the war was changed. In every quarter of the globe success attended our arms. The boldest attempts were made both by land and by sea, and almost every attempt proved fortunate. In America the French lost Quebec; in Africa they were deprived of their principal settlements; their power was abridged in the East Indies; in Europe their armies were defeated; and, to render their humiliation more complete, their navy, their commerce, and their finances were almost ruined. Amidst this full tide of success George II. died, on the 25th of October 1760, and was succeeded by George III., who ascended the throne at a time when the French court had just succeeded in obtaining the co-operation of Spain.

The treaty commonly called "family compact" had been secretly concluded; but the English minister, correctly informed of the hostile intentions of Spain, determined to anticipate that power, and strike a blow before this new enemy should be fully prepared for action. He therefore proposed in the council an immediate declaration of war against Spain, urging forcibly that the present was the favourable moment for humbling the whole House of Bourbon. But when he stated this opinion in the Privy Council, the other ministers, averse to so bold a measure, opposed the proposition of the premier, alleging the necessity of mature deliberation before declaring war against so powerful a state. Irritated by the unexpected opposition of his

colleagues, Pitt replied, "I will not give them leave to think; this is the time; let us crush the whole House of Bourbon. But if the members of this board are of a different opinion, this is the last time I shall ever mix in its councils. I was called into the ministry by the voice of the people, and to them I hold myself answerable for my conduct. I am to thank the ministers of the late king for their support; I have served my country with success; but I will not be responsible for the conduct of the war any longer than while I have the direction of it." To this declaration the president of the council answered, "I find the gentleman is determined to leave us; nor can I say that I am sorry for it, since he would otherwise have certainly compelled us to leave him. But if he is resolved to assume the right of advising his Majesty, and directing the operations of the war, to what purpose are we called to this council? When he talks of being responsible to the people, he talks the language of the House of Commons, and forgets that at this board he is responsible only to the king. However, though he may possibly have convinced himself of his infallibility, still it remains that we should be equally convinced before we can resign our understandings to his direction, or join with him in the measure he proposes." The opposition he thus encountered the nation attributed to the growing influence of Lord Bute. But however this may have been, Pitt was a man of too high, not to say imperious a temper, to remain as the nominal head of a cabinet which he was no longer able to direct. Accordingly, on the 5th of October 1761, he resigned all his appointments; and, as some reward for his services, his wife was created Baroness Chatham in her own right, whilst a pension of L.3000 a year was settled on the lives of himself, his lady, and his eldest son.

No fallen minister, if fallen he could be called, ever carried with him more completely the confidence and regret of the nation, whose affairs he had so successfully administered. But at this time the king was also popular; and the war being continued by his new ministers with vigour and success, no discontent appeared until after the conclusion of the peace. The impulse given by Pitt had carried them forward in the same direction which he had pursued; but they were equally incapable of profiting by the advantages which had been already gained, or of prosecuting the war until the objects for which it was originally undertaken should be accomplished. The victories gained over France and Spain having greatly elated the nation, the feeling which almost universally prevailed amongst the people was, that we should either dictate peace as conquerors, or continue the war until our adversaries were more effectually humbled. This was likewise Pitt's opinion. Accordingly, when the preliminaries of peace came to be discussed in Parliament, he went down to the House of Commons, though suffering severely from an attack of gout, and spoke for nearly three hours in the debate, giving his opinion on each article of the treaty in succession, and, upon the whole, maintaining that it was inadequate to the conquests of our arms, and the just expectations of the country. Peace was, however, concluded on the 10th of February 1763, and Pitt continued unemployed.

After his resignation in 1761, Pitt conducted himself in a manner worthy of his high character. So far from giving a vexatious and undiscriminating opposition to the ministry which had succeeded his own, he maintained his popularity in dignified retirement, and came forward only when questions of great importance were to be discussed. One of these occurred in 1764, on the subject of general warrants, the illegality of which he denounced with all the energy and vigour of his eloquence. Another occasion, when he came forward in all his strength, was the consideration of the discontents which had arisen on account of the Stamp Act. In March 1766, the repeal of that act having been proposed by the Rockingham ministry, Pitt, though not connected with them, ably supported the measure, which was carried, but whether prudently or the contrary is still a matter of dispute. About this time Pitt had devised to him by will a considerable estate in Somersetshire, the property of Sir William Pynsent of Burton-Pynsent in that county, who, from admiration of his public character, disinherited his own relations, in order to bequeath to him the bulk of his fortune. After the dissolution of the Rockingham ministry, a new administration was formed, and in 1766 Pitt was appointed lord privy seal. At the same time he was created a peer by the titles of Viscount Pitt of Burton-Pynsent, in the county of Somerset, and Earl of Chatham, in the county of Kent.

Whatever might be his motives in accepting a peerage, it is certain that it proved very prejudicial to his character, and that in consequence he sank as much in popularity as he rose in nominal dignity. The "great commoner," as he was sometimes called, had formed a rank for himself, on the basis of his talents and exertions, which titular honours might obscure, but could not illustrate; and, with the example of Pulteney before him, he should have been careful to preserve it untarnished by empty distinctions, shared by the mean and the worthless as well as by the great, the gifted, and the good. Lord Chatham, however, did not long continue in office after being elevated to the peerage. On the 2d of November 1768 he resigned the place of lord privy seal, and never afterwards held any public employment; nor does he appear to have been at all desirous of returning to office. He was now sixty, and the gout, by which he had so long been afflicted, disabled him, by its frequent and violent attacks, for close and regular application to business. In the intervals of his disorder, however, he failed not to exert himself upon questions of great magnitude; and in 1775, 1776, and 1777, he most strenuously opposed the measures pursued by the ministers in the contest with America. His last appearance in the House of Lords was on the 2d of April 1778. He was then very ill, and much debilitated; but the question was important, being a motion of the Duke of Richmond to address his Majesty to remove the ministers, and to make peace with America on any terms. His lordship made a long speech, in which he summoned up all his remaining strength to pour out his disapprobation of a measure so inglorious. But the effort overcame him, for in attempting to rise a second time, he fell down in a convulsive fit; and though he recovered for the time, his disorder continued to increase until the 11th of May, when he expired at his seat at Hayes. His death was lamented as a national loss. As soon as the news reached the House of Commons, which was then sitting, Colonel Barré made a motion, that an address should be presented to his Majesty, requesting that the Earl of Chatham should be buried at the public expense. But Mr Rigby having proposed the erection of a statue to his memory, as more likely to perpetuate the sense of his great merits entertained by the public, this was unanimously agreed to. A bill was soon afterwards passed, by which L.4000 a year was settled upon John, now Earl of Chatham, and the heirs of the late earl to whom that title might descend. His lordship was married in 1754 to Lady Hester, sister of Earl Temple, by whom he had three sons and two daughters.

The principal outlines of Pitt's character have been variously sketched, sometimes with, and sometimes without, any depth of shadow. The truth is, that there scarcely ever lived a person who had less claim to be painted altogether *en beau*, or who so little merited unsparing censure. Lord Macaulay says, "That he was a great man, cannot for a moment be doubted; but his was not a complete and well-proportioned greatness. The public life of Hampden

 or of Somers resembles a regular drama, which can be criticised as a whole, and every scene of which is to be viewed in connection with the main action. The public life of Pitt, on the other hand, is a rude though striking piece, abounding in incongruities, and without any unity of plan, but redeemed by some noble passages, the effect of which is increased by the tameness or extravagance of what precedes and of what follows. His opinions were unfixed; and his conduct, at some of the most important conjunctures of his life, was evidently determined by pride and resentment. He had one fault, which of all human faults is most rarely found in company with true greatness. He was extremely affected. He was an almost solitary instance of a man of real genius, and of a brave, lofty, and commanding spirit, without simplicity of character. He was an actor in the closet, an actor in the council, and an actor in Parliament; and even in private society he could not lay aside his theatrical tones and attitudes. We know that one of the most distinguished of his partizans often complained that he could never obtain admittance to Lord Chatham's room till everything was ready for the representation; till the light was thrown with Rembrandt-like effect on the head of the illustrious performer; till the flannels had been arranged with the air of Grecian drapery, and the crutch placed as gracefully as that of Belisarius or Lear." Yet, with all his faults and affectations, he possessed, in a very extraordinary degree, many of the elements of true greatness. He had splendid talents, strong passions, quick sensibility, and vehement enthusiasm for the grand and the beautiful. There was something about him which ennobled even tergiversation itself. He often went wrong, very far wrong; but, amidst the abasement of error, he still retained what he had received from nature, "an intense and glowing mind." In an age of low and despicable prostitution, the age of Dodington and Sandys, it was something to have a man who might perhaps, under some strong excitement, have been tempted to ruin his country, but who never would have stooped to pilfer from her; a man whose errors arose, not from a sordid desire of gain, but from a fierce thirst of power, glory, and vengeance. "History owes him this attestation, that, at a time when anything short of direct embezzlement of the public money was considered as quite fair in public men, he showed the most scrupulous disinterestedness; that, at a time when it seemed to be generally taken for granted that government could be upheld only by the basest and most immoral arts, he appealed to the better and nobler parts of human nature; that he made a brave and splendid attempt to do, by means of public opinion, what no other statesman of his day thought it possible to do except by means of corruption; that he looked for support, not, like the Pelhams, to a strong aristocratical connection, not, like Bute, to the personal favour of the sovereign, but to the middle class of Englishmen; that he inspired that class with a firm confidence in his integrity and ability; that, backed by them, he forced an unwilling court and an unwilling oligarchy to admit him to an ample share of power; and that he used his power in such a manner as clearly proved that he had sought it, not for the sake of profit or patronage, but from a wish to establish for himself a great and durable reputation by means of eminent services rendered to the state."

A great many unmeaning phrases have been employed, and much rhetorical exaggeration has been expended, in attempts to characterize Lord Chatham's style of eloquence. The following estimate by Lord Macaulay, from whom we have borrowed some of the foregoing observations, is at once deep, discriminating, and brilliant.

"In our time the audience of a member of Parliament is the nation. The three or four hundred persons who may be present when a speech is delivered may be pleased or disgusted by the voice and action of the orator; but in the reports which are read the next day by hundreds of thousands, the difference between the noblest and the meanest figure, between the richest and the shrillest tones, between the most graceful and the most uncouth gesture, altogether vanishes. A hundred years ago, scarcely any report of what passed within the walls of the House of Commons was suffered to get abroad. In those times, therefore, the impression which a speaker might make on the persons who actually heard him was everything. The impression out of doors was hardly worth a thought. In the Parliaments of that time, therefore, as in the ancient commonwealths, those qualifications which enhance the immediate effect of a speech were far more important ingredients in the composition of an orator than they would appear to be in our time. All those qualifications Pitt possessed in the highest degree. On the stage, he would have been the finest Brutus or Coriolanus ever seen. Those who saw him in his decay, when his health was broken, when his mind was jangled, when he had been removed from that stormy assembly of which he thoroughly knew the temper, and over which he possessed unbounded influence, to a small, a torpid, and an unfriendly audience, say that his speaking was then for the most part a low monotonous muttering, audible only to those who sate close to him; that, when violently excited, he sometimes raised his voice for a few minutes, but that it soon sank again into an unintelligible murmur. Such was the Earl of Chatham; but such was not William Pitt. His figure, when he first appeared in Parliament, was strikingly graceful and commanding, his features high and noble, his eye full of fire. His voice, even when it sank to a whisper, was heard to the remotest benches; when he strained it to its full extent, the sound rose like the swell of the organ of a great cathedral, shook the house with its peal, and was heard through lobbies and down staircases, to the Court of Requests and the precincts of Westminster Hall. He cultivated all these eminent advantages with the most assiduous care. His action is described, by a very malignant observer, as equal to that of Garrick. His play of countenance was wonderful; he frequently disconcerted a hostile orator by a single glance of indignation or scorn. Every tone, from the impassioned cry to the thrilling aside, was perfectly at his command. It is by no means improbable that the pains which he took to improve his great personal advantages had in some respects a prejudicial operation, and tended to nourish in him that passion for theatrical effect which was one of the most conspicuous blemishes in his character.

But it was not solely or principally to outward accomplishments that Pitt owed the vast influence which, during nearly thirty years, he exercised over the House of Commons. He was undoubtedly a great orator; and from the descriptions of his contemporaries, and the fragments of his speeches which still remain, it is not difficult to discover the nature and extent of his oratorical powers.

He was no speaker of set speeches. His few prepared discourses were complete failures. The elaborate panegyric which he pronounced on General Wolfe was considered as the very worst of all his performances. "No man," says a critic who had often heard him, "ever knew so little what he was going to say." Indeed, his facility amounted to a vice; he was not the master, but the slave of his own speech. So little self-command had he when once he felt the impulse, that he did not like to take part in a debate when his mind was full of an important secret of state. "I must sit still," he once said to Lord Shelburne on such an occasion, "for when once I am up, everything that is in my mind comes out."

Yet he was not a great debater. That he should not have been so when he first entered the House of Commons, is not strange; scarcely any person has ever become so without long practice and many failures. It was by slow

degrees, as Burke said, that Mr Fox became the most brilliant and powerful debater that Parliament ever saw. Mr Fox himself attributed his own success to the resolution which he formed when very young, of speaking, well or ill, at least once every night. "During five whole sessions," he used to say, "I spoke every night but one; and I regret only that I did not speak that night too." Indeed, it would be difficult to name any great debater who has not made himself a master of his art at the expense of his audience.

But as this art is one which even the ablest men have seldom acquired without long practice, so it is one which men of respectable abilities, with assiduous and intrepid practice, seldom fail to acquire. It is singular that, in such an art, Pitt, a man of splendid talents, great fluency, and dauntless boldness, whose whole life was passed in parliamentary conflict, and who during several years was the leading minister of the Crown in the House of Commons, should never have attained to high excellence. He spoke without premeditation; but his speech followed the course of his own thoughts, and not that of the previous discussion. He could, indeed, treasure up in his memory some detached expression of a hostile orator, and make it the text for sparkling ridicule or burning invective. Some of the most celebrated bursts of his eloquence were called forth by an unguarded word, a laugh, or a cheer. But this was the only sort of reply in which he appears to have excelled. He was perhaps the only great English orator who did not think it an advantage to have the last word, and who generally spoke by choice before his most formidable opponents. His merit was almost entirely rhetorical. He did not succeed either in exposition or refutation; but his speeches abounded with lively illustrations, striking apophthegms, well-told anecdotes, happy allusions, passionate appeals. His invective and sarcasm were tremendous. Perhaps no English orator was ever so much feared.

But that which gave most effect to his declamation was the air of sincerity, of vehement feeling, or moral elevation, which belonged to all that he said. His style was not always in the purest taste. Several contemporary judges pronounced it too florid. Walpole, in the midst of the rapturous eulogy which he pronounces on one of Pitt's greatest orations, owns that some of the metaphors were too forced. The quotations and classical stories of the orator are sometimes too trite for a clever school-boy. But these were niceties for which the audience cared little. The enthusiasm of the orator infected all who were near him; his ardour and his noble bearing put fire into the most frigid conceit, and gave dignity to the most puerile allusion."

Such is the character of this great statesman and orator, as drawn by one masterly hand. It may perhaps both instruct and interest our readers if we present another, delineated by an artist equally distinguished for the vigour, judgment, and fidelity with which he paints such grand pieces for the gallery of history. The preceding, as we have already said, is from the pen of Lord Macaulay; the following is understood to be from that of Lord Brougham:—

"The first place among the great qualities which distinguished Lord Chatham is unquestionably due to firmness of purpose, resolute determination in the pursuit of his objects. This was the characteristic of the younger Brutus, as he said, who had spared his life to fall by his hand,—*Quicquid vult, id valde vult;* and although extremely apt to be shown in excess, it must be admitted to be the foundation of all true greatness of character. Everything, however, depends upon the endowments in whose company it is found; and in Lord Chatham these were of a very high order. The quickness with which he could ascertain his object, and discover his road to it, was fully commensurate with his perseverance and his boldness in pursuing it; the firmness of grasp with which he held his advantage was fully equalled by the rapidity of the glance with which he discovered it. Add to this a mind eminently fertile in resources, a courage which nothing could daunt in the choice of his means, a resolution equally indomitable in their application, a genius, in short, original and daring, which bounded over the petty obstacles raised by ordinary men,—their squeamishness, and their precedents, and their forms, and their regularities,—and forced away its path through the entanglements of this base undergrowth to the worthy object ever in his view, the prosperity and the renown of his country. Far superior to the paltry objects of a grovelling ambition, and regardless alike of party and of personal considerations, he constantly set before his eyes the highest duty of a public man, to further the interests of his species. In pursuing his course towards that goal, he disregarded alike the frowns of power and the gales of popular applause; exposed himself undaunted to the vengeance of the court, while he battled against its corruptions, and confronted, unabashed, the rudest shocks of public indignation, while he resisted the dictates of pernicious agitators; and could conscientiously exclaim, with an illustrious statesman of antiquity, "Ego hoc animo semper fui ut invidiam virtute partam, gloriam non invidiam putarem."

Nothing could be more entangled than the foreign policy of this country at the time when he took the supreme direction of her affairs; nothing could be more disastrous than the aspect of her fortunes in every quarter of the globe. With a single ally in Europe, the King of Prussia, and him beset by a combination of all the continental powers in unnatural union to effect his destruction; with an army of insignificant amount, and commanded by men only desirous of grasping at the emoluments, without doing the duties or incurring the risks of their profession; with a navy that could hardly keep the sea, and whose chiefs vied with their comrades on shore in earning the character given them by the new minister, of being utterly unfit to be trusted in any enterprise accompanied with "the least appearance of danger;" with a generally prevailing dislike of both services, which at once repressed all desire of joining either, and damped all public spirit in the country, by extinguishing all hope of success, and even all love of glory; it was hardly possible for a nation to be placed in circumstances more inauspicious to military exertions; and yet war raged in every quarter of the world where our dominion extended, while the territories of our only ally, as well as those of our own sovereign in Germany, were invaded by France, and her forces by sea and land menaced our shores. In the distant possessions of the Crown the same want of enterprise and of spirit prevailed. Armies in the West were paralysed by the inaction of a captain who would hardly take the pains to write a despatch recording the nonentity of his operations; and in the East, while frightful disasters were brought upon our settlements by barbarian powers, the only military capacity that appeared in their defence was the accidental display of genius and valour by a merchant's clerk, who thus raised himself to celebrity (Mr, afterwards Lord, Clive). In this forlorn state of affairs, rendering it as impossible to think of peace as it seemed hopeless to continue the yet inevitable war, the base and sordid views of politicians kept pace with the mean spirit of the military caste; and parties were split or united, not upon any difference or agreement of public principle, but upon mere questions of patronage and share in the public spoil, while all seemed alike actuated by one only passion, the thirst alternately of power and of gain.

As soon as Mr Pitt took the helm, the steadiness of the hand that held it came to be felt in every motion of the vessel. There was no more of wavering councils, of torpid inaction, of listless expectancy, of abject despondency. His firmness gave confidence, his spirit roused courage, his vigilance secured exertion, in every department under his sway.

Pitt. Each man, from the first lord of the Admiralty down to the most humble clerk in the victualling office—each soldier, from the commander-in-chief to the most obscure contractor or commissary—now felt assured that he was acting or indolent under the eye of one who knew his duties and his means as well as his own, and who would very certainly make all defaulters, whether through misfeasance or through nonfeasance, accountable for whatever detriment the commonwealth might sustain at their hands. Over his immediate coadjutors his influence swiftly obtained an ascendant which it ever after retained uninterrupted. Upon his first proposition for changing the conduct of the war he stood single among his colleagues, and tendered his resignation should they persist in their dissent; they at once succumbed, and from that hour ceased to have an opinion of their own upon any branch of the public affairs. Nay, so absolutely was he determined to have the control of those measures of which he knew the responsibility rested upon him alone, that he insisted upon the first lord of the Admiralty not having the correspondence of his own department; and no less eminent a naval character than Lord Anson, with his junior lords, were obliged to sign the orders issued by Mr Pitt while the writing was covered over from their eyes.

The effects of this change in the whole management of the public business, and in all the plans of the government, as well as in their execution, were speedily made manifest to all the world. The German troops were sent home, and a well-regulated militia being established to defend the country, a large disposable force was distributed over the various points whence the enemy might be annoyed. France, attacked on some points and menaced on others, was compelled to retire from Germany, soon afterwards suffered the most disastrous defeats, and, instead of threatening England and her allies with invasion, had to defend herself against attack, suffering severely in several of her most important naval stations. No less than sixteen islands, and settlements, and fortresses of importance, were taken from her in America, and Asia, and Africa, including all her West Indian colonies except St Domingo, and all her settlements in the East. The whole important province of Canada was likewise conquered; and the Havannah was taken from Spain. Besides this, the seas were swept clear of the fleets that had so lately been insulting all our colonies, and even all our coasts. Many general actions were fought and gained; one among them the most decisive that had ever been fought by our navy. Thirty-six sail of the line were taken or destroyed, fifty frigates, forty-five sloops of war. So brilliant a course of uninterrupted success had never in modern times attended the arms of any nation carrying on war with other states equal to it in civilization, and nearly a match in power. But it is a more glorious feature in the unexampled administration which history has to record when it adds, that all public distress had disappeared; all discontent in any quarter, both of the colonies and parent state, had ceased; that no oppression was anywhere practised, no abuse suffered to prevail; that no encroachments were made upon the rights of the subject, no malversations tolerated in the possessors of power; and that England, for the first time and for the last time, presented the astonishing picture of a nation supporting without murmur a widely extended and costly war, and a people hitherto torn with conflicting parties so united in the service of the commonwealth that the voice of faction had ceased in the land, and any discordant whisper was heard no more. "These," said the son of his first and most formidable adversary, Walpole, when informing his correspondent abroad that the session, as usual, had ended without any kind of opposition, or even of debate, "These are the doings of Mr Pitt, and they are wondrous in our eyes."

To genius irregularity is incident, and the greatest genius is often marked by eccentricity, as if it disdained to move in the vulgar orbit. Hence he who is fitted by his nature, and trained by his habits, to be an accomplished "pilot in extremity," and whose inclinations carry him forth to seek the deep when the waves run high, may be found, if not "to steer too near the shore," yet to despise the sunken rocks which they that can only be trusted in calm weather would have more surely avoided. To this rule it cannot be said that Lord Chatham afforded any exception; and although a plot had certainly been formed to eject him from the ministry, leaving the chief control of affairs in the feeble hands of Lord Bute, whose only support was court favour, and whose only talent lay in an expertness at intrigue, yet there can be little doubt that this scheme was only rendered practicable by the hostility which the great minister's unbending habits, his contempt of ordinary men, and his neglect of everyday matters, had raised against him among all the creatures both of Downing Street and St James's. In fact his colleagues, who necessarily felt humbled by his superiority, were needlessly mortified by the constant display of it; and it would have betokened a still higher reach of understanding, as well as a purer fabric of patriotism, if he whose great capacity threw those subordinates into the shade, and before whose vigour in action they were sufficiently willing to yield, had united a little suavity in his demeanour with his extraordinary powers, nor made it always necessary for them to acknowledge as well as to feel their inferiority. It is certain that the insulting arrangement of the Admiralty to which reference has been already made, while it lowered that department in the public opinion, rendered all connected with him his personal enemies; and indeed, though there have since his days been prime ministers whom he would never have suffered to sit even as puny lords at his boards, yet were one like himself again to govern the country, the Admiralty chief, who might be far inferior to Lord Anson, would never submit to the humiliation inflicted upon that gallant and skilful captain. Mr Pitt's policy seemed formed upon the assumption that either each public functionary was equal to himself in boldness, activity, and resource, or that he was to preside over and animate each department in person; and his confidence was such in his own powers that he reversed the maxim of governing, never to force your way where you can win it, and always disdained to insinuate where he could dash in, or to persuade where he could command. It thus happened that his colleagues were but nominally coadjutors, and though they durst not thwart him, yet rendered no heart-service to aid his schemes. Indeed it has clearly appeared since his time that they were chiefly induced to yield him implicit obedience, and leave the undivided direction of all operations in his hands, by the expectation that the failure of what they were wont to sneer at as "Mr Pitt's visions" would turn the tide of public opinion against him, and prepare his downfall from a height of which they felt that there was no one but himself able to dispossess him."

The same powerful writer, having thus sketched the character of the statesman, proceeds next to delineate that of the orator, as far as this can now be done from the extremely scanty and imperfect materials which have been preserved. The fame of Lord Chatham's eloquence is, in truth, almost wholly traditional.

"There is indeed hardly any eloquence, of ancient or of modern times, of which so little that can be relied on as authentic has been preserved; unless perhaps that of Pericles, Julius Cæsar, and Lord Bolingbroke. Of the actions of the two first we have sufficient records, as we have of Lord Chatham's; of their speeches we have little that can be regarded as genuine; although, by unquestionable tradition, we know that each of them was second only to the greatest orator of their respective countries; while of

Bolingbroke we only know, from Dean Swift, that he was the most accomplished speaker of his time; and it is related of Mr Pitt (the younger), that when the conversation rolled upon lost works, and some said they should prefer restoring the books of Livy, some of Tacitus, and some a Latin tragedy, he at once decided for a speech of Bolingbroke. What we know of his own father's oratory is much more to be gleaned from contemporary panegyrics, and accounts of its effects, than from the scanty, and for the most part doubtful, remains which have reached us.

All accounts, however, concur in representing those effects to have been prodigious. The spirit and vehemence which animated its greater passages, their perfect application to the subject-matter of debate, the appositeness of his invective to the individual assailed, the boldness of the feats which he ventured upon, the grandeur of the ideas which he unfolded, the heart-stirring nature of his appeals, are all confessed by the united testimony of all his contemporaries; and the fragments which remain bear out to a considerable extent such representations; nor are we likely to be misled by those fragments, for the more striking portions were certainly the ones least likely to be either forgotten or fabricated. To these mighty attractions was added the imposing, the animating, the commanding power of a countenance singularly expressive; an eye so piercing that hardly any one could stand its glare; and a manner altogether singularly striking, original, and characteristic, notwithstanding a peculiarly defective and even awkward action. Latterly, indeed, his infirmities precluded all action; and he is described as standing in the House of Lords, leaning upon his crutch, and speaking for ten minutes together in an under-tone of voice scarcely audible, but raising his notes to their full pitch when he broke out into one of his grand bursts of invective or exclamation. But in his earlier time, his whole manner is represented as having been beyond conception animated and imposing. Indeed, the things which he effected by it principally, or at least which nothing but a most striking and commanding tone could have made it possible to attempt, almost exceed belief. Some of these sallies are indeed examples of that approach made to the ludicrous by the sublime which has been charged upon him as a prevailing fault, and represented under the name of *charlatanerie*,—a favourite phrase with his adversaries, as it in later times has been with the ignorant undervaluers of Lord Erskine. It is related that once in the House of Commons he began a speech with the words, "Sugar, Mr Speaker,"—and then, observing a smile to prevail in the audience, he paused, looking fiercely around, and with a loud voice, rising in its notes, and swelling into vehement anger, he is said to have pronounced again the word "Sugar!" three times, —and having thus quelled the House, and extinguished every appearance of levity or laughter, turned round and disdainfully asked, "Who will laugh at sugar now?" We have this anecdote on good traditional authority; that it was believed by those who had the best means of knowing Lord Chatham, is certain; and this of itself shows their sense of the extraordinary powers of his manner, and the reach of his audacity in trusting to those powers.

There can be no doubt that of reasoning,—of sustained and close argument,—his speeches had but little. His statements were desultory though striking, perhaps not very distinct, certainly not at all detailed, and as certainly every way inferior to those of his celebrated son. If he did not reason cogently, he assuredly did not compress his matter vigorously. He was anything rather than a concise or a short speaker; not that his great passages were at all diffuse, or in the least degree loaded with superfluous words; but he was prolix in the whole texture of his discourse, and he was certainly the first who introduced into our senate the practice, adopted in the American war by Mr Burke, and continued by others, of long speeches,—speeches of two and three hours, by which oratory has gained little and business less. His discourse was, however, fully informed with matter—his allusions to analogous subjects, and his reference to the history of past events were frequent—his expression of his own opinions was copious and free, and stood very generally in the place of any elaborate reasoning in their support. A noble statement of enlarged views, a generous avowal of dignified sentiments, a manly and somewhat severe contempt for all petty or mean views, whether their baseness proceeded from narrow understanding or from corrupt bias, always pervaded his whole discourse; and, more than any other orator since Demosthenes, he was distinguished by the nobleness of feeling with which he regarded, and the amplitude of survey which he cast upon, the subject-matters of debate. His invective was unsparing and hard to be endured, although he was a less eminent master of sarcasm than his son, and rather overwhelmed his antagonist with the burst of words and vehement indignation, than wounded him by the edge of ridicule, or tortured him with the gall of bitter scorn, or fixed his arrow in the wound by the barb of epigram. These things seemed as it were to betoken too much labour and too much art; more labour than was consistent with absolute scorn, more art than could stand with heartfelt rage, or entire contempt inspired by the occasion, at the moment, and on the spot. But his great passages,—those by which he has come down to us, those which gave his eloquence its peculiar character, and to which its dazzling success was owing,—were as sudden and unexpected as they were natural. Every one was taken by surprise when they rolled forth; every one felt them to be so natural that he could hardly understand why he had not thought of them himself, although into no one's imagination had they ever entered. If the quality of being natural without being obvious is a pretty correct description of felicitous expression, or what is called fine writing, it is a yet more accurate representation of fine passages or felicitous *hits* in speaking. In these all popular assemblies take boundless delight; by these, above all others, are the minds of an audience at pleasure moved or controlled. They form the grand charm of Lord Chatham's oratory; they were the distinguishing excellence of his great predecessor, and gave him at will to wield the fierce democracy of Athens, and to fulmine over Greece."

Many years ago, a small volume was published by Lord Grenville, containing letters written by the Earl of Chatham to his nephew Thomas Pitt, Lord Camelford. They are replete with excellent advice, conveyed in an easy, affectionate, and not inelegant style, having all of them been penned evidently without effort, under the simple impulse of the kindly feelings and anxious interest which they manifest throughout. At the same time, they might have been written by a person vastly inferior to Lord Chatham; and indeed one can scarcely avoid surprise at the absence of every trace of that genius, power, and originality for which the writer was so greatly distinguished.

Almon the bookseller has written *Anecdotes of the Life of the Earl of Chatham*, 3 vols. 8vo; the Rev. Mr Thackeray has illustrated the subject more accurately, as well as fully, in his *History of the Earl of Chatham*, 2 vols. 4to. None of his own writings have been given to the world, except a small volume of letters to the son of his elder brother, afterwards Lord Camelford, published some years ago by Lord Grenville; and his *Correspondence*, in 4 vols. 8vo, 1838–40. The *Correspondence* illustrates very fully his life and character, and furnishes valuable materials for the political history of his time. His wife, who died in 1803, bore him three sons and two daughters. The second son, the subject of the next article, gained a political fame capable of rivalling that of his illustrious father. (J. B—E.)

PITT, WILLIAM.

Pitt, *William*, the second son of William Pitt, Earl of Chatham, and of Lady Hester Grenville, daughter of Hester, Countess Temple, was born on the 28th of May 1759. The child inherited a name which, at the time of his birth, was the most illustrious in the civilised world, and was pronounced by every Englishman with pride, and by every enemy of England with mingled admiration and terror. During the first year of his life, every month had its illuminations and bonfires, and every wind brought some messenger charged with joyful tidings and hostile standards. In Westphalia the English infantry won a great battle which arrested the armies of Louis the Fifteenth in the midst of a career of conquest: Boscawen defeated one French fleet on the coast of Portugal: Hawke put to flight another in the Bay of Biscay: Johnson took Niagara: Amherst took Ticonderoga: Wolfe died by the most enviable of deaths under the walls of Quebec: Clive destroyed a Dutch armament in the Hoogley, and established the English supremacy in Bengal: Coote routed Lally at Wandewash, and established the English supremacy in the Carnatic. The nation, while loudly applauding the successful warriors, considered them all, on sea and on land, in Europe, in America, and in Asia, merely as instruments which received their direction from one superior mind. It was the great William Pitt, the great commoner, who had vanquished French marshals in Germany, and French admirals on the Atlantic; who had conquered for his country one great empire on the frozen shores of Ontario, and another under the tropical sun near the mouths of the Ganges. It was not in the nature of things that popularity such as he at this time enjoyed should be permanent. That popularity had lost its gloss before his children were old enough to understand that their father was a great man. He was at length placed in situations in which neither his talents for administration nor his talents for debate appeared to the best advantage. The energy and decision which had eminently fitted him for the direction of war were not needed in time of peace. The lofty and spirit-stirring eloquence, which had made him supreme in the House of Commons, often fell dead on the House of Lords. A cruel malady racked his joints, and left his joints only to fall on his nerves and on his brain. During the closing years of his life, he was odious to the court, and yet was not on cordial terms with the great body of the opposition. Chatham was only the ruin of Pitt, but an awful and majestic ruin, not to be contemplated by any man of sense and feeling without emotions resembling those which are excited by the remains of the Parthenon and of the Coliseum. In one respect the old statesman was eminently happy. Whatever might be the vicissitudes of his public life, he never failed to find peace and love by his own hearth. He loved all his children, and was loved by them; and, of all his children, the one of whom he was fondest and proudest was his second son.

The child's genius and ambition displayed themselves with a rare and almost unnatural precocity. At seven, the interest which he took in grave subjects, the ardour with which he pursued his studies, and the sense and vivacity of his remarks on books and on events, amazed his parents and instructors. One of his sayings of this date was reported to his mother by his tutor. In August 1766, when the world was agitated by the news that Mr Pitt had become Earl of Chatham, little William exclaimed, "I am glad that I am not the eldest son. I want to speak in the House of Commons like papa." A letter is extant in which Lady Chatham, a woman of considerable abilities, remarked to her lord, that their younger son at twelve had left far behind him his elder brother, who was fifteen. "The fineness," she wrote, "of William's mind makes him enjoy with the greatest pleasure what would be above the reach of any other creature of his small age." At fourteen the lad was in intellect a man. Hayley, who met him at Lyme in the summer of 1773, was astonished, delighted, and somewhat overawed, by hearing wit and wisdom from so young a mouth. The poet, indeed, was afterwards sorry that his shyness had prevented him from submitting the plan of an extensive literary work, which he was then meditating, to the judgment of this extraordinary boy. The boy, indeed, had already written a tragedy, bad of course, but not worse than the tragedies of his friend. This piece is still preserved at Chevening, and is in some respects highly curious. There is no love. The whole plot is political; and it is remarkable that the interest, such as it is, turns on a contest about a regency. On one side is a faithful servant of the Crown, on the other an ambitious and unprincipled conspirator. At length the king, who had been missing, reappears, resumes his power, and rewards the faithful defender of his rights. A reader who should judge only by internal evidence would have no hesitation in pronouncing that the play was written by some Pittite poetaster at the time of the rejoicings for the recovery of George the Third in 1789.

The pleasure with which William's parents observed the rapid development of his intellectual powers was alloyed by apprehensions about his health. He shot up alarmingly fast; he was often ill, and always weak; and it was feared that it would be impossible to rear a stripling so tall, so slender, and so feeble. Port wine was prescribed by his medical advisers; and it is said that he was, at fourteen, accustomed to take this agreeable physic in quantities which would, in our abstemious age, be thought much more than sufficient for any full-grown man. This regimen, though it would probably have killed ninety-nine boys out of a hundred, seems to have been well suited to the peculiarities of William's constitution; for at fifteen he ceased to be molested by disease, and, though never a strong man, continued, during many years of labour and anxiety, of nights passed in debate and of summers passed in London, to be a tolerably healthy one. It was probably on account of the delicacy of his frame that he was not educated like other boys of the same rank. Almost all the eminent English statesmen and orators to whom he was afterwards opposed or allied, North, Fox, Shelburne, Windham, Grey, Wellesley, Grenville, Sheridan, Canning, went through the training of great public schools. Lord Chatham had himself been a distinguished Etonian; and it is seldom that a distinguished Etonian forgets his obligations to Eton. But William's infirmities required a vigilance and tenderness such as could be found only at home. He was therefore bred under the paternal roof. His studies were superintended by a clergyman named Wilson; and those studies, though often interrupted by illness, were prosecuted with extraordinary success. Before the lad had completed his fifteenth year, his knowledge both of the ancient languages and of mathematics was such as very few men of eighteen then carried up to college. He was therefore sent, towards the close of the year 1773, to Pembroke Hall, in the university of Cambridge. So young a student required much more than the ordinary care which a college tutor bestows on undergraduates. The governor, to whom the direction of William's academical life was confided, was a bachelor of arts named Pretyman, who had been senior wrangler in the preceding

year, and who, though not a man of prepossessing appearance or brilliant parts, was eminently acute and laborious, a sound scholar, and an excellent geometrician. At Cambridge, Pretyman was, during more than two years, the inseparable companion, and indeed almost the only companion, of his pupil. A close and lasting friendship sprang up between the pair. The disciple was able, before he completed his twenty-eighth year, to make his preceptor bishop of Lincoln and dean of St Paul's; and the preceptor showed his gratitude by writing a Life of the disciple, which enjoys the distinction of being the worst biographical work of its size in the world.

Pitt, till he graduated, had scarcely one acquaintance, attended chapel regularly morning and evening, dined every day in hall, and never went to a single evening party. At seventeen, he was admitted, after the bad fashion of those times, by right of birth, without any examination, to the degree of Master of Arts. But he continued during some years to reside at college, and to apply himself vigorously, under Pretyman's direction, to the studies of the place, while mixing freely in the best academic society.

The stock of learning which Pitt laid in during this part of his life was certainly very extraordinary. In fact, it was all that he ever possessed; for he very early became too busy to have any spare time for books. The work in which he took the greatest delight was Newton's Principia. His liking for mathematics, indeed, amounted to a passion, which, in the opinion of his instructors, themselves distinguished mathematicians, required to be checked rather than encouraged. The acuteness and readiness with which he solved problems was pronounced by one of the ablest of the moderators, who in those days presided over the disputations in the schools, and conducted the examinations of the Senate-House, to be unrivalled in the university. Nor was the youth's proficiency in classical learning less remarkable. In one respect, indeed, he appeared to disadvantage when compared with even second-rate and third-rate men from public schools. He had never, while under Wilson's care, been in the habit of composing in the ancient languages; and he therefore never acquired that knack of versification which is sometimes possessed by clever boys whose knowledge of the language and literature of Greece and Rome is very superficial. It would have been utterly out of his power to produce such charming elegiac lines as those in which Wellesley bade farewell to Eton, or such Virgilian hexameters as those in which Canning described the pilgrimage to Mecca. But it may be doubted whether any scholar has ever, at twenty, had a more solid and profound knowledge of the two great tongues of the old civilised world. The facility with which he penetrated the meaning of the most intricate sentences in the Attic writers astonished veteran critics. He had set his heart on being intimately acquainted with all the extant poetry of Greece, and was not satisfied till he had mastered Lycophron's Cassandra, the most obscure work in the whole range of ancient literature. This strange rhapsody, the difficulties of which have perplexed and repelled many excellent scholars, "he read," says his preceptor, "with an ease at first sight, which, if I had not witnessed it, I should have thought beyond the compass of human intellect."

To modern literature Pitt paid comparatively little attention. He knew no living language except French; and French he knew very imperfectly. With a few of the best English writers he was intimate, particularly with Shakspeare and Milton. The debate in Pandemonium was, as it well deserved to be, one of his favourite passages; and his early friends used to talk, long after his death, of the just emphasis and the melodious cadence with which they had heard him recite the incomparable speech of Belial. He had indeed been carefully trained from infancy in the art of managing his voice, a voice naturally clear and deep-toned. His father, whose oratory owed no small part of its effect to that art, had been a most skilful and judicious instructor. At a later period, the wits of Brookes's, irritated by observing, night after night, how powerfully Pitt's sonorous elocution fascinated the rows of country gentlemen, reproached him with having been "taught by his dad on a stool."

His education, indeed, was well adapted to form a great parliamentary speaker. One argument often urged against those classical studies which occupy so large a part of the early life of every gentleman bred in the south of our island is, that they prevent him from acquiring a command of his mother tongue, and that it is not unusual to meet with a youth of excellent parts, who writes Ciceronian Latin prose and Horatian Latin Alcaics, but who would find it impossible to express his thoughts in pure, perspicuous, and forcible English. There may perhaps be some truth in this observation. But the classical studies of Pitt were carried on in a peculiar manner, and had the effect of enriching his English vocabulary, and of making him wonderfully expert in the art of constructing correct English sentences. His practice was to look over a page or two of a Greek or Latin author, to make himself master of the meaning, and then to read the passage straight forward into his own language. This practice, begun under his first teacher Wilson, was continued under Pretyman. It is not strange that a young man of great abilities, who had been exercised daily in this way during ten years, should have acquired an almost unrivalled power of putting his thoughts, without premeditation, into words well selected and well arranged.

Of all the remains of antiquity, the orations were those on which he bestowed the most minute examination. His favourite employment was to compare harangues on opposite sides of the same question, to analyse them, and to observe which of the arguments of the first speaker were refuted by the second, which were evaded, and which were left untouched. Nor was it only in books that he at this time studied the art of parliamentary fencing. When he was at home, he had frequent opportunities of hearing important debates at Westminster; and he heard them, not only with interest and enjoyment, but with a close scientific attention resembling that with which a diligent pupil at Guy's Hospital watches every turn of the hand of a great surgeon through a difficult operation. On one of these occasions, Pitt, a youth whose abilities were as yet known only to his own family and to a small knot of college friends, was introduced on the steps of the throne in the House of Lords to Fox, who was his senior by eleven years, and who was already the greatest debater, and one of the greatest orators, that had appeared in England. Fox used afterwards to relate that, as the discussion proceeded, Pitt repeatedly turned to him, and said, "But surely, Mr Fox, that might be met thus;" or, "Yes; but he lays himself open to this retort." What the particular criticisms were Fox had forgotten; but he said that he was much struck at the time by the precocity of a lad who, through the whole sitting, seemed to be thinking only how all the speeches on both sides could be answered.

One of the young man's visits to the House of Lords was a sad and memorable era in his life. He had not quite completed his nineteenth year, when, on the 7th of April 1778, he attended his father to Westminster. A great debate was expected. It was known that France had recognised the independence of the United States. The Duke of Richmond was about to declare his opinion that all thought of subjugating those states ought to be relinquished. Chatham had always maintained that the resistance of the colonies to the mother country was justifiable. But he conceived, very erroneously, that on the day on which their independence should be acknowledged the greatness

of England would be at an end. Though sinking under the weight of years and infirmities, he determined, in spite of the entreaties of his family, to be in his place. His son supported him to a seat. The excitement and exertion were too much for the old man. In the very act of addressing the peers, he fell back in convulsions. A few weeks later his corpse was borne, with gloomy pomp, from the Painted Chamber to the Abbey. The favourite child and namesake of the deceased statesman followed the coffin as chief mourner, and saw it deposited in the transept where his own was destined to lie.

His elder brother, now Earl of Chatham, had means sufficient, and barely sufficient, to support the dignity of the peerage. The other members of the family were poorly provided for. William had little more than three hundred a year. It was necessary for him to follow a profession. He had already begun to eat his terms. In the spring of 1780 he came of age. He then quitted Cambridge, was called to the bar, took chambers in Lincoln's Inn, and joined the western circuit. In the autumn of that year a general election took place; and he offered himself as a candidate for the university; but he was at the bottom of the poll. It is said that the grave doctors who then sate, robed in scarlet, on the benches of Golgotha, thought it great presumption in so young a man to solicit so high a distinction. He was, however, at the request of a hereditary friend, the Duke of Rutland, brought into Parliament by Sir James Lowther for the borough of Appleby.

The dangers of the country were at that time such as might well have disturbed even a constant mind. Army after army had been sent in vain against the rebellious colonists of North America. On pitched fields of battle the advantage had been with the disciplined troops of the mother country. But it was not on pitched fields of battle that the event of such a contest could be decided. An armed nation, with hunger and the Atlantic for auxiliaries, was not to be subjugated. Meanwhile the House of Bourbon, humbled to the dust a few years before by the genius and vigour of Chatham, had seized the opportunity of revenge. France and Spain were united against us, and had recently been joined by Holland. The command of the Mediterranean had been for a time lost. The British flag had been scarcely able to maintain itself in the British Channel. The northern powers professed neutrality; but their neutrality had a menacing aspect. In the East, Hyder had descended on the Carnatic, had destroyed the little army of Baillie, and had spread terror even to the ramparts of Fort Saint George. The discontents of Ireland threatened nothing less than civil war. In England the authority of the government had sunk to the lowest point. The King and the House of Commons were alike unpopular. The cry for parliamentary reform was scarcely less loud and vehement than in the autumn of 1830. Formidable associations, headed, not by ordinary demagogues, but by men of high rank, stainless character, and distinguished ability, demanded a revision of the representative system. The populace, emboldened by the impotence and irresolution of the government, had recently broken loose from all restraint, besieged the chambers of the legislature, hustled peers, hunted bishops, attacked the residences of ambassadors, opened prisons, burned and pulled down houses. London had presented during some days the aspect of a city taken by storm; and it had been necessary to form a camp among the trees of Saint James's Park.

In spite of dangers and difficulties abroad and at home, George the Third, with a firmness which had little affinity with virtue or with wisdom, persisted in his determination to put down the American rebels by force of arms; and his ministers submitted their judgment to his. Some of them were probably actuated merely by selfish cupidity; but their chief, Lord North, a man of high honour, amiable temper, winning manners, lively wit, and excellent talents both for business and for debate, must be acquitted of all sordid motives. He remained at a post from which he had long wished and had repeatedly tried to escape, only because he had not sufficient fortitude to resist the entreaties and reproaches of the King, who silenced all arguments by passionately asking whether any gentleman, any man of spirit, could have the heart to desert a kind master in the hour of extremity.

The opposition consisted of two parties which had once been hostile to each other, and which had been very slowly, and, as it soon appeared, very imperfectly reconciled, but which at this conjuncture seemed to act together with cordiality. The larger of these parties consisted of the great body of the Whig aristocracy. Its head was Charles, Marquess of Rockingham, a man of sense and virtue, and in wealth and parliamentary interest equalled by very few of the English nobles, but afflicted with a nervous timidity which prevented him from taking a prominent part in debate. In the House of Commons, the adherents of Rockingham were led by Fox, whose dissipated habits and ruined fortunes were the talk of the whole town, but whose commanding genius, and whose sweet, generous, and affectionate disposition, extorted the admiration and love of those who most lamented the errors of his private life. Burke, superior to Fox in largeness of comprehension, in extent of knowledge, and in splendour of imagination, but less skilled in that kind of logic and in that kind of rhetoric which convince and persuade great assemblies, was willing to be the lieutenant of a young chief who might have been his son.

A smaller section of the opposition was composed of the old followers of Chatham. At their head was William, Earl of Shelburne, distinguished both as a statesman and as a lover of science and letters. With him were leagued Lord Camden, who had formerly held the Great Seal, and whose integrity, ability, and constitutional knowledge commanded the public respect; Barré, an eloquent and acrimonious declaimer; and Dunning, who had long held the first place at the English bar. It was to this party that Pitt was naturally attracted.

On the 26th of February 1781 he made his first speech in favour of Burke's plan of economical reform. Fox stood up at the same moment, but instantly gave way. The lofty yet animated deportment of the young member, his perfect self-possession, the readiness with which he replied to the orators who had preceded him, the silver tones of his voice, the perfect structure of his unpremeditated sentences, astonished and delighted his hearers. Burke, moved even to tears, exclaimed, "It is not a chip of the old block; it is the old block itself." "Pitt will be one of the first men in Parliament," said a member of the opposition to Fox. "He is so already," answered Fox, in whose nature envy had no place. It is a curious fact, well remembered by some who were very recently living, that soon after this debate Pitt's name was put up by Fox at Brookes's.

On two subsequent occasions during that session Pitt addressed the House, and on both fully sustained the reputation which he had acquired on his first appearance. In the summer, after the prorogation, he again went the western circuit, held several briefs, and acquitted himself in such a manner that he was highly complimented by Buller from the bench, and by Dunning at the bar.

On the 27th of November the Parliament reassembled. Only forty-eight hours before had arrived tidings of the surrender of Cornwallis and his army; and it had consequently been necessary to rewrite the royal speech. Every man in the kingdom, except the King, was now convinced that it was mere madness to think of conquering the United States. In the debate on the report of the address, Pitt

spoke with even more energy and brilliancy than on any former occasion. He was warmly applauded by his allies; but it was remarked that no person on his own side of the house was so loud in eulogy as Henry Dundas, the Lord Advocate of Scotland, who spoke from the ministerial ranks. That able and versatile politician distinctly foresaw the approaching downfall of the government with which he was connected, and was preparing to make his own escape from the ruin. From that night dates his connection with Pitt, a connection which soon became a close intimacy, and which lasted till it was dissolved by death.

About a fortnight later, Pitt spoke in the committee of supply on the army estimates. Symptoms of dissension had begun to appear on the Treasury bench. Lord George Germaine, the Secretary of State who was especially charged with the direction of the war in America, had held language not easily to be reconciled with declarations made by the First Lord of the Treasury. Pitt noticed the discrepancy with much force and keenness. Lord George and Lord North began to whisper together; and Welbore Ellis, an ancient placeman who had been drawing salary almost every quarter since the days of Henry Pelham, bent down between them to put in a word. Such interruptions sometimes discompose veteran speakers. Pitt stopped, and, looking at the group, said, with admirable readiness, "I shall wait till Nestor has composed the dispute between Agamemnon and Achilles."

After several defeats, or victories hardly to be distinguished from defeats, the ministry resigned. The King, reluctantly and ungraciously, consented to accept Rockingham as first minister. Fox and Shelburne became Secretaries of State. Lord John Cavendish, one of the most upright and honourable of men, was made Chancellor of the Exchequer. Thurlow, whose abilities and force of character had made him the dictator of the House of Lords, continued to hold the great seal.

To Pitt was offered, through Shelburne, the Vice-Treasurership of Ireland, one of the easiest and most highly paid places in the gift of the Crown; but the offer was, without hesitation, declined. The young statesman had resolved to accept no post which did not entitle him to a seat in the cabinet; and a few days later, he announced that resolution in the House of Commons. It must be remembered that the cabinet was then a much smaller and more select body than at present. We have seen cabinets of sixteen. In the time of our grandfathers a cabinet of ten or eleven was thought inconveniently large. Seven was an usual number. Even Burke, who had taken the lucrative office of Paymaster, was not in the cabinet. Many therefore thought Pitt's declaration indecent. He himself was sorry that he had made it. The words, he said in private, had escaped him in the heat of speaking; and he had no sooner uttered them than he would have given the world to recall them. They, however, did him no harm with the public. The second William Pitt, it was said, had shown that he had inherited the spirit, as well as the genius, of the first. In the son, as in the father, there might perhaps be too much pride; but there was nothing low or sordid. It might be called arrogance in a young barrister, living in chambers on three hundred a year, to refuse a salary of five thousand a year, merely because he did not choose to bind himself to speak or vote for plans which he had no share in framing; but surely such arrogance was not very far removed from virtue.

Pitt gave a general support to the administration of Rockingham, but omitted, in the meantime, no opportunity of courting that Ultra-Whig party which the persecution of Wilkes and the Middlesex election had called into existence, and which the disastrous events of the war, and the triumph of republican principles in America, had made formidable both in numbers and in temper. He supported a motion for shortening the duration of Parliaments. He made a motion for a committee to examine into the state of the representation, and, in the speech by which that motion was introduced, avowed himself the enemy of the close boroughs, the strongholds of that corruption to which he attributed all the calamities of the nation, and which, as he phrased it in one of those exact and sonorous sentences of which he had a boundless command, had grown with the growth of England and strengthened with her strength, but had not diminished with her diminution or decayed with her decay. On this occasion he was supported by Fox. The motion was lost by only twenty votes in a house of more than three hundred members. The reformers never again had so good a division till the year 1831.

The new administration was strong in abilities, and was more popular than any administration which had held office since the first year of George the Third, but was hated by the King, hesitatingly supported by the Parliament, and torn by internal dissensions. The Chancellor was disliked and distrusted by almost all his colleagues. The two Secretaries of State regarded each other with no friendly feeling. The line between their departments had not been traced with precision; and there were consequently jealousies, encroachments, and complaints. It was all that Rockingham could do to keep the peace in his cabinet; and, before the cabinet had existed three months, Rockingham died.

In an instant all was confusion. The adherents of the deceased statesman looked on the Duke of Portland as their chief. The King placed Shelburne at the head of the Treasury. Fox, Lord John Cavendish, and Burke, immediately resigned their offices; and the new prime minister was left to constitute a government out of very defective materials. His own parliamentary talents were great; but he could not be in the place where parliamentary talents were most needed. It was necessary to find some member of the House of Commons who could confront the great orators of the opposition; and Pitt alone had the eloquence and the courage which were required. He was offered the great place of Chancellor of the Exchequer, and he accepted it. He had scarcely completed his twenty-third year.

The Parliament was speedily prorogued. During the recess, a negotiation for peace which had been commenced under Rockingham was brought to a successful termination. England acknowledged the independence of her revolted colonies; and she ceded to her European enemies some places in the Mediterranean and in the Gulf of Mexico. But the terms which she obtained were quite as advantageous and honourable as the events of the war entitled her to expect, or as she was likely to obtain by persevering in a contest against immense odds. All her vital parts, all the real sources of her power, remained uninjured. She preserved even her dignity; for she ceded to the House of Bourbon only part of what she had won from that House in previous wars. She retained her Indian empire undiminished; and, in spite of the mightiest efforts of two great monarchies, her flag still waved on the rock of Gibraltar. There is not the slightest reason to believe that Fox, if he had remained in office, would have hesitated one moment about concluding a treaty on such conditions. Unhappily that great and most amiable man was, at this crisis, hurried by his passions into an error which made his genius and his virtues, during a long course of years, almost useless to his country.

He saw that the great body of the House of Commons was divided into three parties, his own, that of North, and that of Shelburne; that none of those three parties was large enough to stand alone; that, therefore, unless two of them united, there must be a miserably feeble administration, or, more probably, a rapid succession of miserably feeble administrations, and this at a time when a strong government was essential to the prosperity and respecta-

bility of the nation. It was then necessary and right that there should be a coalition. To every possible coalition there were objections. But, of all possible coalitions, that to which there were the fewest objections was undoubtedly a coalition between Shelburne and Fox. It would have been generally applauded by the followers of both. It might have been made without any sacrifice of public principle on the part of either. Unhappily, recent bickerings had left in the mind of Fox a profound dislike and distrust of Shelburne. Pitt attempted to mediate, and was authorised to invite Fox to return to the service of the Crown. "Is Lord Shelburne," said Fox, "to remain prime minister?" Pitt answered in the affirmative. "It is impossible that I can act under him," said Fox. "Then negotiation is at an end," said Pitt; "for I cannot betray him." Thus the two statesmen parted. They were never again in a private room together.

As Fox and his friends would not treat with Shelburne, nothing remained to them but to treat with North. That fatal coalition which is emphatically called "The Coalition" was formed. Not three quarters of a year had elapsed since Fox and Burke had threatened North with impeachment, and had described him, night after night, as the most arbitrary, the most corrupt, the most incapable of ministers. They now allied themselves with him for the purpose of driving from office a statesman with whom they cannot be said to have differed as to any important question. Nor had they even the prudence and the patience to wait for some occasion on which they might, without inconsistency, have combined with their old enemies in opposition to the government. That nothing might be wanting to the scandal, the great orators who had, during seven years, thundered against the war, determined to join with the authors of that war in passing a vote of censure on the peace.

The Parliament met before Christmas 1782. But it was not till January 1783 that the preliminary treaties were signed. On the 17th of February they were taken into consideration by the House of Commons. There had been, during some days, floating rumours that Fox and North had coalesced; and the debate indicated but too clearly that those rumours were not unfounded. Pitt was suffering from indisposition: he did not rise till his own strength and that of his hearers were exhausted; and he was consequently less successful than on any former occasion. His admirers owned that his speech was feeble and petulant. He so far forgot himself as to advise Sheridan to confine himself to amusing theatrical audiences. This ignoble sarcasm gave Sheridan an opportunity of retorting with great felicity. "After what I have seen and heard to-night," he said, "I really feel strongly tempted to venture on a competition with so great an artist as Ben Jonson, and to bring on the stage a second Angry Boy." On a division, the address proposed by the supporters of the government was rejected by a majority of sixteen.

But Pitt was not a man to be disheartened by a single failure, or to be put down by the most lively repartee. When, a few days later, the opposition proposed a resolution directly censuring the treaties, he spoke with an eloquence, energy, and dignity, which raised his fame and popularity higher than ever. To the coalition of Fox and North he alluded in language which drew forth tumultuous applause from his followers. "If," he said, "this ill-omened and unnatural marriage be not yet consummated, I know of a just and lawful impediment; and, in the name of the public weal, I forbid the banns."

The ministers were again left in a minority, and Shelburne consequently tendered his resignation. It was accepted: but the King struggled long and hard before he submitted to the terms dictated by Fox, whose faults he detested, and whose high spirit and powerful intellect he detested still more. The first place at the board of Treasury was repeatedly offered to Pitt: but the offer, though tempting, was steadfastly declined. The young man, whose judgment was as precocious as his eloquence, saw that his time was coming, but was not come, and was deaf to royal importunities and reproaches. His Majesty, bitterly complaining of Pitt's faintheartedness, tried to break the coalition. Every art of seduction was practised on North, but in vain. During several weeks the country remained without a government. It was not till all devices had failed, and till the aspect of the House of Commons became threatening, that the King gave way. The Duke of Portland was declared First Lord of the Treasury. Thurlow was dismissed. Fox and North became Secretaries of State, with power ostensibly equal. But Fox was the real prime minister.

The year was far advanced before the new arrangements were completed; and nothing very important was done during the remainder of the session. Pitt, now seated on the opposition bench, brought the question of parliamentary reform a second time under the consideration of the Commons. He proposed to add to the House at once a hundred county members and several members for metropolitan districts, and to enact that every borough of which an election committee should report that the majority of voters appeared to be corrupt should lose the franchise. The motion was rejected by 293 votes to 149.

After the prorogation, Pitt visited the Continent for the first and last time. His travelling companion was one of his most intimate friends, a young man of his own age, who had already distinguished himself in Parliament by an engaging natural eloquence, set off by the sweetest and most exquisitely modulated of human voices, and whose affectionate heart, caressing manners, and brilliant wit, made him the most delightful of companions, William Wilberforce. That was the time of Anglomania in France; and at Paris the son of the great Chatham was absolutely hunted by men of letters and women of fashion, and forced, much against his will, into political disputation. One remarkable saying which dropped from him during this tour has been preserved. A French gentleman expressed some surprise at the immense influence which Fox, a man of pleasure, ruined by the dice-box and the turf, exercised over the English nation. "You have not," said Pitt, "been under the wand of the magician."

In November 1783 the Parliament met again. The government had irresistible strength in the House of Commons, and seemed to be scarcely less strong in the House of Lords, but was, in truth, surrounded on every side by dangers. The King was impatiently waiting for the moment at which he could emancipate himself from a yoke which galled him so severely that he had more than once seriously thought of retiring to Hanover; and the King was scarcely more eager for a change than the nation. Fox and North had committed a fatal error. They ought to have known that coalitions between parties which have long been hostile can succeed only when the wish for coalition pervades the lower ranks of both. If the leaders unite before there is any disposition to union among the followers, the probability is that there will be a mutiny in both camps, and that the two revolted armies will make a truce with each other, in order to be revenged on those by whom they think that they have been betrayed. Thus it was in 1783. At the beginning of that eventful year, North had been the recognised head of the old Tory party, which, though for a moment prostrated by the disastrous issue of the American war, was still a great power in the state. To him the clergy, the universities, and that large body of country gentlemen whose rallying cry was "Church and King," had long looked up with respect and confidence. Fox had, on the other hand, been the idol of the Whigs,

and of the whole body of Protestant dissenters. The coalition at once alienated the most zealous Tories from North, and the most zealous Whigs from Fox. The University of Oxford, which had marked its approbation of North's orthodoxy by electing him chancellor, the city of London, which had been, during two and twenty years, at war with the Court, were equally disgusted. Squires and rectors, who had inherited the principles of the cavaliers of the preceding century, could not forgive their old leader for combining with disloyal subjects in order to put a force on the sovereign. The members of the Bill of Rights Society and of the Reform Associations were enraged by learning that their favourite orator now called the great champion of tyranny and corruption his noble friend. Two great multitudes were at once left without any head, and both at once turned their eyes on Pitt. One party saw in him the only man who could rescue the King; the other saw in him the only man who could purify the Parliament. He was supported on one side by Archbishop Markham, the preacher of divine right, and by Jenkinson, the captain of the Prætorian band of the King's friends; on the other side by Jebb and Priestley, Sawbridge and Cartwright, Jack Wilkes and Horne Tooke. On the benches of the House of Commons, however, the ranks of the ministerial majority were unbroken; and that any statesman would venture to brave such a majority was thought impossible. No prince of the Hanoverian line had ever, under any provocation, ventured to appeal from the representative body to the constituent body. The ministers, therefore, notwithstanding the sullen looks and muttered words of displeasure with which their suggestions were received in the closet, notwithstanding the roar of obloquy which was rising louder and louder every day from every corner of the island, thought themselves secure.

Such was their confidence in their strength that, as soon as the Parliament had met, they brought forward a singularly bold and original plan for the government of the British territories in India. What was proposed was that the whole authority, which till that time had been exercised over those territories by the East India Company, should be transferred to seven commissioners who were to be named by Parliament, and were not to be removable at the pleasure of the Crown. Earl Fitzwilliam, the most intimate personal friend of Fox, was to be chairman of this board, and the eldest son of North was to be one of the members.

As soon as the outlines of the scheme were known, all the hatred which the coalition had excited burst forth with an astounding explosion. The question which ought undoubtedly to have been considered as paramount to every other was, whether the proposed change was likely to be beneficial or injurious to the thirty millions of people who were subject to the Company. But that question cannot be said to have been even seriously discussed. Burke, who, whether right or wrong in the conclusions to which he came, had at least the merit of looking at the subject in the right point of view, vainly reminded his hearers of that mighty population whose daily rice might depend on a vote of the British Parliament. He spoke, with even more than his wonted power of thought and language, about the desolation of Rohilcund, about the spoliation of Benares, about the evil policy which had suffered the tanks of the Carnatic to go to ruin; but he could scarcely obtain a hearing. The contending parties, to their shame it must be said, would listen to none but English topics. Out of doors the cry against the ministry was almost universal. Town and country were united. Corporations exclaimed against the violation of the charter of the greatest corporation in the realm. Tories and democrats joined in pronouncing the proposed board an unconstitutional body. It was to consist of Fox's nominees. The effect of his bill was to give, not to the Crown, but to him personally, whether in office or in opposition, an enormous power, a patronage sufficient to counterbalance the patronage of the Treasury and of the Admiralty, and to decide the elections for fifty boroughs. He knew, it was said, that he was hateful alike to King and people; and he had devised a plan which would make him independent of both. Some nicknamed him Cromwell, and some Carlo Khan. Wilberforce, with his usual felicity of expression, and with very unusual bitterness of feeling, described the scheme as the genuine offspring of the coalition, as marked with the features of both its parents, the corruption of one and the violence of the other. In spite of all opposition, however, the bill was supported in every stage by great majorities, was rapidly passed, and was sent up to the Lords. To the general astonishment, when the second reading was moved in the Upper House, the opposition proposed an adjournment, and carried it by eighty-seven votes to seventy-nine. The cause of this strange turn of fortune was soon known. Pitt's cousin, Earl Temple, had been in the royal closet, and had there been authorised to let it be known that His Majesty would consider all who voted for the bill as his enemies. The ignominious commission was performed, and instantly a troop of Lords of the Bedchamber, of Bishops who wished to be translated, and of Scotch peers who wished to be re-elected, made haste to change sides. On a later day, the Lords rejected the bill. Fox and North were immediately directed to send their seals to the palace by their Under Secretaries; and Pitt was appointed First Lord of the Treasury and Chancellor of the Exchequer.

The general opinion was, that there would be an immediate dissolution. But Pitt wisely determined to give the public feeling time to gather strength. On this point he differed from his kinsman Temple. The consequence was, that Temple, who had been appointed one of the Secretaries of State, resigned his office forty-eight hours after he had accepted it, and thus relieved the new government from a great load of unpopularity: for all men of sense and honour, however strong might be their dislike of the India Bill, disapproved of the manner in which that bill had been thrown out. Temple carried away with him the scandal which the best friends of the new government could not but lament. The fame of the young prime minister preserved its whiteness. He could declare with perfect truth that, if unconstitutional machinations had been employed, he had been no party to them.

He was, however, surrounded by difficulties and dangers. In the House of Lords, indeed, he had a majority; nor could any orator of the opposition in that assembly be considered as a match for Thurlow, who was now again Chancellor, or for Camden, who cordially supported the son of his old friend Chatham. But in the other House there was not a single eminent speaker among the official men who sate round Pitt. His most useful assistant was Dundas, who, though he had not eloquence, had sense, knowledge, readiness, and boldness. On the opposite benches was a powerful majority, led by Fox, who was supported by Burke, North, and Sheridan. The heart of the young minister, stout as it was, almost died within him. He could not once close his eyes on the night which followed Temple's resignation. But, whatever his internal emotions might be, his language and deportment indicated nothing but unconquerable firmness and haughty confidence in his own powers. His contest against the House of Commons lasted from the 17th of December 1783 to the 8th of March 1784. In sixteen divisions the opposition triumphed. Again and again the King was requested to dismiss his ministers. But he was determined to go to Germany rather than yield. Pitt's resolution never wavered. The cry of the nation in his favour became vehement and almost furious. Addresses assuring him of public support came up

daily from every part of the kingdom. The freedom of the city of London was presented to him in a gold box. He went in state to receive this mark of distinction. He was sumptuously feasted in Grocers' Hall; and the shopkeepers of the Strand and Fleet Street illuminated their houses in his honour. These things could not but produce an effect within the walls of Parliament. The ranks of the majority began to waver; a few passed over to the enemy; some skulked away; many were for capitulating while it was still possible to capitulate with the honours of war. Negotiations were opened with the view of forming an administration on a wide basis, but they had scarcely been opened when they were closed. The opposition demanded, as a preliminary article of the treaty, that Pitt should resign the Treasury; and with this demand Pitt stedfastly refused to comply. While the contest was raging, the Clerkship of the Pells, a sinecure place for life, worth three thousand a year, and tenable with a seat in the House of Commons, became vacant. The appointment was with the Chancellor of the Exchequer: nobody doubted that he would appoint himself; and nobody could have blamed him if he had done so: for such sinecure offices had always been defended on the ground that they enabled a few men of eminent abilities and small incomes to live without any profession, and to devote themselves to the service of the state. Pitt, in spite of the remonstrances of his friends, gave the Pells to his father's old adherent, Colonel Barré, a man distinguished by talent and eloquence, but poor and afflicted with blindness. By this arrangement a pension which the Rockingham administration had granted to Barré was saved to the public. Never was there a happier stroke of policy. About treaties, wars, expeditions, tariffs, budgets, there will always be room for dispute. The policy which is applauded by half the nation may be condemned by the other half. But pecuniary disinterestedness everybody comprehends. It is a great thing for a man who has only three hundred a year to be able to show that he considers three thousand a year as mere dirt beneath his feet, when compared with the public interest and the public esteem. Pitt had his reward. No minister was ever more rancorously libelled; but even when he was known to be overwhelmed with debt, when millions were passing through his hands, when the wealthiest magnates of the realm were soliciting him for marquisates and garters, his bitterest enemies did not dare to accuse him of touching unlawful gain.

At length the hard fought fight ended. A final remonstrance, drawn up by Burke with admirable skill, was carried on the 8th of March by a single vote in a full House. Had the experiment been repeated, the supporters of the coalition would probably have been in a minority. But the supplies had been voted; the Mutiny Bill had been passed; and the Parliament was dissolved.

The popular constituent bodies all over the country were in general enthusiastic on the side of the new government. A hundred and sixty of the supporters of the coalition lost their seats. The First Lord of the Treasury himself came in at the head of the poll for the University of Cambridge. His young friend, Wilberforce, was elected Knight of the great shire of York, in opposition to the whole influence of the Fitzwilliams, Cavendishes, Dundases, and Saviles. In the midst of such triumphs Pitt completed his twenty-fifth year. He was now the greatest subject that England had seen during many generations. He domineered absolutely over the cabinet, and was the favourite at once of the Sovereign, of the Parliament, and of the nation. His father had never been so powerful, nor Walpole, nor Marlborough.

This narrative has now reached a point, beyond which a full history of the life of Pitt would be a history of England, or rather of the whole civilised world; and for such a history this is not the proper place. Here a very slight sketch must suffice; and in that sketch prominence will be given to such points as may enable a reader who is already acquainted with the general course of events to form a just notion of the character of the man on whom so much depended.

If we wish to arrive at a correct judgment of Pitt's merits and defects, we must never forget that he belonged to a peculiar class of statesmen, and that he must be tried by a peculiar standard. It is not easy to compare him fairly with such men as Ximenes and Sully, Richelieu and Oxenstiern, John De Witt and Warren Hastings. The means by which those politicians governed great communities were of quite a different kind from those which Pitt was under the necessity of employing. Some talents, which they never had any opportunity of showing that they possessed, were developed in him to an extraordinary degree. In some qualities, on the other hand, to which they owe a large part of their fame, he was decidedly their inferior. They transacted business in their closets, or at boards where a few confidential councillors sate. It was his lot to be born in an age and in a country in which parliamentary government was completely established; his whole training from infancy was such as fitted him to bear a part in parliamentary government; and, from the prime of his manhood to his death, all the powers of his vigorous mind were almost constantly exerted in the work of parliamentary government. He accordingly became the greatest master of the whole art of parliamentary government that has ever existed, a greater than Montague or Walpole, a greater than his father Chatham or his rival Fox, a greater than either of his illustrious successors Canning and Peel.

Parliamentary government, like every other contrivance of man, has its advantages and its disadvantages. On the advantages there is no need to dilate. The history of England during the hundred and seventy years which have elapsed since the House of Commons became the most powerful body in the state, her immense and still growing prosperity, her freedom, her tranquillity, her greatness in arts, in sciences, and in arms, her maritime ascendency, the marvels of her public credit, her American, her African, her Australian, her Asiatic empires, sufficiently prove the excellence of her institutions. But those institutions, though excellent, are assuredly not perfect. Parliamentary government is government by speaking. In such a government, the power of speaking is the most highly prized of all the qualities which a politician can possess; and that power may exist, in the highest degree, without judgment, without fortitude, without skill in reading the characters of men or the signs of the times, without any knowledge of the principles of legislation or of political economy, and without any skill in diplomacy or in the administration of war. Nay, it may well happen that those very intellectual qualities which give a peculiar charm to the speeches of a public man may be incompatible with the qualities which would fit him to meet a pressing emergency with promptitude and firmness. It was thus with Charles Townshend. It was thus with Windham. It was a privilege to listen to those accomplished and ingenious orators. But in a perilous crisis they would have been found far inferior in all the qualities of rulers to such a man as Oliver Cromwell, who talked nonsense, or as William the Silent, who did not talk at all. When parliamentary government is established, a Charles Townshend or a Windham will almost always exercise much greater influence than such men as the great Protector of England, or as the founder of the Batavian commonwealth. In such a government, parliamentary talent, though quite distinct from the talents of a good executive or judicial officer, will be a chief qualification for executive and judicial office. From the Book of Dignities a curious list might be made out of Chancellors ignorant of the principles of equity, and First Lords of the Admiralty ignorant of the principles of navigation, of

Colonial ministers who could not repeat the names of the Colonies, of Lords of the Treasury who did not know the difference between funded and unfunded debt, and of Secretaries of the India Board who did not know whether the Mahrattas were Mahometans or Hindoos. On these grounds, some persons, incapable of seeing more than one side of a question, have pronounced parliamentary government a positive evil, and have maintained that the administration would be greatly improved if the power, now exercised by a large assembly, were transferred to a single person. Men of sense will probably think the remedy very much worse than the disease, and will be of opinion that there would be small gain in exchanging Charles Townshend and Windham for the Prince of the Peace, or the poor slave and dog Steenie.

Pitt was emphatically the man of parliamentary government, the type of his class, the minion, the child, the spoiled child, of the House of Commons. For the House of Commons he had a hereditary, an infantine love. Through his whole boyhood, the House of Commons was never out of his thoughts, or out of the thoughts of his instructors. Reciting at his father's knee, reading Thucydides and Cicero into English, analysing the great Attic speeches on the Embassy and on the Crown, he was constantly in training for the conflicts of the House of Commons. He was a distinguished member of the House of Commons at twenty-one. The ability which he had displayed in the House of Commons made him the most powerful subject in Europe before he was twenty-five. It would have been happy for himself and for his country if his elevation had been deferred. Eight or ten years, during which he would have had leisure and opportunity for reading and reflection, for foreign travel, for social intercourse and free exchange of thought on equal terms with a great variety of companions, would have supplied what, without any fault on his part, was wanting to his powerful intellect. He had all the knowledge that he could be expected to have; that is to say, all the knowledge that a man can acquire while he is a student at Cambridge, and all the knowledge that a man can acquire when he is First Lord of the Treasury and Chancellor of the Exchequer. But the stock of general information which he brought from college, extraordinary for a boy, was far inferior to what Fox possessed, and beggarly when compared with the massy, the splendid, the various treasures laid up in the large mind of Burke. After Pitt became minister, he had no leisure to learn more than was necessary for the purposes of the day which was passing over him. What was necessary for those purposes such a man could learn with little difficulty. He was surrounded by experienced and able public servants. He could at any moment command their best assistance. From the stores which they produced his vigorous mind rapidly collected the materials for a good parliamentary case: and that was enough. Legislation and administration were with him secondary matters. To the work of framing statutes, of negotiating treaties, of organising fleets and armies, of sending forth expeditions, he gave only the leavings of his time and the dregs of his fine intellect. The strength and sap of his mind were all drawn in a different direction. It was when the House of Commons was to be convinced and persuaded that he put forth all his powers.

Of those powers we must form our estimate chiefly from tradition; for of all the eminent speakers of the last age, Pitt has suffered most from the reporters. Even while he was still living, critics remarked that his eloquence could not be preserved, that he must be heard to be appreciated. They more than once applied to him the sentence in which Tacitus describes the fate of a senator whose rhetoric was admired in the Augustan age: "Haterii canorum illud et profluens cum ipso simul exstinctum est." There is, however, abundant evidence that nature had bestowed on Pitt the talents of a great orator; and those talents had been developed in a very peculiar manner, first by his education, and secondly by the high official position to which he rose early, and in which he passed the greater part of his public life.

At his first appearance in Parliament he showed himself superior to all his contemporaries in command of language. He could pour forth a long succession of round and stately periods, without premeditation, without ever pausing for a word, without ever repeating a word, in a voice of silver clearness, and with a pronunciation so articulate that not a letter was slurred over. He had less amplitude of mind and less richness of imagination than Burke, less ingenuity than Windham, less wit than Sheridan, less perfect mastery of dialectical fence, and less of that highest sort of eloquence which consists of reason and passion fused together, than Fox. Yet the almost unanimous judgment of those who were in the habit of listening to that remarkable race of men placed Pitt, as a speaker, above Burke, above Windham, above Sheridan, and not below Fox. His declamation was copious, polished, and splendid. In power of sarcasm he was probably not surpassed by any speaker, ancient or modern; and of this formidable weapon he made merciless use. In two parts of the oratorical art which are of the highest value to a minister of state he was singularly expert. No man knew better how to be luminous or how to be obscure. When he wished to be understood, he never failed to make himself understood. He could with ease present to his audience, not perhaps an exact or profound, but a clear, popular, and plausible view of the most extensive and complicated subject. Nothing was out of place; nothing was forgotten; minute details, dates, sums of money, were all faithfully preserved in his memory. Even intricate questions of finance, when explained by him, seemed clear to the plainest man among his hearers. On the other hand, when he did not wish to be explicit,—and no man who is at the head of affairs always wishes to be explicit,—he had a marvellous power of saying nothing in language which left on his audience the impression that he had said a great deal. He was at once the only man who could open a budget without notes, and the only man who, as Windham said, could speak that most elaborately evasive and unmeaning of human compositions, a King's speech, without premeditation.

The effect of oratory will always to a great extent depend on the character of the orator. There perhaps never were two speakers whose eloquence had more of what may be called the race, more of the flavour imparted by moral qualities, than Fox and Pitt. The speeches of Fox owe a great part of their charm to that warmth and softness of heart, that sympathy with human suffering, that admiration for everything great and beautiful, and that hatred of cruelty and injustice, which interest and delight us even in the most defective reports. No person, on the other hand, could hear Pitt without perceiving him to be a man of high, intrepid, and commanding spirit, proudly conscious of his own rectitude and of his own intellectual superiority, incapable of the low vices of fear and envy, but too prone to feel and to show disdain. Pride, indeed, pervaded the whole man, was written in the harsh, rigid lines of his face, was marked by the way in which he walked, in which he sate, in which he stood, and, above all, in which he bowed. Such pride, of course, inflicted many wounds. It may confidently be affirmed that there cannot be found, in all the ten thousand invectives written against Fox, a word indicating that his demeanour had ever made a single personal enemy. On the other hand, several men of note who had been partial to Pitt, and who to the last continued to approve his public conduct and to support his administration, Cumberland, for example, Boswell, and Matthias, were so much irritated by the contempt with which he

treated them, that they complained in print of their wrongs. But his pride, though it made him bitterly disliked by individuals, inspired the great body of his followers in Parliament and throughout the country with respect and confidence. They took him at his own valuation. They saw that his self-esteem was not that of an upstart who was drunk with good luck and with applause, and who, if fortune turned, would sink from arrogance into abject humility. It was that of the magnanimous man so finely described by Aristotle in the Ethics, of the man who thinks himself worthy of great things, being in truth worthy. It sprang from a consciousness of great powers and great virtues, and was never so conspicuously displayed as in the midst of difficulties and dangers which would have unnerved and bowed down any ordinary mind. It was closely connected, too, with an ambition which had no mixture of low cupidity. There was something noble in the cynical disdain with which the mighty minister scattered riches and titles to right and left among those who valued them, while he spurned them out of his own way. Poor himself, he was surrounded by friends on whom he had bestowed three thousand, six thousand, ten thousand a year. Plain Mister himself, he had made more lords than any three ministers that had preceded him. The garter, for which the first dukes in the kingdom were contending, was repeatedly offered to him, and offered in vain.

The correctness of his private life added much to the dignity of his public character. In the relations of son, brother, uncle, master, friend, his conduct was exemplary. In the small circle of his intimate associates, he was amiable, affectionate, even playful. They loved him sincerely; they regretted him long; and they would hardly admit that he who was so kind and gentle with them could be stern and haughty with others. He indulged, indeed, somewhat too freely in wine, which he had early been directed to take as a medicine, and which use had made a necessary of life to him. But it was very seldom that any indication of undue excess could be detected in his tones or gestures; and, in truth, two bottles of port were little more to him than two dishes of tea. He had, when he was first introduced into the clubs of Saint James's Street, shown a strong taste for play; but he had the prudence and the resolution to stop before this taste had acquired the strength of habit. From the passion which generally exercises the most tyrannical dominion over the young he possessed an immunity, which is probably to be ascribed partly to his temperament and partly to his situation. His constitution was feeble: he was very shy; and he was very busy. The strictness of his morals furnished such buffoons as Peter Pindar and Captain Morris with an inexhaustible theme for merriment of no very delicate kind. But the great body of the middle class of Englishmen could not see the joke. They warmly praised the young statesman for commanding his passions, and for covering his frailties, if he had frailties, with decorous obscurity, and would have been very far indeed from thinking better of him if he had vindicated himself from the taunts of his enemies by taking under his protection a Nancy Parsons or a Marianne Clark.

No part of the immense popularity which Pitt long enjoyed is to be attributed to the eulogies of wits and poets. It might have been naturally expected that a man of genius, of learning, of taste, an orator whose diction was often compared to that of Tully, the representative, too, of a great university, would have taken a peculiar pleasure in befriending eminent writers, to whatever political party they might have belonged. The love of literature had induced Augustus to heap benefits on Pompeians, Somers to be the protector of nonjurors, Harley to make the fortunes of Whigs. But it could not move Pitt to show any favour even to Pittites. He was doubtless right in thinking that, in general, poetry, history, and philosophy ought to be suffered, like calico and cutlery, to find their proper price in the market, and that to teach men of letters to look habitually to the state for their recompense is bad for the state and bad for letters. Assuredly nothing can be more absurd or mischievous than to waste the public money in bounties for the purpose of inducing people who ought to be weighing out grocery or measuring out drapery to write bad or middling books. But, though the sound rule is that authors should be left to be remunerated by their readers, there will, in every generation, be a few exceptions to this rule. To distinguish these special cases from the mass is an employment well worthy of the faculties of a great and accomplished ruler; and Pitt would assuredly have had little difficulty in finding such cases. While he was in power, the greatest philologist of the age, his own contemporary at Cambridge, was reduced to earn a livelihood by the lowest literary drudgery, and to spend in writing squibs for the Morning Chronicle years to which we might have owed an all but perfect text of the whole tragic and comic drama of Athens. The greatest historian of the age, forced by poverty to leave his country, completed his immortal work on the shores of Lake Leman. The political heterodoxy of Porson, and the religious heterodoxy of Gibbon, may perhaps be pleaded in defence of the minister by whom those eminent men were neglected. But there were other cases in which no such excuse could be set up. Scarcely had Pitt obtained possession of unbounded power when an aged writer of the highest eminence, who had made very little by his writings, and who was sinking into the grave under a load of infirmities and sorrows, wanted five or six hundred pounds to enable him, during the winter or two which might still remain to him, to draw his breath more easily in the soft climate of Italy. Not a farthing was to be obtained; and before Christmas the author of the English Dictionary and of the Lives of the Poets had gasped his last in the river fog and coal smoke of Fleet Street. A few months after the death of Johnson appeared the Task, incomparably the best poem that any Englishman then living had produced—a poem, too, which could hardly fail to excite in a well constituted mind a feeling of esteem and compassion for the poet, a man of genius and virtue, whose means were scanty, and whom the most cruel of all the calamities incident to humanity had made incapable of supporting himself by vigorous and sustained exertion. Nowhere had Chatham been praised with more enthusiasm, or in verse more worthy of the subject, than in the Task. The son of Chatham, however, contented himself with reading and admiring the book, and left the author to starve. The pension which, long after, enabled poor Cowper to close his melancholy life, unmolested by duns and bailiffs, was obtained for him by the strenuous kindness of Lord Spencer. What a contrast between the way in which Pitt acted towards Johnson and the way in which Lord Grey acted towards his political enemy Scott, when Scott, worn out by misfortune and disease, was advised to try the effect of the Italian air! What a contrast between the way in which Pitt acted towards Cowper and the way in which Burke, a poor man and out of place, acted towards Crabbe! Even Dundas, who made no pretensions to literary taste, and was content to be considered as a hard-headed and somewhat coarse man of business, was, when compared with his eloquent and classically educated friend, a Mæcenas or a Leo. Dundas made Burns an exciseman, with seventy pounds a year; and this was more than Pitt, during his long tenure of power, did for the encouragement of letters. Even those who may think that it is, in general, no part of the duty of a government to reward literary merit, will hardly deny that a government, which has much lucrative church preferment in its gift, is bound, in distributing that preferment, not to overlook divines whose writings have rendered great service to the cause of religion. But it seems never to have occurred to Pitt that he lay

under any such obligation. All the theological works of all the numerous bishops whom he made and translated are not, when put together, worth fifty pages of the Horæ Paulinæ, of the Natural Theology, or of the View of the Evidences of Christianity. But on Paley the all-powerful minister never bestowed the smallest benefice. Artists Pitt treated as contemptuously as writers. For painting he did simply nothing. Sculptors, who had been selected to execute monuments voted by Parliament, had to haunt the antechambers of the Treasury during many years before they could obtain a farthing from him. One of them, after vainly soliciting the minister for payment during fourteen years, had the courage to present a memorial to the King, and thus obtained tardy and ungracious justice. Architects it was absolutely necessary to employ; and the worst that could be found seem to have been employed. Not a single fine public building of any kind or in any style was erected during his long administration. It may be confidently affirmed that no ruler whose abilities and attainments would bear any comparison with his has ever shown such cold disdain for what is excellent in arts and letters.

His first administration lasted seventeen years. That long period is divided by a strongly marked line into two almost exactly equal parts. The first part ended and the second began in the autumn of 1792. Throughout both parts Pitt displayed in the highest degree the talents of a parliamentary leader. During the first part he was a fortunate, and, in many respects, a skilful administrator. With the difficulties which he had to encounter during the second part he was altogether incapable of contending: but his eloquence and his perfect mastery of the tactics of the House of Commons concealed his incapacity from the multitude.

The eight years which followed the general election of 1784 were as tranquil and prosperous as any eight years in the whole history of England. Neighbouring nations which had lately been in arms against her, and which had flattered themselves that, in losing her American colonies, she had lost a chief source of her wealth and of her power, saw, with wonder and vexation, that she was more wealthy and more powerful than ever. Her trade increased. Her manufactures flourished. Her exchequer was full to overflowing. Very idle apprehensions were generally entertained, that the public debt, though much less than a third of the debt which we now bear with ease, would be found too heavy for the strength of the nation. Those apprehensions might not perhaps have been easily quieted by reason. But Pitt quieted them by a juggle. He succeeded in persuading first himself, and then the whole nation, his opponents included, that a new sinking fund, which, so far as it differed from former sinking funds, differed for the worse, would, by virtue of some mysterious power of propagation belonging to money, put into the pocket of the public creditor great sums not taken out of the pocket of the tax-payer. The country, terrified by a danger which was no danger, hailed with delight and boundless confidence a remedy which was no remedy. The minister was almost universally extolled as the greatest of financiers. Meanwhile both the branches of the House of Bourbon found that England was as formidable an antagonist as she had ever been. France had formed a plan for reducing Holland to vassalage. But England interposed, and France receded. Spain interrupted by violence the trade of our merchants with the regions near the Oregon. But England armed, and Spain receded. Within the island there was profound tranquillity. The King was, for the first time, popular. During the twenty-three years which had followed his accession he had not been loved by his subjects. His domestic virtues were acknowleged. But it was generally thought that the good qualities by which he was distinguished in private life were wanting to his political character. As a Sovereign, he was resentful, unforgiving, stubborn, cunning. Under his rule the country had sustained cruel disgraces and disasters; and every one of those disgraces and disasters was imputed to his strong antipathies, and to his perverse obstinacy in the wrong. One statesman after another complained that he had been induced by royal caresses, entreaties, and promises, to undertake the direction of affairs at a difficult conjuncture, and that, as soon as he had, not without sullying his fame and alienating his best friends, served the turn for which he was wanted, his ungrateful master began to intrigue against him, and to canvass against him. Grenville, Rockingham, Chatham, men of widely different characters, but all three upright and high-spirited, agreed in thinking that the Prince under whom they had successively held the highest place in the government was one of the most insincere of mankind. His confidence was reposed, they said, not in those known and responsible counsellors to whom he had delivered the seals of office, but in secret advisers who stole up the back stairs into his closet. In Parliament, his ministers, while defending themselves against the attacks of the opposition in front, were perpetually, at his instigation, assailed on the flank or in the rear by a vile band of mercenaries who called themselves his friends. These men constantly, while in possession of lucrative places in his service, spoke and voted against bills which he had authorised the First Lord of the Treasury or the Secretary of State to bring in. But from the day on which Pitt was placed at the head of affairs there was an end of secret influence. His haughty and aspiring spirit was not to be satisfied with the mere show of power. Any attempt to undermine him at Court, any mutinous movement among his followers in the House of Commons, was certain to be at once put down. He had only to tender his resignation; and he could dictate his own terms. For he, and he alone, stood between the King and the Coalition. He was therefore little less than Mayor of the Palace. The nation loudly applauded the King for having the wisdom to repose entire confidence in so excellent a minister. His Majesty's private virtues now began to produce their full effect. He was generally regarded as the model of a respectable country gentleman, honest, goodnatured, sober, religious. He rose early: he dined temperately: he was strictly faithful to his wife: he never missed church; and at church he never missed a response. His people heartily prayed that he might long reign over them; and they prayed the more heartily because his virtues were set off to the best advantage by the vices and follies of the Prince of Wales, who lived in close intimacy with the chiefs of the opposition.

How strong this feeling was in the public mind appeared signally on one great occasion. In the autumn of 1788 the King became insane. The opposition, eager for office, committed the great indiscretion of asserting that the heir apparent had, by the fundamental laws of England, a right to be Regent with the full powers of royalty. Pitt, on the other hand, maintained it to be the constitutional doctrine that, when a Sovereign is, by reason of infancy, disease, or absence, incapable of exercising the regal functions, it belongs to the estates of the realm to determine who shall be the vicegerent, and with what portion of the executive authority such vicegerent shall be entrusted. A long and violent contest followed, in which Pitt was supported by the great body of the people with as much enthusiasm as during the first months of his administration. Tories with one voice applauded him for defending the sick-bed of a virtuous and unhappy Sovereign against a disloyal faction and an undutiful son. Not a few Whigs applauded him for asserting the authority of Parliaments and the principles of the Revolution, in opposition to a doctrine which seemed to have too much affinity with the servile theory of indefeasible hereditary right. The middle class, always zealous on the side of decency and

the domestic virtues, looked forward with dismay to a reign resembling that of Charles II. The palace, which had now been, during thirty years, the pattern of an English home, would be a public nuisance, a school of profligacy. To the good King's repast of mutton and lemonade, despatched at three o'clock, would succeed midnight banquets, from which the guests would be carried home speechless. To the backgammon board at which the good King played for a little silver with his equerries, would succeed faro tables from which young patricians who had sate down rich would rise up beggars. The drawing-room, from which the frown of the Queen had repelled a whole generation of frail beauties, would now be again what it had been in the days of Barbara Palmer and Louisa de Querouaille. Nay, severely as the public reprobated the Prince's many illicit attachments, his one virtuous attachment was reprobated more severely still. Even in grave and pious circles his Protestant mistresses gave less scandal than his Popish wife. That he must be Regent nobody ventured to deny. But he and his friends were so unpopular that Pitt could, with general approbation, propose to limit the powers of the Regent by restrictions to which it would have been impossible to subject a Prince beloved and trusted by the country. Some interested men, fully expecting a change of administration, went over to the opposition. But the majority, purified by these desertions, closed its ranks, and presented a more firm array than ever to the enemy. In every division Pitt was victorious. When at length, after a stormy interregnum of three months, it was announced, on the very eve of the inauguration of the Regent, that the King was himself again, the nation was wild with delight. On the evening of the day on which His Majesty resumed his functions, a spontaneous illumination, the most general that had ever been seen in England, brightened the whole vast space from Highgate to Tooting, and from Hammersmith to Greenwich. On the day on which he returned thanks in the cathedral of his capital, all the horses and carriages within a hundred miles of London were too few for the multitudes which flocked to see him pass through the streets. A second illumination followed, which was even superior to the first in magnificence. Pitt with difficulty escaped from the tumultuous kindness of an innumerable multitude which insisted on drawing his coach from Saint Paul's Churchyard to Downing Street. This was the moment at which his fame and fortune may be said to have reached the zenith. His influence in the closet was as great as that of Carr or Villiers had been. His dominion over the Parliament was more absolute than that of Walpole or Pelham had been. He was at the same time as high in the favour of the populace as ever Wilkes or Sacheverell had been. Nothing did more to raise his character than his noble poverty. It was well known that, if he had been dismissed from office after more than five years of boundless power, he would hardly have carried out with him a sum sufficient to furnish the set of chambers in which, as he cheerfully declared, he meant to resume the practice of the law. His admirers, however, were by no means disposed to suffer him to depend on daily toil for his daily bread. The voluntary contributions which were awaiting his acceptance in the city of London alone would have sufficed to make him a rich man. But it may be doubted whether his haughty spirit would have stooped to accept a provision so honourably earned and so honourably bestowed.

To such a height of power and glory had this extraordinary man risen at twenty-nine years of age. And now the tide was on the turn. Only ten days after the triumphant procession to Saint Paul's, the States-General of France, after an interval of a hundred and seventy-four years, met at Versailles.

The nature of the great Revolution which followed was long very imperfectly understood in this country. Burke saw much further than any of his contemporaries; but whatever his sagacity descried was refracted and discoloured by his passions and his imagination. More than three years elapsed before the principles of the English administration underwent any material change. Nothing could as yet be milder or more strictly constitutional than the minister's domestic policy. Not a single act indicating an arbitrary temper or a jealousy of the people could be imputed to him. He had never applied to Parliament for any extraordinary powers. He had never used with harshness the ordinary powers entrusted by the constitution to the executive government. Not a single state prosecution which would even now be called oppressive had been instituted by him. Indeed, the only oppressive state prosecution instituted during the first eight years of his administration was that of Stockdale, which is to be attributed, not to the government, but to the chiefs of the opposition. In office, Pitt had redeemed the pledges which he had, at his entrance into public life, given to the supporters of parliamentary reform. He had, in 1785, brought forward a judicious plan for the improvement of the representative system, and had prevailed on the King, not only to refrain from talking against that plan, but to recommend it to the Houses in a speech from the throne.[1] This attempt failed: but there can be little doubt that, if the French Revolution had not produced a violent reaction of public feeling, Pitt would have performed, with little difficulty and no danger, that great work which, at a later period, Lord Grey could accomplish only by means which for a time loosened the very foundations of the commonwealth. When the atrocities of the slave trade were first brought under the consideration of Parliament, no abolitionist was more zealous than Pitt. When sickness prevented Wilberforce from appearing in public, his place was most efficiently supplied by his friend the minister. A humane bill, which mitigated the horrors of the middle passage, was, in 1788, carried by the eloquence and determined spirit of Pitt, in spite of the opposition of some of his own colleagues; and it ought always to be remembered to his honour that, in order to carry that bill, he kept the Houses sitting, in spite of many murmurs, long after the business of the government had been done, and the Appropriation Act passed. In 1791 he cordially concurred with Fox in maintaining the sound constitutional doctrine, that an impeachment is not terminated by a dissolution. In the course of the same year the two great rivals contended side by side in a far more important cause. They are fairly entitled to divide the high honour of having added to our statute-book the inestimable law which places the liberty of the press under the protection of juries. On one occasion, and one alone, Pitt, during the first half of his long administration, acted in a manner unworthy of an enlightened Whig. In the debate on the Test Act, he stooped to gratify the master whom he served, the university which he represented, and the great body of clergymen and country gentlemen on whose support he rested, by talking, with little heartiness, indeed, and with no asperity, the language of a Tory. With this single exception, his conduct from the end of 1783 to the middle of 1792 was that of an honest friend of civil and religious liberty.

Nor did anything, during that period, indicate that he loved war, or harboured any malevolent feeling against any neighbouring nation. Those French writers who have

[1] The speech with which the King opened the session of 1785 concluded with an assurance that His Majesty would heartily concur in every measure which could tend to secure the true principles of the constitution. These words were at the time understood to refer to Pitt's Reform Bill.

represented him as a Hannibal sworn in childhood by his father to bear eternal hatred to France, as having, by mysterious intrigues and lavish bribes, instigated the leading Jacobins to commit those excesses which dishonoured the Revolution, as having been the real author of the first coalition, know nothing of his character or of his history. So far was he from being a deadly enemy to France, that his laudable attempts to bring about a closer connection with that country by means of a wise and liberal treaty of commerce brought on him the severe censure of the opposition. He was told in the House of Commons that he was a degenerate son, and that his partiality for the hereditary foes of our island was enough to make his great father's bones stir under the pavement of the Abbey.

And this man, whose name, if he had been so fortunate as to die in 1792, would now have been associated with peace, with freedom, with philanthropy, with temperate reform, with mild and constitutional administration, lived to associate his name with arbitrary government, with harsh laws harshly executed, with alien bills, with gagging bills, with suspensions of the Habeas Corpus Act, with cruel punishments inflicted on some political agitators, with unjustifiable prosecutions instituted against others, and with the most costly and most sanguinary wars of modern times. He lived to be held up to obloquy as the stern oppressor of England, and the indefatigable disturber of Europe. Poets, contrasting his earlier with his later years, likened him sometimes to the apostle who kissed in order to betray, and sometimes to the evil angels who kept not their first estate. A satirist of great genius introduced the fiends of Famine, Slaughter, and Fire, proclaiming that they had received their commission from One whose name was formed of four letters, and promising to give their employer ample proofs of gratitude. Famine would gnaw the multitude till they should rise up against him in madness. The demon of Slaughter would impel them to tear him from limb to limb. But Fire boasted that she alone could reward him as he deserved, and that she would cling round him to all eternity. By the French press and the French tribune every crime that disgraced and every calamity that afflicted France was ascribed to the monster Pitt and his guineas. While the Jacobins were dominant, it was he who had corrupted the Gironde, who had raised Lyons and Bordeaux against the Convention, who had suborned Paris to assassinate Lepelletier, and Cecilia Regnault to assassinate Robespierre. When the Thermidorian reaction came, all the atrocities of the Reign of Terror were imputed to him. Collot D'Herbois and Fouquier Thinville had been his pensioners. It was he who had hired the murderers of September, who had dictated the pamphlets of Marat and the Carmagnoles of Barrere, who had paid Lebon to deluge Arras with blood, and Carrier to choke the Loire with corpses.

The truth is, that he liked neither war nor arbitrary government. He was a lover of peace and freedom, driven, by a stress against which it was hardly possible for any will or any intellect to struggle, out of the course to which his inclinations pointed, and for which his abilities and acquirements fitted him, and forced into a policy repugnant to his feelings and unsuited to his talents.

The charge of apostasy is grossly unjust. A man ought no more to be called an apostate because his opinions alter with the opinions of the great body of his contemporaries than he ought to be called an oriental traveller because he is always going round from west to east with the globe and everything that is upon it. Between the spring of 1789 and the close of 1792, the public mind of England underwent a great change. If the change of Pitt's sentiments attracted peculiar notice, it was not because he changed more than his neighbours; for in fact he changed less than most of them; but because his position was far more conspicuous than theirs, because he was, till Bonaparte appeared, the individual who filled the greatest space in the eyes of the inhabitants of the civilised world. During a short time the nation, and Pitt, as one of the nation, looked with interest and approbation on the French Revolution. But soon vast confiscations, the violent sweeping away of ancient institutions, the domination of clubs, the barbarities of mobs maddened by famine and hatred, produced a reaction here. The court, the nobility, the gentry, the clergy, the manufacturers, the merchants, in short, nineteen twentieths of those who had good roofs over their heads and good coats on their backs, became eager and intolerant Antijacobins. This feeling was at least as strong among the minister's adversaries as among his supporters. Fox in vain attempted to restrain his followers. All his genius, all his vast personal influence, could not prevent them from rising up against him in general mutiny. Burke set the example of revolt; and Burke was in no long time joined by Portland, Spencer, Fitzwilliam, Loughborough, Carlisle, Malmesbury, Windham, Elliot. In the House of Commons, the followers of the great Whig statesman and orator diminished from about a hundred and sixty to fifty. In the House of Lords he had but ten or twelve adherents left. There can be no doubt that there would have been a similar mutiny on the ministerial benches, if Pitt had obstinately resisted the general wish. Pressed at once by his master and by his colleagues, by old friends and by old opponents, he abandoned, slowly and reluctantly, the policy which was dear to his heart. He laboured hard to avert the European war. When the European war broke out, he still flattered himself that it would not be necessary for this country to take either side. In the spring of 1792 he congratulated the Parliament on the prospect of long and profound peace, and proved his sincerity by proposing large remissions of taxation. Down to the end of that year he continued to cherish the hope that England might be able to preserve neutrality. But the passions which raged on both sides of the Channel were not to be restrained. The republicans who ruled France were inflamed by a fanaticism resembling that of the Mussulmans, who, with the Koran in one hand and the sword in the other, went forth, conquering and converting, eastward to the Bay of Bengal, and westward to the Pillars of Hercules. The higher and middle classes of England were animated by zeal not less fiery than that of the Crusaders who raised the cry of *Deus vult* at Clermont. The impulse which drove the two nations to a collision was not to be arrested by the abilities or by the authority of any single man. As Pitt was in front of his fellows, and towered high above them, he seemed to lead them. But in fact he was violently pushed on by them, and, had he held back but a little more than he did, would have been thrust out of their way or trampled under their feet.

He yielded to the current: and from that day his misfortunes began. The truth is that there were only two consistent courses before him. Since he did not choose to oppose himself, side by side with Fox, to the public feeling, he should have taken the advice of Burke, and should have availed himself of that feeling to the full extent. If it was impossible to preserve peace, he should have adopted the only policy which could lead to victory. He should have proclaimed a Holy War for religion, morality, property, order, public law, and should have thus opposed to the Jacobins an energy equal to their own. Unhappily he tried to find a middle path; and he found one which united all that was worst in both extremes. He went to war: but he would not understand the peculiar character of that war. He was obstinately blind to the plain fact, that he was contending against a state which was also a sect, and that the new quarrel between England and France was of quite a different kind from the old quarrels about colonies in

America and fortresses in the Netherlands. He had to combat frantic enthusiasm, boundless ambition, restless activity, the wildest and most audacious spirit of innovation; and he acted as if he had had to deal with the harlots and fops of the old Court of Versailles, with Madame De Pompadour and the Abbé de Bernis. It was pitiable to hear him, year after year, proving to an admiring audience that the wicked Republic was exhausted, that she could not hold out, that her credit was gone, that her assignats were not worth more than the paper of which they were made; as if credit was necessary to a government of which the principle was rapine, as if Alboin could not turn Italy into a desert till he had negotiated a loan at five per cent., as if the exchequer bills of Attila had been at par. It was impossible that a man who so completely mistook the nature of a contest could carry on that contest successfully. Great as Pitt's abilities were, his military administration was that of a driveller. He was at the head of a nation engaged in a struggle for life and death, of a nation eminently distinguished by all the physical and all the moral qualities which make excellent soldiers. The resources at his command were unlimited. The Parliament was even more ready to grant him men and money than he was to ask for them. In such an emergency, and with such means, such a statesman as Richelieu, as Louvois, as Chatham, as Wellesley, would have created in a few months one of the finest armies in the world, and would soon have discovered and brought forward generals worthy to command such an army. Germany might have been saved by another Blenheim; Flanders recovered by another Ramilies; another Poitiers might have delivered the Royalist and Catholic provinces of France from a yoke which they abhorred, and might have spread terror even to the barriers of Paris. But the fact is, that, after eight years of war, after a vast destruction of life, after an expenditure of wealth far exceeding the expenditure of the American war, of the Seven Years' War, of the war of the Austrian Succession, and of the war of the Spanish Succession united, the English army, under Pitt, was the laughing-stock of all Europe. It could not boast of one single brilliant exploit. It had never shown itself on the Continent but to be beaten, chased, forced to reembark, or forced to capitulate. To take some sugar island in the West Indies, to scatter some mob of half naked Irish peasants, such were the most splendid victories won by the British troops under Pitt's auspices.

The English navy no mismanagement could ruin. But during a long period whatever mismanagement could do was done. The Earl of Chatham, without a single qualification for high public trust, was made, by fraternal partiality, First Lord of the Admiralty, and was kept in that great post during two years of a war in which the very existence of the state depended on the efficiency of the fleet. He continued to doze away and trifle away the time which ought to have been devoted to the public service, till the whole mercantile body, though generally disposed to support the government, complained bitterly that our flag gave no protection to our trade. Fortunately he was succeeded by George Earl Spencer, one of those chiefs of the Whig party who, in the great schism caused by the French Revolution, had followed Burke. Lord Spencer, though inferior to many of his colleagues as an orator, was decidedly the best administrator among them. To him it was owing that a long and gloomy succession of days of fasting, and, most emphatically, of humiliation, was interrupted, twice in the short space of eleven months, by days of thanksgiving for great victories.

It may seem paradoxical to say that the incapacity which Pitt showed in all that related to the conduct of the war is, in some sense, the most decisive proof that he was a man of very extraordinary abilities. Yet this is the simple truth. For assuredly one-tenth part of his errors and disasters would have been fatal to the power and influence of any minister who had not possessed, in the highest degree, the talents of a parliamentary leader. While his schemes were confounded, while his predictions were falsified, while the coalitions which he had laboured to form were falling to pieces, while the expeditions which he had sent forth at enormous cost were ending in rout and disgrace, while the enemy against whom he was feebly contending was subjugating Flanders and Brabant, the Electorate of Mentz and the Electorate of Treves, Holland, Piedmont, Liguria, Lombardy, his authority over the House of Commons was constantly becoming more and more absolute. There was his empire. There were his victories, his Lodi and his Arcola, his Rivoli and his Marengo. If some great misfortune, a pitched battle lost by the allies, the annexation of a new department to the French Republic, a sanguinary insurrection in Ireland, a mutiny in the fleet, a panic in the city, a run on the bank, had spread dismay through the ranks of his majority, that dismay lasted only till he rose from the Treasury bench, drew up his haughty head, stretched his arm with commanding gesture, and poured forth, in deep and sonorous tones, the lofty language of inextinguishable hope and inflexible resolution. Thus, through a long and calamitous period, every disaster that happened without the walls of Parliament was regularly followed by a triumph within them. At length he had no longer an opposition to encounter. Of the great party which had contended against him during the first eight years of his administration more than one half now marched under his standard, with his old competitor the Duke of Portland at their head; and the rest had, after many vain struggles, quitted the field in despair. Fox had retired to the shades of St Anne's Hill, and had there found, in the society of friends whom no vicissitude could estrange from him, of a woman whom he tenderly loved, and of the illustrious dead of Athens, of Rome, and of Florence, ample compensation for all the misfortunes of his public life. Session followed session with scarcely a single division. In the eventful year 1799, the largest minority that could be mustered against the government was twenty-five.

In Pitt's domestic policy there was at this time assuredly no want of vigour. While he offered to French Jacobinism a resistance so feeble that it only encouraged the evil which he wished to suppress, he put down English Jacobinism with a strong hand. The Habeas Corpus Act was repeatedly suspended. Public meetings were placed under severe restraints. The government obtained from Parliament power to send out of the country aliens who were suspected of evil designs; and that power was not suffered to be idle. Writers who propounded doctrines adverse to monarchy and aristocracy were proscribed and punished without mercy. It was hardly safe for a republican to avow his political creed over his beefsteak and his bottle of port at a chop-house. The old laws of Scotland against sedition, laws which were considered by Englishmen as barbarous, and which a succession of governments had suffered to rust, were now furbished up and sharpened anew. Men of cultivated minds and polished manners were, for offences which at Westminster would have been treated as mere misdemeanours, sent to herd with felons at Botany Bay. Some reformers, whose opinions were extravagant, and whose language was intemperate, but who had never dreamed of subverting the government by physical force, were indicted for high treason, and were saved from the gallows only by the righteous verdicts of juries. This severity was at the time loudly applauded by alarmists whom fear had made cruel, but will be seen in a very different light by posterity. The truth is, that the Englishmen who wished for a revolution were, even in number, not formidable, and, in everything but number, a faction utterly contemptible, without

arms, or funds, or plans, or organisation, or leader. There can be no doubt that Pitt, strong as he was in the support of the great body of the nation, might easily have repressed the turbulence of the discontented minority by firmly yet temperately enforcing the ordinary law. Whatever vigour he showed during this unfortunate part of his life was vigour out of place and season. He was all feebleness and languor in his conflict with the foreign enemy who was really to be dreaded, and reserved all his energy and resolution for the domestic enemy who might safely have been despised.

One part only of Pitt's conduct during the last eight years of the eighteenth century deserves high praise. He was the first English minister who formed great designs for the benefit of Ireland. The manner in which the Roman Catholic population of that unfortunate country had been kept down during many generations seemed to him unjust and cruel; and it was scarcely possible for a man of his abilities not to perceive that, in a contest against the Jacobins, the Roman Catholics were his natural allies. Had he been able to do all that he wished, it is probable that a wise and liberal policy would have averted the rebellion of 1798. But the difficulties which he encountered were great, perhaps insurmountable; and the Roman Catholics were, rather by his misfortune than by his fault, thrown into the hands of the Jacobins. There was a third great rising of the Irishry against the Englishry, a rising not less formidable than the risings of 1641 and 1689. The Englishry remained victorious; and it was necessary for Pitt, as it had been necessary for Oliver Cromwell and William of Orange before him, to consider how the victory should be used. It is only just to his memory to say that he formed a scheme of policy, so grand and so simple, so righteous and so humane, that it would alone entitle him to a high place among statesmen. He determined to make Ireland one kingdom with England, and, at the same time, to relieve the Roman Catholic laity from civil disabilities, and to grant a public maintenance to the Roman Catholic clergy. Had he been able to carry these noble designs into effect, the Union would have been an Union indeed. It would have been inseparably associated in the minds of the great majority of Irishmen with civil and religious freedom; and the old Parliament in College Green would have been regretted only by a small knot of discarded jobbers and oppressors, and would have been remembered by the body of the nation with the loathing and contempt due to the most tyrannical and the most corrupt assembly that had ever sate in Europe. But Pitt could execute only one half of what he had projected. He succeeded in obtaining the consent of the Parliaments of both kingdoms to the Union: but that reconciliation of races and sects, without which the Union could exist only in name, was not accomplished. He was well aware that he was likely to find difficulties in the closet. But he flattered himself that, by cautious and dexterous management, those difficulties might be overcome. Unhappily, there were traitors and sycophants in high place who did not suffer him to take his own time and his own way, but prematurely disclosed his scheme to the king, and disclosed it in the manner most likely to irritate and alarm a weak and diseased mind. His Majesty absurdly imagined that his coronation oath bound him to refuse his assent to any bill for relieving Roman Catholics from civil disabilities. To argue with him was impossible. Dundas tried to explain the matter, but was told to keep his Scotch metaphysics to himself. Pitt, and Pitt's ablest colleagues, resigned their offices. It was necessary that the King should make a new arrangement. But by this time his anger and distress had brought back the malady which had, many years before, incapacitated him for the discharge of his functions. He actually assembled his family, read the Coronation oath to them, and told them that, if he broke it, the Crown would immediately pass to the House of Savoy. It was not until after an interregnum of several weeks that he regained the full use of his small faculties, and that a ministry after his own heart was at length formed.

The materials out of which he had to construct a government were neither solid nor splendid. To that party, weak in numbers, but strong in every kind of talent, which was hostile to the domestic and foreign policy of his late advisers, he could not have recourse. For that party, while it differed from his late advisers on every point on which they had been honoured with his approbation, cordially agreed with them as to the single matter which had brought on them his displeasure. All that was left to him was to call up the rear ranks of the old ministry to form the front ranks of a new ministry. In an age pre-eminently fruitful of parliamentary talents, a cabinet was formed containing hardly a single man who, in parliamentary talents, could be considered as even of the second rate. The most important offices in the state were bestowed on decorous and laborious mediocrity. Henry Addington was at the head of the Treasury. He had been an early, indeed a hereditary, friend of Pitt, and had by Pitt's influence been placed, while still a young man, in the chair of the House of Commons. He was universally admitted to have been the best speaker that had sate in that chair since the retirement of Onslow. But nature had not bestowed on him very vigorous faculties; and the highly respectable situation which he had long occupied with honour had rather unfitted than fitted him for the discharge of his new duties. His business had been to bear himself evenly between contending factions. He had taken no part in the war of words; and he had always been addressed with marked deference by the great orators who thundered against each other from his right and from his left. It was not strange that when, for the first time, he had to encounter keen and vigorous antagonists, who dealt hard blows without the smallest ceremony, he should have been awkward and unready, or that the air of dignity and authority which he had acquired in his former post, and of which he had not divested himself, should have made his helplessness laughable and pitiable. Nevertheless, during many months, his power seemed to stand firm. He was a favourite with the King, whom he resembled in narrowness of mind, and to whom he was more obsequious than Pitt had ever been. The nation was put into high good humour by a peace with France. The enthusiasm with which the upper and middle classes had rushed into the war had spent itself. Jacobinism was no longer formidable. Everywhere there was a strong reaction against what was called the atheistical and anarchical philosophy of the eighteenth century. Bonaparte, now First Consul, was busied in constructing out of the ruins of old institutions a new ecclesiastical establishment and a new order of knighthood. That nothing less than the dominion of the whole civilised world would satisfy his selfish ambition was not yet suspected; nor did even wise men see any reason to doubt that he might be as safe a neighbour as any prince of the House of Bourbon had been. The treaty of Amiens was therefore hailed by the great body of the English people with extravagant joy. The popularity of the minister was for the moment immense. His want of parliamentary ability was, as yet, of little consequence: for he had scarcely any adversary to encounter. The old opposition, delighted by the peace, regarded him with favour. A new opposition had indeed been formed by some of the late ministers, and was led by Grenville in the House of Lords, and by Windham in the House of Commons. But the new opposition could scarcely muster ten votes, and was regarded with no favour by the country. On Pitt the ministers relied as on their firmest support. He had not, like some of his colleagues, retired in anger. He had expressed the

Pitt, William.

greatest respect for the conscientious scruple which had taken possession of the royal mind; and he had promised his successors all the help in his power. In private his advice was at their service. In Parliament he took his seat on the bench behind them; and, in more than one debate, defended them with powers far superior to their own. The King perfectly understood the value of such assistance. On one occasion, at the palace, he took the old minister and the new minister aside. "If we three," he said, "keep together, all will go well."

But it was hardly possible, human nature being what it is, and, more especially, Pitt and Addington being what they were, that this union should be durable. Pitt, conscious of superior powers, imagined that the place which he had quitted was now occupied by a mere puppet which he had set up, which he was to govern while he suffered it to remain, and which he was to fling aside as soon as he wished to resume his old position. Nor was it long before he began to pine for the power which he had relinquished. He had been so early raised to supreme authority in the state, and had enjoyed that authority so long, that it had become necessary to him. In retirement his days passed heavily. He could not, like Fox, forget the pleasures and cares of ambition in the company of Euripides or Herodotus. Pride restrained him from intimating, even to his dearest friends, that he wished to be again minister. But he thought it strange, almost ungrateful, that his wish had not been divined, that it had not been anticipated, by one whom he regarded as his deputy.

Addington, on the other hand, was by no means inclined to descend from his high position. He was, indeed, under a delusion much resembling that of Abon Hassan in the Arabian tale. His brain was turned by his short and unreal Caliphate. He took his elevation quite seriously, attributed it to his own merit, and considered himself as one of the great triumvirate of English statesmen, as worthy to make a third with Pitt and Fox.

Such being the feelings of the late minister and of the present minister, a rupture was inevitable; and there was no want of persons bent on making that rupture speedy and violent. Some of these persons wounded Addington's pride by representing him as a lacquey, sent to keep a place on the Treasury bench till his master should find it convenient to come. Others took every opportunity of praising him at Pitt's expense. Pitt had waged a long, a bloody, a costly, an unsuccessful war. Addington had made peace. Pitt had suspended the constitutional liberties of Englishmen. Under Addington those liberties were again enjoyed. Pitt had wasted the public resources. Addington was carefully nursing them. It was sometimes but too evident that these compliments were not unpleasing to Addington. Pitt became cold and reserved. During many months he remained at a distance from London. Meanwhile his most intimate friends, in spite of his declarations that he made no complaint, and that he had no wish for office, exerted themselves to effect a change of ministry. His favourite disciple, George Canning, young, ardent, ambitious, with great powers and great virtues, but with a temper too restless and a wit too satirical for his own happiness, was indefatigable. He spoke; he wrote; he intrigued; he tried to induce a large number of the supporters of the government to sign a round robin desiring a change; he made game of Addington and of Addington's relations in a succession of lively pasquinades. The minister's partisans retorted with equal acrimony, if not with equal vivacity. Pitt could keep out of the affray only by keeping out of politics altogether; and this it soon became impossible for him to do. Had Napoleon, content with the first place among the sovereigns of the Continent, and with a military reputation surpassing that of Marlborough or of Turenne, devoted himself to the noble task of making France happy by mild administration and wise legislation, our country might have long continued to tolerate a government of fair intentions and feeble abilities. Unhappily, the treaty of Amiens had scarcely been signed, when the restless ambition and the insupportable insolence of the First Consul convinced the great body of the English people that the peace, so eagerly welcomed, was only a precarious armistice. As it became clearer and clearer that a war for the dignity, the independence, the very existence of the nation was at hand, men looked with increasing uneasiness on the weak and languid cabinet which would have to contend against an enemy who united more than the power of Lewis the Great to more than the genius of Frederick the Great. It is true that Addington might easily have been a better war minister than Pitt, and could not possibly have been a worse. But Pitt had cast a spell on the public mind. The eloquence, the judgment, the calm and disdainful firmness which he had, during many years, displayed in Parliament, deluded the world into the belief that he must be eminently qualified to superintend every department of politics; and they imagined, even after the miserable failures of Dunkirk, of Quiberon, and of the Helder, that he was the only statesman who could cope with Bonaparte. This feeling was nowhere stronger than among Addington's own colleagues. The pressure put on him was so strong, that he could not help yielding to it: yet, even in yielding, he showed how far he was from knowing his own place. His first proposition was, that some insignificant nobleman should be First Lord of the Treasury and nominal head of the administration, and that the real power should be divided between Pitt and himself, who were to be secretaries of state. Pitt, as might have been expected, refused even to discuss such a scheme, and talked of it with bitter mirth. "Which secretaryship was offered to you?" his friend Wilberforce asked. "Really," said Pitt, "I had not the curiosity to inquire." Addington was frightened into bidding higher. He offered to resign the Treasury to Pitt, on condition that there should be no extensive change in the government. But Pitt would listen to no such terms. Then came a dispute such as often arises after negotiations orally conducted, even when the negotiators are men of strict honour. Pitt gave one account of what had passed; Addington gave another; and though the discrepancies were not such as necessarily implied any intentional violation of truth on either side, both were greatly exasperated.

Meanwhile the quarrel with the First Consul had come to a crisis. On the 16th of May 1803, the King sent a message calling on the House of Commons to support him in withstanding the ambitious and encroaching policy of France; and on the 22d, the House took the message into consideration.

Pitt had now been living many months in retirement. There had been a general election since he had spoken in Parliament, and there were two hundred members who had never heard him. It was known that on this occasion he would be in his place, and curiosity was wound up to the highest point. Unfortunately, the short-hand writers were, in consequence of some mistake, shut out on that day from the gallery, so that the newspapers contained only a very meagre report of the proceedings. But several accounts of what passed are extant; and of those accounts, the most interesting is contained in an unpublished letter written by a very young member, John William Ward, afterwards Earl of Dudley. When Pitt rose, he was received with loud cheering. At every pause in his speech there was a burst of applause. The peroration is said to have been one of the most animated and magnificent ever heard in Parliament. "Pitt's speech," Fox wrote a few days later, "was admired very much, and very justly. I think it was the best he ever made in that style." The debate was

adjourned; and on the second night Fox replied in an oration which, as the most zealous Pittites were forced to acknowledge, left the palm of eloquence doubtful. Addington made a pitiable appearance between the two great rivals; and it was observed that Pitt, while exhorting the Commons to stand resolutely by the executive government against France, said not a word indicating esteem or friendship for the prime minister.

War was speedily declared. The First Consul threatened to invade England at the head of the conquerors of Belgium and Italy, and formed a great camp near the Straits of Dover. On the other side of those Straits the whole population of our island was ready to rise up as one man in defence of the soil. At this conjuncture, as at some other great conjunctures in our history, the conjuncture of 1660, for example, and the conjuncture of 1688, there was a general disposition among honest and patriotic men to forget old quarrels, and to regard as a friend every person who was ready, in the existing emergency, to do his part towards the saving of the state. A coalition of all the first men in the country would, at that moment, have been as popular as the coalition of 1783 had been unpopular. Alone in the kingdom the King looked with perfect complacency on a cabinet in which no man superior to himself in genius was to be found, and was so far from being willing to admit all his ablest subjects to office that he was bent on excluding them all.

A few months passed before the different parties which agreed in regarding the government with dislike and contempt came to an understanding with each other. But in the spring of 1804 it became evident that the weakest of ministries would have to defend itself against the strongest of oppositions, an opposition made up of three oppositions, each of which would, separately, have been formidable from ability, and which, when united, were also formidable from number. The party which had opposed the peace, headed by Grenville and Windham, and the party which had opposed the renewal of the war, headed by Fox, concurred in thinking that the men now in power were incapable of either making a good peace or waging a vigorous war. Pitt had, in 1802, spoken for peace against the party of Grenville, and had, in 1803, spoken for war against the party of Fox. But of the capacity of the cabinet, and especially of its chief, for the conduct of great affairs, he thought as meanly as either Fox or Grenville. Questions were easily found on which all the enemies of the government could act cordially together. The unfortunate First Lord of the Treasury, who had, during the earlier months of his administration, been supported by Pitt on one side, and by Fox on the other, now had to answer Pitt, and to be answered by Fox. Two sharp debates, followed by close divisions, made him weary of his post. It was known, too, that the Upper House was ever more hostile to him than the Lower, that the Scotch representative peers wavered, that there were signs of mutiny among the Bishops. In the cabinet itself there was discord, and, worse than discord, treachery. It was necessary to give way: the ministry was dissolved; and the task of forming a government was entrusted to Pitt.

Pitt was of opinion that there was now an opportunity, such as had never before offered itself, and such as might never offer itself again, of uniting in the public service, on honourable terms, all the eminent talents of the kingdom. The passions to which the French Revolution had given birth were extinct. The madness of the innovator and the madness of the alarmist had alike had their day. Jacobinism and Anti-jacobinism had gone out of fashion together. The most liberal statesman did not think that season propitious for schemes of parliamentary reform; and the most conservative statesman could not pretend that there was any occasion for gagging bills and suspensions of the Habeas Corpus Act. The great struggle for independence and national honour occupied all minds; and those who were agreed as to the duty of maintaining that struggle with vigour might well postpone to a more convenient time all disputes about matters comparatively unimportant. Strongly impressed by these considerations, Pitt wished to form a ministry including all the first men in the country. The Treasury he reserved for himself; and to Fox he proposed to assign a share of power little inferior to his own.

The plan was excellent: but the King would not hear of it. Dull, obstinate, unforgiving, and, at that time, half mad, he positively refused to admit Fox into his service. Anybody else, even men who had gone as far as Fox, or further than Fox, in what His Majesty considered as Jacobinism, Sheridan, Grey, Erskine, should be graciously received; but Fox never. During several hours Pitt laboured in vain to reason down this senseless antipathy. That he was perfectly sincere there can be no doubt; but it was not enough to be sincere; he should have been resolute. Had he declared himself determined not to take office without Fox, the royal obstinacy would have given way, as it gave way, a few months later, when opposed to the immutable resolution of Lord Grenville. In an evil hour Pitt yielded. He flattered himself with the hope that, though he consented to forego the aid of his illustrious rival, there would still remain ample materials for the formation of an efficient ministry. That hope was cruelly disappointed. Fox entreated his friends to leave personal considerations out of the question, and declared that he would support, with the utmost cordiality, an efficient and patriotic ministry from which he should be himself excluded. Not only his friends, however, but Grenville and Grenville's adherents, answered with one voice, that the question was not personal, that a great constitutional principle was at stake, and that they would not take office while a man eminently qualified to render service to the commonwealth was placed under a ban merely because he was disliked at Court. All that was left to Pitt was to construct a government out of the wreck of Addington's feeble administration. The small circle of his personal retainers furnished him with a very few useful assistants, particularly Dundas, who had been created Viscount Melville, Lord Harrowby, and Canning.

Such was the inauspicious manner in which Pitt entered on his second administration. The whole history of that administration was of a piece with the commencement. Almost every month brought some new disaster or disgrace. To the war with France was soon added a war with Spain. The opponents of the minister were numerous, able, and active. His most useful coadjutors he soon lost. Sickness deprived him of the help of Lord Harrowby. It was discovered that Lord Melville had been guilty of highly culpable laxity in transactions relating to public money. He was censured by the House of Commons, driven from office, ejected from the Privy Council, and impeached of high crimes and misdemeanours. The blow fell heavy on Pitt. It gave him, he said in Parliament, a deep pang; and, as he uttered the word pang, his lip quivered; his voice shook; he paused; and his hearers thought that he was about to burst into tears. Such tears shed by Eldon would have moved nothing but laughter. Shed by the warm-hearted and open-hearted Fox, they would have moved sympathy, but would have caused no surprise. But a tear from Pitt would have been something portentous. He suppressed his emotion, however, and proceeded with his usual majestic self-possession.

His difficulties compelled him to resort to various expedients. At one time Addington was persuaded to accept office with a peerage; but he brought no additional strength to the government. Though he went through the form of reconciliation, it was impossible for him to forget the past.

While he remained in place he was jealous and punctilious; and he soon retired again. At another time Pitt renewed his efforts to overcome his master's aversion to Fox; and it was rumoured that the King's obstinacy was gradually giving way. But, meanwhile, it was impossible for the minister to conceal from the public eye the decay of his health and the constant anxiety which gnawed at his heart. His sleep was broken. His food ceased to nourish him. All who passed him in the Park, all who had interviews with him in Downing Street, saw misery written in his face. The peculiar look which he wore during the last months of his life was often pathetically described by Wilberforce, who used to call it the Austerlitz look.

Still the vigour of Pitt's intellectual faculties, and the intrepid haughtiness of his spirit, remained unaltered. He had staked everything on a great venture. He had succeeded in forming another mighty coalition against the French ascendancy. The united forces of Austria, Russia, and England might, he hoped, oppose an insurmountable barrier to the ambition of the common enemy. But the genius and energy of Napoleon prevailed. While the English troops were preparing to embark for Germany, while the Russian troops were slowly coming up from Poland, he, with rapidity unprecedented in modern war, moved a hundred thousand men from the shores of the Ocean to the Black Forest, and compelled a great Austrian army to surrender at Ulm. To the first faint rumours of this calamity Pitt would give no credit. He was irritated by the alarms of those around him. "Do not believe a word of it," he said: "it is all a fiction." The next day he received a Dutch newspaper containing the capitulation. He knew no Dutch. It was Sunday; and the public offices were shut. He carried the paper to Lord Malmesbury, who had been minister in Holland; and Lord Malmesbury translated it. Pitt tried to bear up; but the shock was too great; and he went away with death in his face.

The news of the battle of Trafalgar arrived four days later, and seemed for a moment to revive him. Forty-eight hours after that most glorious and most mournful of victories had been announced to the country came the Lord Mayor's day; and Pitt dined at Guildhall. His popularity had declined. But on this occasion the multitude, greatly excited by the recent tidings, welcomed him enthusiastically, took off his horses in Cheapside, and drew his carriage up King Street. When his health was drunk, he returned thanks in two or three of those stately sentences of which he had a boundless command. Several of those who heard him laid up his words in their hearts; for they were the last words that he ever uttered in public: "Let us hope that England, having saved herself by her energy, may save Europe by her example."

This was but a momentary rally. Austerlitz soon completed what Ulm had begun. Early in December Pitt had retired to Bath, in the hope that he might there gather strength for the approaching session. While he was languishing there on his sofa arrived the news that a decisive battle had been fought and lost in Moravia, that the coalition was dissolved, that the Continent was at the feet of France. He sank down under the blow. Ten days later, he was so emaciated that his most intimate friends hardly knew him. He came up from Bath by slow journeys, and, on the 11th of January 1806, reached his villa at Putney. Parliament was to meet on the 21st. On the 20th was to be the parliamentary dinner at the house of the First Lord of the Treasury in Downing Street; and the cards were already issued. But the days of the great minister were numbered. The only chance for his life, and that a very slight chance, was, that he should resign his office, and pass some months in profound repose. His colleagues paid him very short visits, and carefully avoided political conversation. But his spirit, long accustomed to dominion, could not, even in that extremity, relinquish hopes which everybody but himself perceived to be vain. On the day on which he was carried into his bedroom at Putney, the Marquess Wellesley, whom he had long loved, whom he had sent to govern India, and whose administration had been eminently able, energetic, and successful, arrived in London after an absence of eight years. The friends saw each other once more. There was an affectionate meeting, and a last parting. That it was a last parting Pitt did not seem to be aware. He fancied himself to be recovering, talked on various subjects cheerfully, and with an unclouded mind, and pronounced a warm and discerning eulogium on the Marquess's brother Arthur. "I never," he said, "met with any military man with whom it was so satisfactory to converse." The excitement and exertion of this interview were too much for the sick man. He fainted away; and Lord Wellesley left the house, convinced that the close was fast approaching.

And now members of Parliament were fast coming up to London. The chiefs of the opposition met for the purpose of considering the course to be taken on the first day of the session. It was easy to guess what would be the language of the King's speech, and of the address which would be moved in answer to that speech. An amendment condemning the policy of the government had been prepared, and was to have been proposed in the House of Commons by Lord Henry Petty, a young nobleman who had already won for himself that place in the esteem of his country which, after the lapse of more than half a century, he still retains. He was unwilling, however, to come forward as the accuser of one who was incapable of defending himself. Lord Grenville, who had been informed of Pitt's state by Lord Wellesley, and had been deeply affected by it, earnestly recommended forbearance; and Fox, with characteristic generosity and good nature, gave his voice against attacking his now helpless rival. "Sunt lacrymæ rerum," he said, "et mentem mortalia tangunt." On the first day, therefore, there was no debate. It was rumoured that evening that Pitt was better. But on the following morning his physicians pronounced that there were no hopes. The commanding faculties of which he had been too proud were beginning to fail. His old tutor and friend, the Bishop of Lincoln, informed him of his danger, and gave such religious advice and consolation as a confused and obscured mind could receive. Stories were told of devout sentiments fervently uttered by the dying man. But these stories found no credit with anybody who knew him. Wilberforce pronounced it impossible that they could be true; "Pitt," he added, "was a man who always said less than he thought on such topics." It was asserted in many after-dinner speeches, Grub Street elegies, and academic prize poems and prize declamations, that the great minister died exclaiming, "Oh my country!" This is a fable; but it is true that the last words which he uttered, while he knew what he said, were broken exclamations about the alarming state of public affairs. He ceased to breathe on the morning of the 23d of January 1806, the twenty-fifth anniversary of the day on which he first took his seat in Parliament. He was in his forty-seventh year, and had been, during near nineteen years, First Lord of the Treasury, and undisputed chief of the administration. Since parliamentary government was established in England, no English statesman has held supreme power so long. Walpole, it is true, was First Lord of the Treasury during more than twenty years, but it was not till Walpole had been some time First Lord of the Treasury that he could be properly called Prime Minister.

It was moved in the House of Commons that Pitt should be honoured with a public funeral and a monument. The motion was opposed by Fox in a speech which deserves to be studied as a model of good taste and good feeling,

The task was the most invidious that ever an orator undertook: but it was performed with a humanity and delicacy which were warmly acknowledged by the mourning friends of him who was gone. The motion was carried by 288 votes to 89.

The 22d of February was fixed for the funeral. The corpse having lain in state during two days in the Painted Chamber, was borne with great pomp to the northern transept of the Abbey. A splendid train of princes, nobles, bishops, and privy councillors followed. The grave of Pitt had been made near to the spot where his great father lay, near also to the spot where his great rival was soon to lie. The sadness of the assistants was beyond that of ordinary mourners. For he whom they were committing to the dust had died of sorrows and anxieties of which none of the survivors could be altogether without a share. Wilberforce, who carried the banner before the hearse, described the awful ceremony with deep feeling. As the coffin descended into the earth, he said, the eagle face of Chatham from above seemed to look down with consternation into the dark house which was receiving all that remained of so much power and glory.

All parties in the House of Commons readily concurred in voting forty thousand pounds to satisfy the demands of Pitt's creditors. Some of his admirers seemed to consider the magnitude of his embarrassments as a circumstance highly honourable to him; but men of sense will probably be of a different opinion. It is far better, no doubt, that a great minister should carry his contempt of money to excess than that he should contaminate his hands with unlawful gain. But it is neither right nor becoming in a man to whom the public has given an income more than sufficient for his comfort and dignity to bequeath to that public a great debt, the effect of mere negligence and profusion. As First Lord of the Treasury and Chancellor of the Exchequer, Pitt never had less than six thousand a year, besides an excellent house. In 1792 he was forced by his royal master's friendly importunity to accept for life the office of Warden of the Cinque Ports, with near four thousand a year more. He had neither wife nor child: he had no needy relations: he had no expensive tastes: he had no long election bills. Had he given but a quarter of an hour a week to the regulation of his household, he would have kept his expenditure within bounds. Or, if he could not spare even a quarter of an hour a week for that purpose, he had numerous friends, excellent men of business, who would have been proud to act as his stewards. One of those friends, the chief of a great commercial house in the city, made an attempt to put the establishment in Downing Street to rights; but in vain. He found that the waste of the servants' hall was almost fabulous. The quantity of butcher's meat charged in the bills was nine hundredweight a week. The consumption of poultry, of fish, of tea, was in proportion. The character of Pitt would have stood higher if, with the disinterestedness of Pericles and of De Witt, he had united their dignified frugality.

The memory of Pitt has been assailed, times innumerable, often justly, often unjustly; but it has suffered much less from his assailants than from his eulogists. For, during many years, his name was the rallying cry of a class of men with whom, at one of those terrible conjunctures which confound all ordinary distinctions, he was accidentally and temporarily connected, but to whom, on almost all great questions of principle, he was diametrically opposed. The haters of parliamentary reform called themselves Pittites, not choosing to remember that Pitt made three motions for parliamentary reform, and that, though he thought that such a reform could not safely be made while the passions excited by the French Revolution were raging, he never uttered a word indicating that he should not be prepared at a more convenient season to bring the question forward a fourth time. The toast of Protestant ascendency was drunk on Pitt's birthday by a set of Pittites who could not but be aware that Pitt had resigned his office because he could not carry Catholic emancipation. The defenders of the Test Act called themselves Pittites, though they could not be ignorant that Pitt had laid before George the Third unanswerable reasons for abolishing the Test Act. The enemies of free trade called themselves Pittites, though Pitt was far more deeoly imbued with the doctrines of Adam Smith than either Fox or Grey. The very negro-drivers invoked the name of Pitt, whose eloquence was never more conspicuously displayed than when he spoke of the wrongs of the negro. This mythical Pitt, who resembles the genuine Pitt as little as the Charlemagne of Ariosto resembles the Charlemagne of Eginhard, has had his day. History will vindicate the real man from calumny disguised under the semblance of adulation, and will exhibit him as what he was, a minister of great talents, honest intentions, and liberal opinions, pre-eminently qualified, intellectually and morally, for the part of a parliamentary leader, and capable of administering with prudence and moderation the government of a prosperous and tranquil country, but unequal to surprising and terrible emergencies, and liable, in such emergencies, to err grievously, both on the side of weakness and on the side of violence. (T. B. M.)

PITTACUS, one of "the seven wise men of Greece," was born at Mitylene in Lesbos, B.C. 652. His father's name was Hyrrhadius or Caicus. With the assistance of the sons of Alcæus, he delivered his country from the oppression of the tyrant Melanchrus; and, in the war which the Athenians waged against Lesbos, he appeared at the head of his countrymen, and challenged to single combat Phrynon, the enemy's general. As the event of the war seemed to depend upon this combat, Pittacus had recourse to artifice, and, when engaged, entangled his adversary in a net which he had concealed under his shield, and easily despatched him. He was amply rewarded for this victory, and his countrymen, sensible of his merit, unanimously appointed him governor of their city, with unlimited authority. In this capacity Pittacus behaved with the greatest moderation and prudence; and after he had governed his fellow-citizens with the strictest justice, and enforced the most salutary laws, he voluntarily resigned the sovereign power, after having enjoyed it for ten years; observing, that the virtues and innocence of private life were incompatible with the power and influence of a sovereign. His disinterestedness gained him many admirers; and when the Mitylenians wished to reward his public services by presenting him with an immense tract of territory, he refused to accept more land than could be contained within the space to which a javelin could be thrown. He died in the seventieth year of his age, about 582 B.C., after he had spent the last ten years of his life in literary ease and peaceful retirement. Numerous anecdotes of his clemency, wisdom, and contempt of wealth are related by Diogenes Laërtius, Plutarch, Ælian, and other writers. The former mentions various communications between him and Crœsus, and preserves a short letter, said to have been written by Pittacus, declining an invitation to Sardis. Pittacus composed, according to Diogenes, 600 elegiac verses, of which only a few lines remain. (See Bergk, *Poet. Lyr. Græc.*)

PITTENWEEM, a royal and parliamentary burgh and seaport of Scotland, in the county of Fife, on the north shore of the Firth of Forth, about a mile W. of Anstruther, and 24 N.N.E. of Edinburgh. It is an old town, and con-

Pitts || Pittsburgh.

sists of two main streets, with others crossing them. There are here a town-hall, with a small prison, an ancient parish church, a United Presbyterian and an Episcopal church. The inhabitants are chiefly engaged in fishing and curing fish. Pittenweem unites with East and West Anstruther, Crail, Cupar-Fife, Kilrenny, and St Andrews in returning a member to the House of Commons. Pop. (1851), of the parish, 1473; of the parliamentary burgh, 1450.

PITTS, WILLIAM, was born in London in 1790, and brought up by his father to his own business, that of an engraver. At the age of nineteen he was married, and was employed by Flaxman in chasing the shield of Achilles. Pitts was also employed on the Wellington shield, which was executed under the immediate inspection of Stothard. Afterwards Pitts engraved two series of designs from Virgil and Ossian. William Pitts was an unassuming artist, and altogether unskilled in winning his way to popularity and fortune. How far this had any reason in impelling him to the fatal deed which he is known to have committed, it is difficult to judge. He destroyed himself with poison on the 16th of April 1840.

The following is a list of his chief productions, arranged according to their dates:—"The Deluge," 1823; "Samson Slaying the Lion," the "Creation of Eve," and "Herod's Cruelty," 1824; "A Chariot Race," "Pleiades," and "Shield of Æneas," 1828; the "Rape of Proserpine," and the "Nuptials of Perithous," 1824; the "Brunswick Shield," 1830; the "Apotheoses of Spenser, Shakspeare, and Milton," 1831; the "Shield of Hercules," 1834; a long bas-relief or frieze of all the English sovereigns from the Conquest, 1837; a design for a masonic trophy, 1839; the "Triumph of Ceres," 1840; the "Kemble Tribute," and a vase executed for her Majesty as a sponsal present by her, of exquisite design as to its general form, and poetically embellished with groups in relief signifying Birth, Infancy, Instruction, Education, and Love.

PITTSBURGH, or PITTSBURG, a town of the United States of North America, state of Pennsylvania, stands at the head of the Ohio river, which is formed here by the confluence of the swift-flowing Alleghany from the N., and the deep and still Monongahela from the S., 252 miles W. by N. of Harrisburg, and 357 W. of Philadelphia. It is built on a triangular plain between the two rivers, and bounded on the E. by several hills. On the N. bank of the Alleghany stand Alleghany city and Manchester; and to the S. of the Monongahela, South Pittsburgh and Birmingham; all which suburbs form virtually one town with Pittsburgh itself, with which they are connected by bridges and steam ferries. The city proper is regularly laid out, the older portion, consisting of streets parallel and at right angles to the Monongahela, and the more recent streets being similarly arranged along the Alleghany; so that the various streets meet obliquely, and resemble in this respect the lower part of New York. The houses are generally of brick, many of them handsome, especially towards the E. end, where there are numerous delightful residences. The neighbouring country is picturesque and beautiful; and the only drawback to Pittsburgh as a place of residence, is the dense clouds of smoke which issue from the many chimneys, and hang over the town and vicinity. Among the public buildings, one of the most conspicuous is the court-house, which stands on a hill near the E. end of the town. It is in the Grecian style, with a portico in front, and a dome 148 feet high. The custom-house, which includes also the post-office, the two new market-houses, and a large theatre, are all fine buildings. The churches in Pittsburgh and its suburbs are about ninety in number, and many of them are of great beauty. The Roman Catholic cathedral, the Episcopal church of St Peter, and the First Presbyterian church, are the most conspicuous. Of the educational establishments in Pittsburgh, the most important are the theological seminary of the Associated Reform Church, with three professors and thirty-five students in 1856–7; and that of the Presbyterian Church, situated in Alleghany Town, with two professors and forty-eight students in 1856–7. The Western University of Pennsylvania, which formerly existed here, was destroyed by fire in 1845, and has not since been restored. Besides the institutions already named, the town contains upwards of fifty schools of various kinds, attended by about 12,000 pupils. The town and suburbs also contain several literary associations, hospitals, banks, hotels, &c.; and numerous newspapers and other periodicals are published. Pittsburgh is chiefly important as a manufacturing and commercial town, in which respect it is rapidly increasing; and from its great natural advantages, will probably soon become one of the greatest cities in the world. The immense supplies of excellent coal, which are obtained in the vicinity with comparatively little labour and expense, not only supply a profitable article of export, but afford fuel for the numerous mills and factories in the town. Besides coal, various ores, timber, and agricultural produce can be easily obtained in the neighbourhood in the utmost profusion. Pittsburgh contained in 1850 16 iron-works of various kinds, employing 2161 hands, consuming annually 4,152,300 bushels of coal, 900 cords of wood, and 65,896 tons of iron; and producing 52,932 tons of iron and steel in various forms. In the same year there were 30 large and several smaller foundries, producing goods to the value of L.400,000 annually; 33 glass-works; 5 white-lead factories; 5 large and several smaller cotton-factories, with a capital of L.300,000, and producing annually L.320,000 worth of goods; a copper rolling-mill; a copper smelting-house; and manufactories of gun-barrels, saws, axes, agricultural implements, &c. The whole number of manufactories in Pittsburgh, according to the census of 1850, was 819, and in Alleghany city 120; employing 10,253 hands, and producing annually goods to the value of L.2,475,710. This calculation, however, is thought to be much understated; and it is probable that in 1853 the value of manufactured goods was as much as L.5,000,000. The total amount of coal consumed in the same year for manufactures and other purposes was 22,305,000 bushels. Besides this, large quantities of coal are exported from Pittsburgh, amounting in 1853 to 14,403,921 bushels. In commerce as well as in manufactures, Pittsburgh occupies an important place among American towns; and for this it is indebted in a great degree to the advantages of its situation, at the foot of the western slope of the Alleghanies, and at the meeting of three navigable rivers, which afford easy communication, over many thousand miles of water, to the W.; while at the same time it is within a convenient distance of the great lakes to the N., and of the large cities on the Atlantic, with both of which it communicates by railway and canal. Thus not only the entire trade of Pennsylvania, but large quantities of goods from New York, pass through Pittsburgh to the cities and regions of the West. The principal harbour is on the Monongahela, which is deeper than the Alleghany. The building of steamers is extensively carried on at Pittsburgh, where they can be constructed better and more cheaply than at the western ports. The number of steam-vessels launched in 1854 was upwards of 80, many of them of great size and power. The aggregate tonnage of Pittsburgh, June 30, 1852, was 64,157, of which 57,783 were steamers. Pittsburgh is thus, in the amount of its steam navigation, the third city in the States, being surpassed only by New Orleans and New York in this respect. There were exported by canal from Pittsburgh in 1852, 17,577,187 lb. of iron, 7,361,436 lb. of steel, 39,586,694 lb. of bacon, 20,490,918 lb. of unmanufactured tobacco, 1,670,922 lb. of cotton, &c.;

and among the articles imported by canal in the same year were,—50,564,566 lb. of iron, 17,457,753 lb. of hardware, 17,885,702 lb. of groceries, 17,102,061 lb. of coffee, and 237,616 lb. of leather. Of the entire trade of the town there are no statistics: it is, however, great and rapidly increasing, the trade with the lakes having doubled itself every year since 1844. The site of Pittsburgh was first visited by Europeans in 1753, when, as the French were proceeding to take possession of the country along the Alleghany and Ohio, Washington was sent by Governor Dinwiddie of Virginia to reconnoitre their movements. He reached the confluence of the Alleghany and Monongahela, and recommended it as a good site for a fort. In the next year, accordingly, a party was sent out to erect one; but before it was completed they were obliged to surrender it to a superior body of French, who took possession, and completed the fort—an act of aggression which led to the war with the French that raged simultaneously in all the quarters of the globe. In 1755 General Braddock made an unsuccessful attempt to regain the fort; but in 1758 it was taken by General Forbes, and named Fort Pitt in honour of the first great minister of that name. The fort was besieged by the Indians in 1765; and in the same year the town of Pittsburgh was founded. In 1806 it was incorporated as a borough; and in 1816 chartered as a city. The bridges over the Alleghany and Monongahela were constructed in 1819, and the Pennsylvania Canal was opened in 1829. Since then the town has been rapidly and steadily increasing in size and prosperity; and though in 1845 a fire destroyed more than 1100 buildings and L.140,000 worth of property, yet within a year the vacant space was nearly all rebuilt, and the town soon recovered from the calamity. Pop. (1850), Pittsburgh proper, 46,601; Alleghany city, 21,261; Birmingham, 3742; city and district (1850), 86,771; (1853) 110,241.

PIURA, a town of Peru, capital of a province of that name, in the department of Truxillo, on the left bank of the river Piura, 240 miles N.N.W. of Truxillo. It is built for the most part of brick, and the streets are narrow and unpaved. There is a public square in the middle of the town. The town contains several churches, government offices, and a college attended by 120 pupils. Some trade is carried on in maize, cotton, sugar, fruit, &c. Piura was the first Spanish settlement in Peru. It originally stood near the sea, but was removed to its present site on account of the unhealthiness of its former one. Pop. about 10,000.

PIUS I. succeeded Hyginus as bishop of Rome in 142, and died in 157.

Pius II., *Æneas Sylvius Piccolomini*, was born on the 18th of October 1405, at Corsigni in the Sienese, the name of which he afterwards changed into that of *Pienza*. Æneas was carefully educated, and made considerable proficiency in the belles-lettres. After having finished his studies at Siena, he in 1431 went to the council of Basil with Cardinal Capranica, surnamed *De Fermo*, because he was intrusted with the government of that church. Æneas, who acted as his secretary, was then only twenty-six years of age. He afterwards acted in the same capacity to some other prelates, and to Cardinal Albergati. The council of Basil honoured him with different commissions, in order to recompense him for the zeal with which he had defended that assembly against Pope Eugenius IV. He was afterwards secretary to Frederic III., who decreed to him the poetical crown, and sent him as ambassador to Rome, Milan, Naples, Bohemia, and other places. Nicholas V. advanced him to the bishopric of Trieste, which he quitted some time afterwards for that of Siena. At last, after having distinguished himself as nuncio on various occasions, he was invested with the Roman purple by Calixtus III., whom he succeeded two years afterwards, on the 27th of August 1458. Pius II., now advanced to the Holy See, exemplified the proverb, "Honores mutant mores." From the commencement of his pontificate he appeared to be jealous of the papal prerogatives. In 1460 he issued a bull declaring appeals from the Pope to a council to be null, erroneous, detestable, and contrary to the sacred canons. That bull, however, did not prevent the procurator-general of the Parliament of Paris from appealing to a council in defence of the Pragmatic Sanction, which the Pope had strenuously opposed. Pius was then at Mantua, whither he had gone to engage the Catholic princes to unite in a war against the Turks. The greater part of them had agreed to furnish troops or money; but others refused both, particularly France, which from that moment incurred his Holiness's aversion. But his aversion abated under Louis XI., whom in 1461 he persuaded to abolish the Pragmatic Sanction, which the Parliament of Paris had with so much vigour supported.

The following year, 1462, was rendered famous by a controversy which took place between the Cordeliers and Dominicans, whether or not the blood of Jesus Christ was separated from his body whilst he lay in the sepulchre. It was also made a question whether it was separated from his divinity. The Cordeliers affirmed that it was, but the Dominicans were of an opposite opinion. As usually happens in such disputes, the disputants called each other heretics; and this obliged the Pontiff to issue a bull, forbidding them, under pain of censure, to brand one another with such odious epithets. The bull, which his Holiness published on the 26th of April, retracting what he had written to the council of Basil when he was its secretary, if it somewhat impeached his consistency, was at least highly honourable to his frankness and candour. "If you find, then, anything contrary to her doctrine, either in our dialogues, in our letters, or in other of our works, despise these opinions, reject them, and adopt our present sentiments. Believe me rather now that I am an old man, than when I addressed you in my earlier days; esteem a sovereign Pontiff more than a private person; except against Æneas Sylvius, but receive Pius II." It might perhaps be objected to his Holiness, that it was his dignity alone which had made him alter his opinion. He anticipates that objection by giving a short account of his life and actions, with the whole history of the council of Basil, to which he went with Cardinal Capranica in 1431; "but," says he, "I was then a young man, and without any experience, like a bird just come from its nest." In the meantime, the Turks were threatening Christendom. Pius, ever zealous in the defence of religion against the infidels, formed the resolution of fitting out a fleet at the expense of the church, and of passing over into Asia himself, to animate the Christian princes by his example. He repaired to Ancona with a design to embark; but he there fell sick from the fatigue of the journey, and expired on the 16th of August 1464, aged fifty-nine.

Pius was one of the most learned men of his time, and also one of the most zealous pontiffs; but being of an ambitious disposition, he sometimes sacrificed to that weakness. His principal works are,—*Memoirs of the Council of Basil, from the Suspension of Eugenius to the Election of Felix; The History of the Bohemians, from their Origin to the year* 1458; *Two books on Cosmography; The History of Frederic III.*, published in 1785, in folio; *A Treatise on the Education of Children; A Poem upon the Passion of Jesus Christ; A Collection of Four Hundred and Thirty-Two Letters*, printed at Milan 1473; *The Memoirs of his own Life*, published by John Gobelin Personne, his secretary, and printed at Rome in 1584, in 4to; *Historia Rerum Ubicumque Gestarum*, of which only the first part was published at Venice in 1477, in folio. His works were printed at Helmstadt in 1700, in folio, with a Life prefixed

Pius III., whose original name was *Antonio Todeschini*

succeeded Alexander VI. in 1503, and died in the course of twenty-five days afterwards.

Pius IV., whose real name was *Giovanni Angelo Medici* or *Medichino*, was originally of Milan, and was elected pope in 1559. The principal event in his pontificate was the conclusion of the long-protracted council of Trent, which took place in 1563, two years before his death.

Pius V., who was originally called *Michele Ghislieri*, was born at Boschi, in the north of Italy, in 1504, and succeeded Pius IV. in 1566. He mounted the papal chair with a reputation which foreboded no leniency towards the enemies of the Church. His character had become encrusted with a hard severity amid the gloom and asceticism of a Dominican convent. His enmity against heretics had been whetted to the keenest edge in the discharge of the functions of inquisitor. He had also cultivated a commanding eloquence, which could efficiently second his most thorough-going measures. Accordingly, Pius forthwith organized a rigorous system of policy for the reformation and strengthening of the Church. His first endeavour was to prove himself a rigid disciplinarian to the corrupt priesthood. He enforced the stringent rules of convent life upon the loose-living monks; he drove the non-resident clergy home to their benefices; he stript off the gaudy trappings and overthrew the luxurious tables of the worldly-minded cardinals. The same ardent zeal turned Pius into a firebrand against heretics. The pile was lighted under Carnesecchi, a Florentine nobleman who had dared to investigate the opinions of the Reformers. The same punishment was administered to Palearius, a celebrated writer who had asserted in one of his works that the Inquisition was a sword drawn against learning. It was not even thought beyond the sphere of the Popedom to kindle and fan the flame of war in 1568 against the Protestants in France. Nor was Pius less arrogant in claiming supremacy over the kings of the earth. In 1568 he issued his famous bull entitled *In Cœnâ Domini*, anathematizing every one who should dare to question, limit, or abjure the absolute authority of the Holy See, both in matters sacred and secular. In the following year he hurled the thunders of excommunication against Elizabeth, Queen of England, and absolved her subjects from their allegiance. A project for effectually humbling the Turks was also occupying his mind when he died of stone in 1572.

Pius VI., whose original name was *Giovanni Angelo Braschi*, was born at Cesena in 1717, and succeeded Clement XIV. in 1774. Elegant, devoted to letters, fond of the fine arts, and a well-wisher of progress, the new Pope inaugurated his rule with a series of enlightened and liberal-minded measures. The port of Ancona was adorned and improved by the addition of a beautiful lighthouse; the draining of the Pontine Marshes was undertaken, and carried on towards completion; the museum of the Vatican was extended to receive a new supply of the precious relics of antiquity; fountains and palaces were erected to revive the splendour of the Eternal City; and artists and scholars were summoned from all parts of Italy to recall the brilliant times of Leo X. Pius VI., however, though a successful promoter of the arts of peace, had not sufficient political sagacity to foresee and avert the attacks that were about to be made upon his authority. Accordingly the rest of his pontificate was involved in a long series of troubles. In 1780 the Emperor Joseph II. began to curtail the wealth and power of the Church. The example spread; and in 1787 the King of Naples abolished for ever certain feudal homages which were due to the court of Rome. Immediately afterwards followed the revolt of the Grand Duke of Tuscany from the spiritual supremacy of the Popedom. At length this ecclesiastical insurrection found its climax amid the general overthrow and destruction of the French Revolution. In that crisis the Pontiff's own possessions, and those of the Church within the kingdom of France, were confiscated by the National Assembly. On his protesting against these and other radical measures, his effigy, arrayed in all the pontifical insignia, was burnt by the mob in the garden of the Palais Royal. The murder of Basseville, the French ambassador in 1793, by the Roman populace, widened the breach beyond all hope of settlement by negotiation; and in 1797 the papal territories were invaded by the troops of republican France. A submission, and an agreement to pay a fine of thirty millions of livres to the invaders were only the means of exciting new troubles. Compelled to impoverish his subjects in order to raise the contribution, he caused a general feeling of discontent. An insurrection was the consequence; the French general Duphot was slain in the midst of the tumult; and the French army returned under Berthier to take more summary measures. In 1798 the Pontiff was dethroned, his property was confiscated, and he was obliged to leave Rome under the escort of a body of cavalry. Even in his state of degradation there was no rest to be found. He was removed from Siena to Florence, from Florence to France, until, in August 1799, he died at Valence, on the Rhone.

Pius VII., whose real name was *Gregorio Luigi Barnaba Chiaramonti*, was born of a noble family at Cesena in 1742, and was declared the successor of Pius VI. on the 14th March 1800. He had not long occupied the chair of St Peter when Napoleon set himself to turn the Popedom into a mere tool for his own ambition. Accordingly the new Pontiff began to be assailed with a series of the most arrogant exactions. In 1804 he was summoned to Paris to crown the French usurper. In the following year his port of Ancona was furtively seized by French troops. A command was then issued that he should shut up his dominions and close his harbours against all the enemies of France. In vain he remonstrated, asserting that he was the vicar of the Prince of Peace, and ought to stand aloof from all political dissensions. The bold aggressors, without waiting for what had been asked, gradually occupied the seaports; and, entering Rome in 1808, took the government into their own hands. In vain he had recourse to his last weapon, the bull of excommunication. The irreverent invaders entered the Quirinal Palace on the 6th July 1809, and carried him off, first to Grenoble, and then to Savona. Pius VII. was now more closely pressed than ever by Napoleon. In 1812 he was conveyed to Fontainebleau, that he might be awed into submission by the vicinity of the French capital. There also every stratagem was employed to make him subservient to the ambitious projects of the French potentate. He was plied successively with blandishments, taunts, and menaces, until, on the 25th January 1813, he was prevailed upon to sign a concordat. Then, when immediately afterwards he retracted his concessions, no attention was paid to him. It was not until, in 1814, the allied forces had overthrown Bonaparte, that he was restored to his place and power. The rest of the life of Pius VII. was chiefly devoted to social and political improvements. He died from an accident in August 1823.

Pius VIII., who was originally called *Francesco Xaviero Castiglioni*, was born near Ancona in 1761, became pope on the death of Leo XII. in 1829, and died in 1830.

PIZZO, Il, a town of Naples, in the province of Calabria Ultra II., stands on the Gulf of St Eufemia, 6 miles N.N.E. of Monteleone. It has a small harbour, and some coasting trade, in which, and in fishing, the inhabitants are mostly employed. It was at Pizzo that Murat, the ex-King of Naples, landed with a few followers, October 8, 1815, with the view of recovering his kingdom. He was immediately taken prisoner, and shot in the Castle of Pizzo on the 13th. His remains lie in the middle aisle of the church, which was erected partly by his own liberality. Pop. 5700.

PLACENTIA. See Piacenza.

Placentia, or *Plasentia*, a town of Spain, Estremadura, in the province of Caceres, nearly encircled by the clear river Xerte, in a beautiful valley between the snowy Sierras de Bejar and de la Vera, 120 miles W.S.W. of Madrid. The ancient walls of the town, with their strong semicircular towers, the ruined castle, the long aqueduct raised on 80 arches, and the three picturesque bridges that cross the river, combine with the scenery to give Placentia a very beautiful aspect. The cathedral, built in 1498, is a fine Gothic edifice, though some parts are unfinished, and others have been altered for the worse. It contains several fine pictures and monuments. There are here several other churches, convents, a bishop's palace, a large town-house, several schools, and a college (*seminario conciliar*), connected with the university of Salamanca. Oil, soap, leather, hats, woollen, linen, and hempen stuffs are manufactured. Placentia was plundered by Soult in 1809, a calamity from which it has never recovered. Pop. 6800.

PLAGIARY, the purloiner of another man's works. Amongst the Romans *plagiarius* was properly a person who bought, sold, or retained a freeman for a slave; and was so called because, by the Flavian law, such persons were condemned *ad plagas*, or to be whipped. A plagiary, in the modern sense of the term, is one who borrows without acknowledgment, in literary composition, the thoughts or words of another, and the theft is styled *plagiarism*.

PLAGUE. The terms *pest*, *pestilence*, and *plague* were long employed in Great Britain, as were the corresponding terms in other languages, both in ancient and in modern times, to denote simply a disease attacking a great number of persons simultaneously and in succession, and destroying a large proportion of those whom it attacked; in short, a widely-diffused and malignant epidemic. At the present day these terms are restricted to signify a particular form of disease, of frequent occurrence in the countries bordering on the eastern extremity of the Mediterranean, the Levant, and Archipelago, but occasionally appearing also in countries more or less remote from these regions.

Symptoms by which the plague is characterized.

The disease in question, the plague of the Levant, as it is often termed, exhibits, not in every individual case, but in a large proportion of those affected, in the progress of its epidemic prevalence, two classes of symptoms, the *constitutional* and the *local*. Under the constitutional symptoms may be comprehended those indicatory of fever of a malignant or typhoid character, with various concomitant phenomena that are in wont to attend fever of this character in different regions of the globe; the local consist chiefly of glandular swellings, or buboes, as they are termed, and of malignant or gangrenous boils, or carbuncles.

Relations of the constitutional and local symptoms.

These two classes of symptoms stand variously related to one another in different individual cases; and even, there seems reason to believe, in different periods of the same epidemic. Dr Patrick Russell, in his *Treatise of the Plague*, in which he has given the results of his own extensive observation of this disease during its epidemic prevalence in Aleppo in the years 1760, 1761, and 1762, mentions one class of patients who seldom or never had buboes or carbuncles; and another class, in a few of whom, when the disease proved quickly fatal, these symptoms were likewise absent. "These two eruptions," he says, "are equally diagnostics of the true plague; their presence, separately or in conjunction, leaves the nature of the distemper unequivocal; but fatal has been the error of rashly, from their absence, pronouncing a distemper not to be the plague which in the sequel has depopulated regions, and which early precaution might probably have prevented from spreading." Dr Louis Frank also mentions, that though the appearance of buboes is the most constant and characteristic symptom of the plague, yet he has seen many affected with this disease in whom buboes were altogether wanting, or appeared only at the period of death. As cases of this kind are particularly liable to occur at the commencement of an epidemic, a considerable number of persons may, it is obvious, come to be affected before the pestilential character of the disease is ascertained, or even suspected, particularly in regions in which the plague is of rare occurrence.

But as the constitutional symptoms of plague may occur without the local, so the local may occur with little fever or constitutional disturbance of any kind. Dr Russell, under his fifth class of cases, to which he refers those of slight infection, in which all the infected recovered, and which, he says, "was very numerous," mentions that in these the access was often attended with so little apparent disorder that the eruptions gave the first alarm, "the buboes were often the first symptom of infection;" and the fever, which came on afterwards, was frequently so slight as not to confine the sick to the house: others found themselves indisposed for two or three days, but were not sensible of any febrile heat whatever. In these cases, and in some others in which the fever ran somewhat higher, but without the concurrence of alarming symptoms, "all the infected had buboes or carbuncles, and very often both eruptions concurred in the same subject. Persons not confined by indisposition were often, by the inguinal buboes, prevented from walking abroad."

In cases of plague in which both the constitutional and the local symptoms manifest themselves, there is considerable difference in the relative time of their appearance. "In a very large proportion of the sick," Dr Russell informs us, "the buboes made their appearance in the course of the first day; but in many instances they did not appear before the second or third day, or even later."

In the few remarks we purpose to offer relative to the plague, we shall consider some points of its natural history, as it presents itself,—1*st*, In the countries in which it is of frequent occurrence; and, 2*d*, In those countries in which it rarely shows itself.

As occurring on the borders of the Levant, &c.

I. In the countries bordering on the Levant and Archipelago the plague is liable to present itself either in single, or, as they are termed by medical men, *sporadic* cases; or in a great number of cases simultaneously or in succession, so as to constitute an *epidemic*.

Its sporadic occurrence.

It is stated, indeed, by Dr Patrick Russell, that "in the intervals between the plagues of Aleppo,"—that is to say, between the successive epidemic prevalences of this disease,—"the city remains absolutely free; and the plague is never sporadic there, except in its beginning and decline; it never subsists for any length of time in a few scattered cases without consequence." But this statement is not conformable with the reports of others. M. Pugnet, who accompanied Bonaparte's expedition to Egypt, affirms, in his *Mémoire sur les Fièvres du mauvais caractère du Lévant*, that that country is seldom absolutely free from the plague during several successive years, and that in almost every month of every year there occur a number of cases, though these are not noted when they do not occasion its epidemic prevalence. Sir James M'Grigor, who had the medical charge of the army which was brought from India to Egypt in 1801, in like manner expresses his belief that "the contagion of plague is seldom or never out of Egypt." Dr Murdoch Mackenzie, in his "Letters concerning the Plague at Constantinople," published in the *Philosophical Transactions*, vol. xlvii., remarks that, during the twenty years he had lived at Constantinople and Smyrna, there had scarcely been a year, excepting three, in which the plague did not threaten more or less, with little or no perceptible difference in the character of the season to explain it.

Various estimates have been given of the frequency of plague epidemics in the principal towns of Egypt, Syria,

Plague.

Frequency of its epidemic prevalence.

and Turkey. Prosper Alpinus, who resided in Egypt between 1580 and 1584, refers to a belief of its recurring in that country every seventh year, but represents this belief as being incorrect. Dr Alexander Russell mentions it as the common opinion of the inhabitants of Aleppo, that they are visited with the plague about once in ten years; which opinion, he observes, seems in some measure to be founded on experience. Dr Mackenzie, writing from Constantinople in 1763, says that "the plague is now more frequent in the Levant than it was when I first came into this country about thirty years ago; for then they were almost strangers to it in Aleppo and Tripoli of Syria, and they had it but seldom at Smyrna; whereas now they have it frequently at Aleppo, and summer and winter in Smyrna, which," he adds, "must be owing to the great communication by commerce all over the Levant, and more extended into the country villages than it used to be."

Disappearance during a particular part of the year.

When the plague assumes an epidemic character in the countries in which it is common, the epidemic frequently continues for several years; not, however, uninterruptedly, for in general it is observed that for a part of the year the disease in a great measure, or altogether, disappears, breaking out again after an interval of various duration. In the same way, in non-epidemic seasons sporadic cases of plague are seldom or never met with during a particular portion of the year. It seems reasonable to conclude that this disappearance of plague, or great abatement in its prevalence, during a particular portion of the year, must be connected with some peculiar condition of the weather then prevailing, and consequently that the period must be liable to variations, not only in different countries, but also to some extent in the same country in different years.

Season at which this occurs.

Dr L. Frank mentions his having been assured that at Cairo the time of year in which the operation of the plague-poison is suspended uniformly commences with the summer solstice (21st June), as stated by Prosper Alpinus with regard both to that city and Egypt generally; but that at Alexandria, Rosetta, and Damietta,—that is, in the towns along the coast,—the plague terminates about the feast of St John (24th June), though not uniformly every year, as it sometimes continues till about the middle of July. In respect to the period of the plague's terminating at Cairo, Dr P. Russell mentions that several accounts which, on making strict inquiry, he received from persons long resident in that city, Europeans as well as natives, all concurred in the fact of the plague's declining rapidly in June, but not ceasing entirely; and he particularly refers to information which he had received of the Europeans having remained, in 1759, shut up till the middle of July, "which was considered as very extraordinary." Dr Russell also remarks, that in most places in the Levant a popular tradition is to be found of the extinction of the plague at a certain fixed period, which varies, however, at different places. At Aleppo, he adds, it is fixed nearly a month later than at Cairo. His brother, Dr A. Russell, states that at Aleppo the plague comes to its height in June, decreases greatly in July, and certainly disappears in August. Dr P. Russell, in reference to the same epidemic, says,—"The natives all agreed in declaring the plague had never before been so formidable in the winter; and many went so far as to affirm that it was the first instance of the plague's having been ever known at all at that season. In 1753 it began the last day of May, and continued uninterruptedly till the middle of September 1754.

Season of its re-appearance.

Admitting that, in general, though certainly not universally, plague disappears in Egypt soon after the 21st of June, in Syria about a month later, and probably at a still more advanced period of the year in Asia Minor and Turkey, is there any constancy in regard of its re-appearance? Sir J. M'Grigor mentions that the month of November, or more usually of December, is the time of year in which the plague is wont to re-appear in Egypt, and that, according to the observation of the natives, when it breaks out before December, they have always a generally prevailing and very destructive disease. According to Pugnet, there are three periods in the prevalence of the plague in Egypt,—its *invasion*, which occupies the months of December, January, and February; its *acme*, which occupies March, April, and May; and its *extinction*, which occurs suddenly during the second half of June. Frank says that, according to the general accounts, the plague seldom occurs in Egypt in the months of September, October, November, December, and January, but usually appears in the months of February, March, and April; and he adds, conformably with Sir J. M'Grigor's statement, that "it is well ascertained, that when it begins in September or October, it is more terrible than if it appears later, because it then continues for a longer time, and is the cause of greater mortality. Perhaps, also, the pestilential miasma becomes more deadly." At Aleppo, according to Dr A. Russell, the plague is constantly moderated during the winter, and grows more violent as the spring advances. Mr Hayes mentions the months of March and April as the period at which the plague usually begins at Smyrna. Timone states, in regard to the plague at Constantinople, that it is pretty soundly lulled by the cold of winter, emitting, however, here and there sparks during that season as well as in spring; it increases in summer, and rages with the greatest violence in August. The spread of the infection is not stopped by the coldish north winds blowing at stated times of the summer; but if the south winds blow during that season, constantly and of sufficient warmth, they suppress the plague.

We shall presently have occasion to see the application of these facts relative to the periods at which the plague subsides and revives in Egypt, Syria and Turkey, to the explanations that have been proposed of the causes or agencies by which this disease is produced.

Nature of the agent by which it is produced.

Great difference of opinion has subsisted as to the nature of the agent which, by its operation on the animal economy, produces this form of disease; whether the plague is generated by a particular state of the atmosphere, itself the result of the reciprocal action of various concurrent agents, and which is sufficient to produce the disease in a large proportion of those who are exposed to its influence, as is the case in respect of ague or intermittent fever; or whether the disease is communicated from person to person through the medium of some impalpable effluvium from the body, as in the cases of measles and scarlet fever? Whether, in the language of medical men, the plague depends on terrestrial or atmospheric miasm, improperly named infection by some, or upon human contagion.

The quarantine laws.

The laws of quarantine, so far as they refer to the plague, obviously proceed on the supposition that this disease is capable of being communicated by person to person; and also that the plague-poison is capable of being imbibed by substances that have come in contact with the bodies of those affected, or that have been exposed to the air which they breathe; of remaining attached to such substances for a considerable space of time, when excluded from free ventilation; of mixing with the atmosphere when exposed to it, and infecting those who breathe it; or of communicating the disease to persons who touch or handle the articles to which it is attached. The inconvenience with which the enforcement of the quarantine laws is necessarily attended, particularly to those engaged in commerce, has naturally rendered many anxious for their repeal or modification. The grounds upon which those who have represented them as unnecessary have rested their case may be referred to the two following,—1*st*, That the plague always depends on miasm, and consequently, where the circumstances necessary for the production of plague-miasm concur, the disease will happen in spite of all quarantine regulations; and 2*d*, That

Plague.

supposing the disease to be contagious, there are climates in which its contagion cannot be received and propagated, and consequently, as regards these, quarantine laws must be superfluous.

Dependence on contagion satisfactorily established.

The evidence in favour of the contagious character of the plague in Egypt, Syria, Turkey, &c., and of its dissemination both by person and by fomites, as deduced from the places and individuals that escape, as well as from the places and individuals that become affected, is so ample and complete as to leave room for doubt only in minds preoccupied with theoretical dogmata or considerations of personal advantage. Accordingly, the opinion adverse to the contagious character of plague in these countries seems to be now very generally abandoned by those who can be regarded as impartial and competent judges of the fact. When a select committee was appointed by the House of Commons in 1819 to consider the validity of the doctrine of contagion in the plague, all the medical men examined, with the exception of two, were in favour of the received doctrine, that the plague is a disease communicable by contagion. One of these anti-contagionists in plague was Dr Charles Maclean, the other Dr Mitchell. Of the medical officers of the French and English armies in Egypt between 1799 and 1802, who have published an account of the diseases which presented themselves to their observation during that campaign, Assalini seems to have been the only one who came to the conclusion that the plague is not a truly contagious disease, and that it is produced solely by local causes.

Whether also dependent on terrestrial miasma.

By some, however, it has been supposed that both terrestrial miasm and human contagion are concerned in spreading the plague, the disease being first generated by miasm, but subsequently diffusing itself by contagion, both in the districts in which the miasm is produced, and in countries to which it does not extend, and in which it cannot be supposed to be generated. Amongst those holding this doctrine there has been a difference of opinion as to the number of districts in which the supposed plague-miasm may be produced. Some conceive that there is one particular portion of the globe only in which the circumstances essential for the development of plague-miasm occur in combination,—an opinion readily adopted by the different nations and provinces among whom the disease frequently prevails, though they differ very much as to the parent soil, each being desirous to transfer that odium from itself to its neighbour. M. Fodéré, who, though he had never personally seen the plague, had bestowed much pains in studying its history, maintains that the plague is a production of the soil of Lower Egypt alone,—that is to say, of the combination of the waters of the Nile, and of the materials brought down by that river, with the vegetable earth of the delta, when, after the inundation, the heat causes these waters to be volatilized, and gives rise to the production of an immense multitude of insects and of reptiles. When the disease has once been produced in the human body by this miasm, he has no doubt as to its being capable of being communicated from person to person. He holds, therefore, that in Lower Egypt the plague is both an endemic and a contagious disease; whilst, when it occurs in Upper Egypt, in Syria, and the other countries of Turkey, and in Europe, it is simply a contagious disease, being transported to them from Lower Egypt.

Dependence on atmospheric conditions;

Others, again, are of opinion, that in Egypt, as elsewhere, the plague always requires a human effluvium for its production and communication; but that the propagation of this contagious effluvium is greatly influenced by, if not dependent upon, particular conditions of the atmosphere. This unknown condition of the atmosphere is supposed either to cause the effluvia of non-pestilential diseases to assume a pestilential character, or the plague-effluvium to be generated of a peculiarly virulent character, or to render the human body more susceptible of its action. The influence of the atmosphere in promoting and in checking plague seems sufficiently established by the circumstances already stated relative to the variations in its prevalence in the different seasons of the year; but in what manner or by what qualities the atmosphere exerts this influence, is a matter of the greatest uncertainty.

Plague.

on temperature;

Some authors have been of opinion that it is simply the *temperature* of the atmosphere which determines the prevalence of plague in the countries along the shores of the Mediterranean; that the atmosphere may be either too hot or too cold for its propagation. Thus Dr A. Russell mentions that the season wherein the plague always ceases at Aleppo is that in which the heats are the most excessive. "Extreme heat," he says, "seems to check the progress of the disease; for though, during the few first hot days, the mortality, as well as the number of those newly infected, increase, yet a few days' longer continuance of that weather greatly diminishes the number of the sick." Mr Dawes, in mentioning August and September as the months in which the plague usually, though not constantly, ceases at Aleppo, notices them as being the hottest months in the year. Conformably with the same view, the occurrence of the hot winds is conceived by some to be the agent which puts a stop to the prevalence of the plague in Egypt. From the statements of Timone, and of several other authors, as we have already seen, it appears that, at Constantinople, the cold of winter generally exercises a great influence in suppressing or diminishing the extension of this disease. Dr James Frank, who was upon the expedition with Sir Ralph Abercromby in the year 1800, and had the first establishment of the Plague Hospital at Aboukir, says, in his evidence before the committee of the House of Commons in 1819,—"The great cold of Constantinople puts an end to it, and the great heat of Cairo puts an end to it." And to the same effect, Mr Edward Hayes, a native of Smyrna, and who had resided there nearly forty-four years, on being asked by the committee, "When does the plague generally subside in your country?" replied, "When the great cold or the great heat destroys it."

on heat and moisture conjointly.

M. Pugnet, again, affirms that the prevalence of the plague in Egypt is always proportional to the *moisture* of the atmosphere taken in connection with its *heat*, whether the moisture shall depend on a greater than usual inundation of the Nile, or on the fall of rain; and explains by these different sources of moisture the plague making its appearance in different districts of Egypt in different years. The circumstance of the heat bearing either a very great or a very small proportion to the moisture of the atmosphere is, according to Pugnet, unfavourable to the extension of plague; but at the same time he holds that, besides moisture and heat, the germ of the disease, as he terms the contagious principle, is requisite for its development. In noticing that most of those who have travelled in Egypt say the plague is brought there from Greece, and those who have travelled in Greece pretend that that country only receives it from Egypt, M. Pugnet remarks,—"I think that the defenders of Egypt and those of Greece are equally in the right; the plague comes no less from Egypt than from Greece, or from Greece than from Egypt. It has established itself a durable focus in these two opposite points; and when one of them seems to become extinguished, the other revives it."

Supposed connection with the overflowing of the Nile.

Dr L. Frank, who, after sojourning with the French army in Egypt, subsequently resided for a year in Tunis, and travelled for six years over the continent of Greece, principally for the purpose of investigating everything connected with the plague, is adverse to the idea of the production of the pestilential poison being in any way connected with the overflowing of the Nile. The Nile begins to decrease in September, and in December all the waters dis-

Plague.

appear from the inundated surface. Consequently, he argues, if the putrefaction of stagnant waters could produce the plague, this disease should manifest itself chiefly in the months of October, November, and December, whilst, in fact, it very rarely occurs in these months. Frank conceives, with Alpinus, that it is in the character of the *winds* that the cause of the prevalence or cessation of the plague in Egypt is to be looked for; the unhealthy season corresponding with the part of the year during which the winds and weather are variable, and the healthy season with the period during which the north wind blows steadily,—that is, from June to September.

Dependence on the prevailing winds.

Those who, in admitting the contagious character of the plague, have argued in favour of the possibility of its poison being engendered independently of human effluvia, and simply from the reciprocal action of the atmosphere and the earth upon one another, seem to have been led to this view by their believing that the plague-poison is wholly extinguished during a certain portion of the year, and consequently, that for the reproduction of the disease there must be a reproduction, or *generatio de novo*, as medical men term it, of the poison.

Supposition of plague-poison being reproduced from time to time.

When, by the return of the period of the year which is unfavourable to its dissemination, the plague ceases, one of two things may happen: it may remain absent from the country or district for a succession of years, or it may recur with the period of the year which is compatible with its propagation. Now it does not appear to be necessary, in either of these cases, to admit the supposition of a fresh generation of pestilential poison from terrestrial miasmata. In the case of the shorter interval, the epidemic may have slumbered, but not died; in short, there may have occurred sporadic cases of the disease in sufficient number to maintain the stock. When, again, a more considerable interval elapses between the cessation of the plague and its re-appearance at a particular place, a fresh importation may have taken place from regions in which it has been prevailing epidemically during its absence from the country under observation.

Besides being maintained by sporadic cases during the non-epidemic season of the year, the contagion of the plague may also be maintained in the form of *fomites;* that is, attached to substances that have been in contact with the bodies of patients, or exposed to the air which they breathe. Dr Russell mentions that at Aleppo, in 1762, several instances occurred of the revival of plague in houses which had suffered the year before, attended with circumstances highly suspicious of the contagion having been preserved several months for want of cleansing. It has very generally been believed, also, that by fomites the contagion of plague may be carried to regions very remote from that in which these substances acquired it. When the articles to which the pestiferous poison has attached itself are freely exposed to ventilation, it does not seem to be retained for any considerable length of time; but when, on the contrary, they are excluded from open communication with the air, there is good ground for suspecting that the poison may remain attached to them for a long space of time. Indeed we are not acquainted with any natural limit to its continuance besides that of the free exposure of the fomites to the air.

Circumstances diminishing the probability of infection.

In considering the plague to be capable, at least during a certain portion of the year, of being diffused by contagion, it is not necessarily inferred that all persons who approach within a given distance of a person labouring under the disease must become affected with it. There seem to be a variety of circumstances that diminish the probability of infection, with some of which we are more or less acquainted, whilst of others we are entirely ignorant.

1*st*, It has been supposed that exposure during one period of the epidemic is attended with less risk of infection than exposure during another. 2*d*, That exposure to a mild case of plague is attended with less risk of infection than exposure to one of a very malignant character. 3*d*, That a person who is exposed to plague-contagion by degrees runs less risk of infection than one who is suddenly brought within the sphere of its operation. 4*th*, That persons possessing equanimity of mind, of temperate habits, &c., run less risk than those who are in opposite circumstances.

Individual peculiarities in respect of the susceptibility or non-susceptibility of plague-contagion are very singular and unaccountable, but not more so than are observed in respect of other contagious diseases. A person whose exposure to the affected has been slight and of short continuance may be seized with the disease; whilst another who has undergone a very great degree of exposure remains free. And a person who has remained free during close and long-continued exposure, may ultimately become affected, without any change of circumstances, extrinsic or intrinsic, which it is possible to detect.

Dr L. Frank conceives that the proportion of persons who pass their life in Egypt without experiencing an attack of plague is greater than the proportion of persons who never experience an attack of small-pox, which he reckons as scarcely one in ten thousand.

Possibility of recurrence in the same individual.

It has been much disputed whether having once passed through plague renders a person unsusceptible of re-infection; and if it does not afford absolute security against more than one attack, in what proportion of cases a second or more frequent recurrence takes place. Some authors have denied the reality, if not the possibility, of a second attack of plague; others have related, as very singular events, single cases which had been noticed in particular epidemics; whilst others, again, represent such occurrences as by no means rare. Dr Mackenzie mentions his having been assured by the Greek padré who took care of the Greek hospital at Smyrna for fifty years that he had had the plague twelve different times during that period; and it is very certain, adds Dr Mackenzie, that he died of it in 1736. The abbé who took care of the Frank Hospital at Pera assured Dr M. that he had had the disease at Constantinople and at Smyrna four different times.

Latent period of infection.

In various respects it is extremely desirable to know what length of time may elapse between a person's exposure to plague-poison and the appearance of the disease. On the decision of this question it is obvious that duration of personal quarantine should be founded. Dr P. Russell mentions that at Aleppo he met with no instance of the disease appearing later than the ninth or tenth day after the day of shutting up, in those who adopted that precaution. Sir J. M'Grigor, in noticing that in different people, and under different circumstances, there is the greatest variety in respect of the time the matter of the pestilential contagion takes before it comes into action, mentions one case in which ten days seemed to be the shortest period that could possibly have intervened; and another in which a person continued well till the seventeenth day after being placed in quarantine.

In other countries than those of the Levant.

II. The few remarks which we have room to offer relative to the plague as occurring occasionally in other regions than those bordering on the Levant and Archipelago, must bear reference chiefly to the question whether, admitting the plague to be a contagious disease in the countries we have hitherto alluded to, there is any reason to apprehend the possibility of its being introduced into the British Isles; or whether the quarantine laws as regards the plague might be safely abolished. To justify such a measure, it would, it appears to us, be necessary to establish the correctness of one or other of the following propositions:—

Possibility of plague occurring in the British Isles.

1*st*, That it is impossible, in the nature of things, that

the plague should exist in the British Isles, and that, in point of fact, it never existed in them; 2*d*, That if it ever existed in these islands, it was indigenous, not imported, and consequently could not have been prevented by quarantine laws; or, 3*d*, That if it ever was imported into these islands, it was under circumstances which cannot recur.

1*st*, Our opinion as to whether a particular disease can occur in any country may rest upon two grounds; the first, our belief as to the conditions on which its prevalence in the countries it is known to infest may depend; and the second, our knowledge as to whether it has ever prevailed in the country in former times. These two considerations may reflect mutual light on each other. If we are very certain as to the conditions requisite for the existence of the particular disease, and are told that it has occurred in a country which we know not to fulfil these, we will disbelieve the correctness of the statement. And, conversely, if we are perfectly satisfied that the disease has prevailed in a country which does not fulfil the conditions we are disposed to consider requisite for its existence, our opinion as to these conditions must be modified. In respect of the plague, it is plain, from the discrepancies which we have seen to prevail in the explanations given of the causes by which it is produced and propagated in Egypt, &c., that the reality of its existence is exposed to much less dubiety than the explanation of the conditions on which that existence depends.

The fact already mentioned, of the very wide signification that used to be attached to the term plague or pest, renders it necessary indeed that, in judging whether a particular epidemic was really plague or not, we should not trust to the mere name which it received, but inquire into the symptoms which it actually exhibited. But, with symptoms so very characteristic as those that attend true plague, or rather, as we have already said, a large proportion of the cases that occur in the course of a plague-epidemic, a very slight description of a *pestilence* must suffice for determining as to its identity with genuine plague. Accordingly, we have experienced considerable surprise, in looking over the evidence taken by the committee of the House of Commons in 1819, at the number of witnesses who either positively denied that the so-called plague in London of 1665 (to omit previous epidemics to which that title was applied) was really that disease, or expressed much doubt on the subject. If the general statement of Sydenham to that effect left any room for doubt on this head, the minute description of Dr Hodges, and particularly that portion of it that relates to the more peculiar symptoms, including buboes, carbuncles, &c., is more than sufficient, we should have thought, to remove all doubt from the minds of the most sceptical.

Whether indigenous or imported.

2*d*, As to the plague of 1665 having been indigenous, and not imported, we have a very explicit statement of Dr Hodges as to its having been brought from Turkey to Holland, and from Holland to England. Attempts have indeed been made to point out discrepancies in his explanation of its first appearance and propagation in England: but to us the objections appear inconclusive, and the deficiencies in the chain of proofs such as might occur in tracing the diffusion of a disease universally recognised as contagious. The non-recurrence of the plague in this country since that period is certainly not more easy to explain on the supposition of the epidemic in question having been indigenous, than on that of its having been imported.

3*d*, The circumstances favourable to the reception and dissemination of plague-contagion, which may be supposed to have existed in 1665, but to be now extinct and incapable of recurring, may be of different kinds. The beneficial change may be in the character of the climate, in the condition of the soil, or in the habits of the people. But if our immunity has depended on a change in the climate, who can be responsible for the continuance of this change? What the climate has been, it may, for anything we know, become again. And as to any immunity that could be supposed to result from a change in the habits of society, and particularly from the superior attention paid to cleanliness and ventilation in our cities, from the introduction of public sewers, &c., to which much importance has been attached, we must confess our apprehensions that any seeds of disease which depend for their development upon filth will not perish for want of a hotbed in many districts of the larger cities of the three kingdoms.

Treatment of the plague.

When a person who has been exposed to the contagion of plague begins to feel unwell, it is proper to remove from his stomach all undigested matter by means of an emetic, taking care that it do not produce excessive nausea after the evacuation; and this, if it happens, is to be allayed by administering effervescing draughts, or a small quantity of laudanum. It will be proper also to empty the bowels by some mild but effectual purgative, avoiding diarrhœa. A gentle perspiration has appeared in some cases to carry off the disease; and we may attempt this by antimonial medicines, or the diluted acetate of ammonia. The mineral and vegetable acids will also be found useful; diminishing the heat of the body by prudent sponging with vinegar and water; giving medicines to allay irritation and procure sleep, as camphor and opium; frequently changing the bed and body linen of the patient, and quickly removing all offensive matters from his apartment.

Prevention of the plague.

The great means of spreading the plague is by contact with infected persons, or the contact of substances to which the pestilential infection adheres, as clothes, cotton, furniture, papers, and the like. When the plague has broken out in a place, every effort must be made, by means of lazarettoes or plague-hospitals, to separate completely between the sick and the healthy. Great attention should be paid to ventilation, and the sound, should on such occasions keep to windward of the sick. Anything worn about the person, if it gives confidence to the individual, will be of service in enabling him to resist contagion; hence camphor, vinegar, or any aromatic, may sometimes act as a preventive. Friction of the body with oil has obtained the reputation of a positive antidote; and whatever may be its ultimate virtue, it certainly should not be neglected. (J. T—N.)

PLAN, in general, denotes the representation of some object drawn upon a plane, such as maps, charts, ichnographies, and the like. The term *plan*, however, is particularly used for a draught of a building, such as it appears, or is intended to appear, on the ground, showing the extent, division, and distribution of its area or ground-plot into apartments, rooms, passages, &c. A geometrical plan is that in which the solid and vacant parts are represented in their natural proportions. The raised plan of a building is the same with what is otherwise called an *elevation* or *orthography*. A perspective plan is that exhibited by degradations or diminutions, according to the rules of perspective.

PLANE, in *Geometry*, denotes a plain surface, or one that lies evenly between its bounding lines; and as a right line is the shortest extension from one point to another, so a plane surface is the shortest extension from one line to another. In astronomy, conic sections, &c., the term *plane* is frequently used for an imaginary surface, supposed to cut and pass through solid bodies; and on this foundation is built the whole doctrine of conic sections. In mechanics, planes are either horizontal,—that is, parallel to the horizon, —or inclined to it. In optics the planes of reflection and refraction are those drawn through the incident and reflected or refracted rays. In perspective we meet with the perspective plane, which is supposed to be pellucid,

and perpendicular to the horizon; the horizontal plane, supposed to pass through the spectator's eye, parallel to the horizon; and the geometrical plane, likewise parallel to the horizon, in which the object to be represented is supposed to be placed. The plane of projection in the stereographic projection of the sphere, is that on which the projection is made, corresponding to the perspective plane.

PLANET (πλανήτης, *a wanderer*), a celestial body revolving round the sun as a centre.

PLANETARY MACHINES. The establishment of mechanical and physical science on an experimental basis, in the sixteenth and seventeenth centuries, is an event, or rather a series of events, for which the world cannot be sufficiently grateful. The splendid discoveries which were from time to time announced, and the various machines constructed for their illustration, directed men's minds strongly to mechanical pursuits. The results were of great value to civilization; and even when the objects sought for were frivolous, they were not altogether useless, as in the construction of *clocks* which, in addition to their ordinary duties, were made to undertake many wonderful and unnecessary things; *automata* of various kinds, which accomplished objects equally wonderful and unnecessary; and *planetary machines* for representing the motions of the heavenly bodies. The value of these things consisted in gratifying the public taste for ingenious toys, in fostering mechanical skill, and in supplying clever combinations, which have subsequently been reproduced in really useful automatic machines.

The term *orrery* is sometimes applied to planetary machines, and the origin of this word is stated by Desaguliers to have arisen from the following circumstances:—About the year 1700 Graham contrived a movement for exhibiting the motion of the earth about the sun, together with the moon revolving about the earth. This machine was sent to an instrument-maker's, for the purpose of being packed up with some other instruments about to be forwarded to Prince Eugene; but the maker having copied it, sold his copy to the Earl of Orrery, who it appears showed it to Steele, and he, referring to it in one of his lucubrations, called it an *orrery*,—a name which was at once adopted, and has since been retained.

Graham's machine, however, was by no means the first of its kind. The Chinese are said to have constructed planetary machines 2000 years before the Christian era. Archimedes and Posidonius also constructed them; and Cicero makes use of both machines in his argument on design in creation. (*De Nat. Deor.*, lib. ii., cap. 34 and 35.) During many centuries, planetary machines consisted of moveable spheres, with the earth in the centre,—a construction which continued in use until about fifteen years after the death of Copernicus, when the last celebrated example of a machine illustrative of that system was placed in the library of the Pantheon at Paris. Huyghens and Römer also constructed machines for illustrating the Copernican system. Huyghens first introduced a systematic method of calculating the necessary wheel-work for the machine which he named the *automaton*. This long continued to be a pattern in the construction of orreries; as was also Römer's instrument, intended chiefly to exhibit the orbital motions of the planets. Römer also invented a machine for representing the motions of Jupiter's satellites about their primary, together with the motions of the latter about the sun. In 1679 he presented a machine of this kind to the English astronomer Flamsteed. Among other great names which have been concerned in the construction of planetary machines, must be mentioned those of Dr Thomas Young and the Rev. W. Pearson, who furnished the plan for the planetarium of the Royal Institution of London.

Planetary machines have been variously named according to the objects intended to be attained by them. Thus we have the *planetarium*, which represents the orbital motions of the planets about the sun; the *tellurium* and the *lunarium*, for exhibiting the motion of the moon about the earth, and that of the earth about the sun, together with the principal phenomena which accompany the changes in their relative positions,—such as the succession of day and night, and the variable length of both according to the season of the year; the eclipses of the sun and moon; variations in the moon's latitude, velocity, and distance from the earth; the progressive motion of her apogee, and the retrogradation of her nodes, &c. The *satellite machine* by Römer, already referred to, is the last of the four planetary machines to which distinct names have been given corresponding to the phenomena they are intended to exhibit; but they are all generally included under the term *orrery*.

The most important part of an orrery is the mechanism of the planetarium, for exhibiting the paths of the planets about the sun, and their relative periodic times, together with the motions of the satellites about their primaries. The former object is usually attained by means of a system of upright concentric tubes of different lengths, the innermost being the longest; to the upper extremity of each is attached a radius vector, which revolves once during each revolution of the tube; the lower ends of the tubes form the arbors of as many toothed wheels, which are driven either by pinions adjusted to a vertical axle called the *annual arbor*, or they are moved by those pinions through the intervention of a train of wheels. The calculation of the relative number of teeth to be given to the wheels and pinions, in order to produce the required motions, belongs to that part of mechanics which treats of wheel-work.

It is not necessary to dwell at greater length on the construction of a machine which is at best a clumsy, useless, and expensive toy. As science advances, the instruments of research become more and more perfect; and although, as the great German chemist expresses it, it is not the instrument that does the work, but the mind of the inventor (*Das Instrument macht ja das Werk nicht, sondern der menschliche Geist*), still the instruments of the day will fairly represent the science of the day, and in this science the planetary machine has no place. That this machine never did, and never can, represent the truth as it is in nature, will be evident from the following computation, which we borrow from a great living astronomer:—"Choose any well levelled field or bowling-green. On it place a globe two feet in diameter; this will represent the sun: Mercury will be represented by a grain of mustard-seed, on the circumference of a circle 164 feet in diameter for its orbit; Venus, a pea, on a circle 284 feet in diameter; the earth also a pea, on a circle of 430 feet; Mars, a rather large pin's head, on a circle of 654 feet; Juno, Ceres, Vesta, and Pallas, grains of sand, in orbits of from 1000 to 1200 feet; Jupiter, a moderate-sized orange, in a circle nearly half a mile across; Saturn, a small orange, on a circle of four-fifths of a mile; and Uranus, a full-sized cherry or small plum, upon the circumference of a circle more than a mile and a half in diameter. As to getting correct notions on this subject by drawing circles on paper, or, still worse, from those very childish toys called orreries, it is out of the question." (Herschel's *Astronomy*, 1848.) (C. T.)

PLANISPHERE signifies a projection of the sphere and its various circles upon a plane.

PLANT. See BOTANY.

PLANTAGENET, the surname of the kings of England from Henry II. to Richard III. inclusive. Fulk, the first Earl of Anjou, stung with remorse for some wicked action, went, as a work of atonement, in pilgrimage to Jerusalem, where, being soundly scourged with broom twigs, which grew plentifully on the spot, he afterwards took the surname of *Plantagenet*, which was retained by his posterity.

PLANTING.

Planting, or the culture of trees, is a branch of agriculture necessarily of much more recent date than either the culture of grain and herbage plants, or the breeding and rearing of cattle. The culture of those plants which in every country supply the food of mankind, whether directly, or by nourishing the domestic animals used for food by man, must have exclusively occupied his attention for many ages; whilst the timber which was employed in houses, ships, and machines, or for fuel, was found in the native woods. Hence, though we hear of the culture of fruit-trees, and occasionally also of ornamental trees and shrubs, amongst the Egyptians, Greeks, and Romans, the cultivation of timber-trees on a large scale by art only took place in modern times. In the days of Charlemagne, the greater part of France and Germany was covered with immense forests; and one of the benefits conferred on France by that prince, was the rooting up of portions of these forests here and there throughout the country, and substituting in their room orchards or vineyards. Artificial plantations appear to have been formed in Germany sooner than in any other country, and apparently as early as the fifteenth century. In Britain they took place, though but sparingly, nearly a century afterwards. Planting, however, was by no means general in England till the beginning of the seventeenth century, when, in consequence of the extensive transfers of property which took place in the preceding century, on the seizure of the church-lands by Henry VIII., much timber was sold by the new owners, in order to make good their payments. The quantity of timber thus thrown into the market lowered its price considerably, insomuch, as Hollingshed informs us, that the builders of cottages, who had formerly employed willow, and other cheap and common woods, now built them of as good oak as their lords. The demand for timber thus constantly increasing, and a demand for an extended surface of farming land going on at the same time, the natural forests became everywhere greatly circumscribed, till at last timber for naval purposes and house-building began to be imported, and the proprietors of land to think, first of protecting their native woods from the inroads of cattle; afterwards of enclosing pieces of waste ground, and allowing them to become covered with young trees from seeds carried thither by the wind or other accidental circumstances; and ultimately of sowing acorns and mast in such enclosures, or of filling them with young plants collected in the woods; a practice which exists in Sussex, and some other parts of England, even at the present day. Planting received a great stimulus in Britain soon after the breaking out of the late general war, partly in consequence of a real or supposed scarcity of timber fit for naval purposes, and partly owing to the high price to which the article for general use rose, in consequence of the increased expense of obtaining supplies from other countries. Since the peace, the rage for planting, with a view to profit, has subsided; but there is still a universal taste for cultivating trees and shrubs, with a combined view to ornament and use; and there is also an increased and increasing taste for the introduction of trees and shrubs from foreign countries.

Having in this slight manner noticed the origin of planting, we shall next give a brief outline of its present practice in Britain; noticing in succession: 1. A general view of the different properties possessed by trees; 2. selections suitable for different purposes; 3. the nursery culture of trees; and, 4. the culture of trees in plantations.

It is necessary to premise, that in this article we confine ourselves entirely to trees which are well known in Britain, and quite hardy; and to the formation of such plantations as are made with a view to their timber-produce. Fruit-trees and fruit-shrubs, flowering shrubs of every kind, and ornamental plantations, we consider as belonging to gardening, and as already disposed of under the article Horticulture.

I.—*General View of the different Properties possessed by Trees which may be cultivated in Britain.*

The sort of trees which it is desirable to plant, is necessarily the first point which a proprietor will take into consideration before he commences a plantation. Trees differ from one another in many particulars: in magnitude; in slowness or rapidity of growth; in their suitableness for poor soils or rich soils, moist grounds or dry grounds, elevated exposed situations, or low and sheltered plains; in the texture, colour, and durability of their timber; in their delicacy or hardiness in any given climate; in their being difficult or easy to propagate and rear; in retaining their leaves all the year, or dropping them every autumn; in producing showy flowers or fruits; and in a great variety of other particulars. In regard to magnitude, those trees which, in the latitude of Britain, and in the same parallels of latitude throughout the northern hemisphere, attain the greatest height, are the spruce and silver fir, the larch, and the Scotch pine; and these also are the trees which, in most parts of Britain, produce the greatest quantity of timber in their trunks relatively to that contained in their branches, and that in the shortest time. The poplar, the willow, and some species of elm, are rapid-growing trees, and produce a great bulk of head in a short period; but the timber of these trees is not all contained in one straight trunk, as in the case of the pines and firs, a considerable portion of it being distributed among the branches. Hence, where the speedy production of timber is the main object of planting, the pines and firs above mentioned are decidedly the trees that ought to be preferred. The production of timber, however, is not always the sole object of planting. Effect, or, in other words, the production of the appearance of woodiness on an estate, is perhaps oftener the object than mere timber. For this purpose the Scotch and English elms, the white, black, and black Italian poplars, the Huntingdon willow, and in some situations the birch, and in others, such as on the sea-shore, the sycamore, are the most desirable trees. Where the object is to clothe a sterile surface of dry sand, the birch and the Scotch pine are among the best trees that we have; and if the situation be exposed to the sea-breeze, the common and the Norway maple may be substituted for the birch and the pine; and, in the warmer parts of the island, the evergreen oak. For moist soils which cannot be drained, there are trees that have the remarkable property of sending their horizontal roots along the surface of the ground; among these are the white, the trembling, and the Ontario poplars; and, for the marshes of the warmer parts of the island, the deciduous cypress. There are trees which will grow near water, in situations where their roots can enter into it, but which will not grow in undrained soil, such as the different species of willow, and most of the poplars. It is a remarkable fact, that there is no tree in any part of the world which is truly aquatic; that is, which will spring up from the bottom of a pond or river. Had there been such trees created, there could then have been neither rivers nor lakes, and the whole of the terrestrial globe must necessarily have been either in a state of marsh or mountain.

In general it may be observed, that trees are not so absolute in their choice of soils as for each species to require one of a different nature; on the contrary, on almost any kind of soil not beyond the average in point of moisture, dryness, or tenacity, all the known species of trees and shrubs may be grown to a tolerably mature size and age. In some soils, however, they will thrive better than in others; and the timber produced generally varies in quality according to the soil. Thus a rich soil, while it contributes to the rapid growth of the pine and fir tribe, renders their timber less durable; and the same law holds good, more or less, with regard to every other species of tree.

The influence of climate on trees is incomparably greater than that of soil; for, whilst any tree may be said to grow on any soil, every tree may be said to have its particular climate; that is, a climate in which, the soil and other circumstances being suitable, it will attain its greatest bulk, and its timber endure the longest. Hence, when we take the geographical and physical range of any particular species of tree, the oak, for example, we shall find that there is what may be called a central climate, where, when on suitable soil, it attains its largest size; and that as it recedes from this climate, whether by latitude or elevation, either into one which is colder, or one that is hotter, it gradually diminishes in size, till it at last appears in the form of a shrub. Thus the common oak, which in Britain attains its largest size in Sussex and Hampshire, dwindles into a shrub on the mountains of the Highlands of Scotland, and also in the north of Africa; its degeneracy being occasioned in the one case by extreme cold, and in the other by extreme heat. Even within the range of the climate of Britain, the absolute character of trees, relatively to climate, is made obvious. The English or narrow-leaved elm, which is supposed to be a native of Asia Minor, and also of China, attains a large size in the neighbourhood of London, producing a great bulk of timber in a short period, and ripening its seeds; while north of York it does not thrive, and in Scotland it is considered only as an ornamental tree. The Lombardy poplar, which is known in the central counties of England to attain 100 feet in height in forty or fifty years, is nowhere seen of a timber-like size in Scotland; and it may be observed of the sweet chestnut and the walnut, that though they are grown both for their fruit and their timber in many parts of England, yet that they cannot be profitably employed for either purpose north of Newcastle.

Climate, relatively to trees, may be considered in regard to its average temperature throughout the year, to its temperature in summer and winter and in spring and autumn, and to its degree of atmospheric moisture. A high average temperature is no proof that a climate is suitable for trees; but a high summer temperature is suitable for many kinds, though the temperature of the winter may be very low. Thus the oaks and many other trees of North America, attaining there a prodigious size, survive a winter as cold as that of St Petersburg, where no native oaks of any kind are ever found; but the oaks of North America enjoy a very high temperature during summer, which rapidly develops their foliage and young shoots, and fully matures the latter, so as to enable them to withstand the most rigorous frosts of winter. In England the average temperature of the year is as great as that of the oak countries of the United States; but our summers are comparatively cold, moist, and gloomy; and though our winters are so much milder than those of America, yet the spongy, unripened, young shoots are always more or less injured by the frost. Another disadvantage of a country having a mild winter is, that the trees of those countries which have a very severe winter come into leaf earlier in the spring than the indigenous trees of the mild climate; and frosts being more or less prevalent at that season, they are proportionably liable to injury from that cause.

Evergreen trees form a very important division of the ligneous kingdom; and of these there are two classes, very distinct relatively to climate and temperature. The first of these classes comprises the needle-leaved trees, such as the pine and fir tribe, which will endure a degree of cold as great as that in which any deciduous tree will thrive; and the second, the broad-leaved evergreen trees, such as the holly, the box, the laurustinus, the laurel, the evergreen oak, the cork-tree, and the evergreen mangolia, all of which are trees of comparatively mild climates, and which are always found in a natural state on islands, or on continents at low elevations, and at no great distance from the sea: hence the very considerable number of evergreen trees which will endure the open air in Britain, compared with those which stand through the winter in the same parallel of latitude on the continent.

Of the trees cultivated in Great Britain, only a small proportion are indigenous. A considerable number are natives of other parts of Europe, and about two thirds of the whole are from North America. Of these North American trees there is scarcely one that is worth cultivating in Britain for its timber; and the reason seems to be, chiefly, that our climate is not sufficiently hot and light in summer to bring that timber to maturity. The truly useful timber-trees of Britain are those which are indigenous, such as the oak, the ash, the broad-leaved elm, the Scotch pine, &c.: or those which are found in the same hemisphere and in the same parallels of latitude, such as the larch, the spruce fir, the silver fir, &c. Of all the trees which are cultivated in Europe, that which is most to be depended on for the strength and durability of its timber is the common oak; and next, and perhaps equal to it, is the larch. The trunk of the oak-tree, when freed from the soft or outer wood, and thoroughly seasoned by exposure to the atmosphere, will endure an unknown period of time in buildings and machines; and, even when split up into thin laminæ, and put up in the open air as fencing, without any painting or other preparation, it has been known to last for upwards of a century. The common European oak is found to be more durable as timber than any of the American oaks, even when grown in America, unless we except the live oak; and there is perhaps no timber in the world equal to it for ship-building, excepting the teak-wood of India. The most generally useful timber grown in Britain is the Scotch pine; but as this timber is also imported from the north of Europe, and a substitute for it from North America in great quantities, it is not planted in Britain nearly so extensively as it otherwise would be. The timber of the larch is undoubtedly of greater durability than that of the Scotch pine; but being apt to warp, and not being so easily worked, it is less convenient for the purposes of house-carpentry and joinery. The timber of the common ash is valuable in the construction of agricultural instruments and machines, and it is one of the few woods which are almost as valuable when young as when of mature age. The wood of the broad-leaved elm is strong and durable, but that of the English and Dutch elms is much less so. The wood of the poplar, and that of the willow, when exposed to constant atmospherical changes, speedily decay; but when thoroughly seasoned, and afterwards kept perfectly dry, they will last for centuries. In general, it may be observed, that every description of timber, when at maturity, if thoroughly seasoned, and preserved in an atmosphere tolerably uniform in point of dryness, will last a long period.

The great majority of trees which are planted in Britain may be considered as ornamental; for though the timber of all of them is more or less useful, yet, if the mere production of timber were the main object of planting, all trees except the oak, the larch, the Scotch pine, and two or three others, would be rejected, either on account of their

slow growth, or of the inferior quality of the timber which they produce in our climate. Trees may be considered as ornamental, from their general shape, from their foliage, from their flowers or fruit, or from their rarity. In order that the shapes of trees may be displayed to advantage, it is necessary that they should stand singly; and when this is the case with some species of trees, such, for example, as the different species of the pine and fir tribe, their shapes become strikingly different from what they are when grown in masses. The Scotch pine, when drawn up in close forests, produces a clean, straight trunk, free from branches for the greater part of its height; but when by chance or design it stands singly, it throws out gigantic branches on every side, and becomes one of the most irregular and picturesque-headed of trees. But of all the trees which assume ornamental shapes in consequence of standing singly or nearly so, the most remarkable is the cedar of Lebanon. When this tree is grown in masses, it shoots up with a straight, clean trunk, and terminates in a small, spiry top; but when planted alone, and allowed to spread its branches on every side, it throws out its gigantic arms in successive tiers, and forms an irregular pyramidal mass, unequalled for grandeur, singularity, and picturesque beauty, by any other tree of the temperate regions of either hemisphere. All trees indeed become comparatively the same naked poles with scanty tops when grown in masses, and all assume irregular and picturesque forms when grown singly. Hence, whenever trees are grown chiefly for the purpose of displaying their shapes, they ought to be placed at such a distance from each other as that their branches may not touch; which in practice is effected by scattering them in groups in parks or pleasure-grounds, or planting them in hedgerows. Trees which are valued as ornamental chiefly for their foliage, fruit, or flowers, will obviously display these to the best advantage when standing singly; but for such an object isolation is much less necessary, as the ornamental foliage will be displayed even when the plantation is in masses, and seen at a distance; and the flowers and fruits by planting the trees in the margins of plantations of other sorts.

II.—*Selections of Trees for particular purposes.*

The object of the preceding remarks is to communicate some general ideas on the subject of selection, and on the properties of particular species; and we shall next pursue the same subject more in detail, by giving the names of the principal trees deserving of culture in Britain, thrown into groups characterized by some property common to the whole.

Needle-leaved or Resinous Trees are characterized by straight erect trunks, regularly furnished with branches in tiers, which never, except under particular circumstances, acquire the size of timber. They never send up shoots from the collar or stool when cut over by the surface. The leaves are narrow, or needle-shaped, without veins, and they are evergreen. The seeds are produced in cones, and the whole plant is more or less resinous. They belong to the Gymnosperms of the natural system, which form an order intermediate between the Dicotyledoneæ, and the Monocotyledoneæ.

Larix Europæa, *Dec.*, is the most valuable species for its timber, which is of great durability, both in its young and mature state. Young larches, five feet or six feet high, and the spray of larch-trees of any age, last a very long period, when intertwined with larch stakes, so as to form a dead fence. Young trees from ten feet to fifteen feet in height are found, in the neighbourhood of Farnham and other places, to form the most durable hop-poles; and the durability of the mature timber, in every department, both in civil and naval architecture, has been placed beyond all doubt, by the experience of John duke of Atholl, as recorded in the Transactions of the Highland Society of Scotland, vol. xi. p. 165; and Loudon's *Arboretum Britannicum*, vol. iv. p. 2387. The bark of the larch is also of considerable value in tanning; and the leaves being deciduous, the tree is more favourable to the growth of grass under its shade, than any other species of pine or fir. The larch is readily increased by seeds which are ripened in abundance in Britain; and it prospers best in cool, argillaceous soil, moist rather than dry, and placed at a considerable elevation above the level of the sea. The larch is subject to various diseases, and, in certain soils, to the decay of the heart-wood; but very little is known at present, either of the cause of these diseases, or of their prevention or cure. The larch cultivated in Britain is a native of the Tyrol, and of the Alps of Switzerland; but there are some other species or varieties, natives of Siberia and North America, which, however, are considered as scarcely worth culture as forest-trees.

The Scotch pine, Pinus sylvestris, *L.*, is, next to the larch, the most valuable needle-leaved tree grown in Britain. Its timber forms the yellow deal of the Baltic and Norway; and it is unequalled by any species of pine or fir timber contained in any other part of Europe, or North America. The best Scotch-pine timber grown in Britain is produced in the native Highland forests; but there is reason to believe that artificial plantations, on soils and situations as nearly similar as practicable, would produce timber of nearly equal value. It has been the practice for many years past to decry the Scotch pine grown in Britain as a timber-tree; and as we have now no difficulty in importing deal from the north of Europe, this condemnation has been assented to by many without due consideration. If, however, we could import no pine or fir deal from any other country, and were obliged to grow it ourselves, we would ask where is the tree that would produce it in so short a time, and of so good a quality, as the Scotch pine? This tree is readily increased from seeds, which, unfortunately, as is the case with several other trees, are produced in the greatest abundance on stunted trees, or, at all events, on trees not remarkable for their large size, or the durability of their timber. Hence it becomes desirable to select the seeds from the best varieties, and this is now done systematically by the principal Scotch nurserymen. The Highland variety, with horizontal branches, P. sylvestris horizontalis, *Arb. Brit.*, is the variety at present of highest repute. The Scotch pine is a native of the continent of Europe, but not of any part of America.

The spruce fir, Abies excelsa, *Dec.*, is, as a British timber-tree, next in value to the Scotch pine. The young plants and the spray are almost as durable as those of the larch; the trunk grows straighter, more erect and slender, than in that tree, and when used with the bark on, as poles or as fence-wood, it is equally durable. The spruce makes much better hop-poles than the larch; but as the trunk of full-grown trees seldom attains a diameter of above one or two feet at the ground, even in countries where it is a native, the trunk can very seldom be profitably sawn up into boards. The great value of the tree is for poles of every kind, from those fit for the hop, up to the masts for the smaller ships. In most parts of Europe, all the poles used in the scaffolding employed in erecting buildings are formed of this tree. The spruce fir ripens seeds abundantly in Britain, from which plants are as readily raised as in the case of the Scotch pine and the larch. It prefers a soft soil, rather moist, and only attains a great height in sheltered situations; but it will grow to a size fit for hop-poles or fencing in a short time, and anywhere. Like the Scotch pine, it is subject to few diseases. The spruce fir is a native of the north of Germany, Sweden, Russia, and Norway, but not of Britain or of North America. There are three or

four species of spruce natives of the latter country, but they are of no value as timber-trees.

The pinaster, Pinus Pinaster, *Ait.*, is by no means adapted for general culture in Britain, and therefore scarcely merits to be ranked among our needle-leaved timber-trees. In some parts of England, however, particularly in Norfolk, considerable plantations of this tree have been raised; and it is found in deep sandy soil to produce a considerable bulk of timber in a short time. It has also the advantage of thriving better when exposed to the sea-breeze than any other pine or fir. The wood is not so durable as that of the Scotch pine; but it is of the same colour, and may be employed in the joinery of ordinary apartments. In general, however, it is by no means sufficiently strong for the roofing, joists, and other carpentry of dwelling-houses. A great use of the tree in France, and particularly in the neighbourhood of Bordeaux, where it is extensively grown on the sandy wastes, is for the production of resin, tar, and pitch, which are obtained by incisions made in the trunk, and by subjecting the wood to the action of fire. Seeds of this tree are ripened in England; but they may be obtained in any quantity, at a very moderate rate, from Bordeaux. The young plants require more care in transplanting than those of most other pines and firs, being furnished with a stronger tap-root than any of them. The pinaster is a native of the south of Europe and north of Asia, but not of America. It has been introduced, however, into most countries, probably from the large size and handsome appearance of the cones. Accordingly, specimens of this tree have been sent home from China, New Zealand, St Helena, North America, &c.; and the produce of the seeds from these places are commonly, but improperly, treated by nurserymen as varieties.

The silver fir, Picea pectinata, *Arb. Brit.*, in favourable soils and situations produces a great bulk of timber in a comparatively short period; but the timber is much less strong and durable than that of either the spruce fir or the Scotch pine. The tree is of slow growth for the first ten or twelve years of its existence, and the leading shoot is at that age very apt to be injured by spring frosts; nevertheless, even in the north and west of Scotland it has been known to attain to the height of 100 feet in sixty or seventy years. The timber is white, and makes excellent flooring for bed-rooms. The tree ripens seeds in Britain, though more sparingly than the spruce fir, and plants are easily raised. It is in general healthy, though the points of the shoots are occasionally destroyed by frost or by insects. The silver fir is a native of Central Germany, and of the Alps of Italy and Spain; but of no other country. There are other species of Picea, natives of North America and Nepaul; but relatively to Britain they can only be considered as ornamental trees.

Other needle leaved trees might be enumerated as attaining a timber-like size in the climate of England; but there is not one of them that we think can be ranked in value along with those already mentioned as timber-trees. Of the American pines, that of which we have had most experience in this country is the Weymouth pine, Pinus Strobus, *L.*, which furnishes the white pine-wood of American commerce; but this wood, grown in any given situation in Britain, is far inferior to that of the Scotch pine grown in the same locality; and there are only a few situations in England where the Weymouth pine will produce the same bulk of timber as the Scotch pine in the same period. The other American pines, as timber-trees adapted for Britain, scarcely deserve notice. Pinus tæda, serotina, and rigida, have attained a timber size in a few places in England; but the time they have required to do this, even under the most favourable circumstances, precludes the hope of their ever becoming British timber-trees. Several Californian species of pine have recently been introduced; but half a century will be required to enable us to judge of their suitableness for this country. The Californian spruce fir, Abies Douglasii, is the most promising needle-leaved tree that has been introduced from that country; but it remains to be proved whether we shall ever be able to rank it with the common spruce. Of Nepaul pines there are two species, P. excelsa and P. Lambertiana, which resemble the Weymouth pine; and there is a spruce fir, Abies Smithiana, *Arb. Brit.*, A. Morinda, *Hort.*, which promises to be as hardy as the Norway spruce; but the other pines and firs of the Himalayas are all rather tender. The cedar of Lebanon, if planted in masses, like the larch or the Scotch pine, would, in good free soil, produce abundance of timber, but of far inferior strength and durability to what the Scotch pine would produce similarly treated. However ornamental, therefore, this tree may be, it cannot be recommended as fit to be cultivated for its timber. There are some European pines and firs which deserve to be noticed, as possibly containing some trees among them that might be cultivated as timber. Among these are the Corsican pine, Pinus laricio, *Poir.*, including several varieties, among which, as we think, may be reckoned the black pine of Austria, Pinus Austriaca, *Hoss*, as well as the Pyrenean pine, Pinus Pyrenaica, *La Peyrouse*, P. Hispanica, *Cook*. All these species or varieties appear to thrive in the climate of London; and there is a Corsican pine in the arboretum at Kew which is upwards of eighty feet high. Whether the rate of growth, and the strength and durability of the timber, will ultimately prove equal to that of the Scotch pine, appears to us doubtful. We think, however, that in point of bulk of timber, the Corsican pine would equal the Pinaster. The Cembrian pine, P. Cembra, *L.*, of which there are two varieties, one a native of Switzerland and the other of Siberia, grows as rapidly even in Scotland as it does in its native localities; but it is of extremely slow growth everywhere, and not worth cultivating as a timber-tree. Specimens in the climate of London, which have been nearly 100 years planted, have trunks only forty or fifty feet high, and from a foot to eighteen inches in diameter at the ground. The yew-tree, Taxus baccata, *L.*, though it attains its full perfection in this country, being indigenous, yet, from its slow growth, and the little demand for its timber, it cannot be recommended to the planter whose main object is profit. The arbor vitæ, evergreen cypress, deciduous cypress, and juniper, all belong to the needle-leaved division of trees; but none of them are worth cultivation with a view to profit.

Broad-leaved Trees, in contradistinction to needle-leaved, are classed, according to their timber, in two subdivisions, hard-wooded trees, and soft-wooded trees. They are characterized by large trunks and widely-spreading woody branches, and broad leaves with branching veins; they send up shoots from the collar or stool when cut over by the ground; and they are deciduous. They belong to the Dicotyledoneæ of the natural system.

The *hard-wooded Timber-trees of Britain* are characterized by the comparative hardness and durability of their wood, and consist chiefly of the oak, ash, elm, beech, sweet chestnut, walnut, and locust or false acacia.

The British oak may be considered as including two species or subspecies, the stalked fruited, or most common oak, Quercus Robur pedunculata, *Arb. Brit.*, and the stalkless fruited, or less common oak, Quercus Robur sessiliflora, *Arb. Brit.* The latter species or subspecies is found to grow more erect and more rapidly than the other, more particularly if the soil be good and deep. The two sorts are found indiscriminately mixed together in many parts of England, as in Woburn Park, Bedfordshire, and in various parts of Sussex; in other places one species exclusively prevails, as at Tiberton Park, near Hereford, where there

are some of the largest oaks in England, on a deep, loamy soil, and almost all Q. R. sessiliflora. At Welbeck, in Nottinghamshire, on the other hand, there are a great many oaks, almost exclusively Q. R. pedunculata. In all the places mentioned, the trees are the remains of native forests. Though the wood of the oak is the strongest and most durable of that of all British timber-trees, the tree is not always that which the planter would make choice of with a view to profit, on account of the slowness of its growth. It has, however, this advantage, that as it bears a higher price than any other British timber, so it will pay better at a distance from the market; and thus, while oak will pay after conveying it fifty or sixty miles to a seaport, elm will scarcely pay at half that distance, and the soft woods at still less. Oak plantations are also more valuable than others when in a young state, on account of the value of their bark. From the value of oak as ship-timber, the price of trees fit for that purpose is always considerable; though what is paid for the largest trunks employed in naval architecture will not remunerate any one for the number of years they must have stood on the ground. Accordingly we find that the governments both of France and England grow this description of timber exclusively in national forests. The wood of the oak has also the advantage of being applicable to a greater number of uses than that of most other trees. Houses, ships, furniture, and machines, may be formed almost entirely of oak, and consequently there is a ready sale for this kind of timber almost everywhere; hence the oak may be more planted in Britain than any other hard-wooded tree. It is easily raised from acorns, which ought to be collected from the tallest and handsomest trees. The British, or naval oak, as it may perhaps be more properly called, is a native of Britain and most parts of Europe, but not of Asia, Africa, or North America. There are several subordinate varieties, but none worth notice as timber-trees, excepting the kinds which we have noticed.

The ash, Fraxinus excelsior, *L.*, is in most parts of Britain next in value as a timber-tree to the oak. The wood is chiefly used in the manufacture of agricultural implements, such as ploughs, handles to spades, mattocks, handles to carpenters' implements, carts, waggons, threshing-machines, &c. Young ash-trees, and ash poles and suckers, are also much in demand for crate-ware, hoops, whip-handles, walking-sticks, and especially for hop-poles. Before the general introduction of cast iron in machinery, ash-wood was much more in demand than it is at present. The tree requires a good, deep, loamy soil, dry rather than moist; and a situation naturally sheltered, such as the steep banks of glens, rivers, or lakes. As the value of the timber depends chiefly on its toughness and elasticity, the tree is best grown in groves or masses, in consequence of which, where the soil is good, the growth is rapid, and the trunk is drawn up free from large side-branches. The tree is easily propagated from its seeds or keys. It is a native of Central Europe, but of no other part of the world. There are several species of ash natives of North America, and one or two of Europe; but these are of no value in this country, excepting as ornamental trees.

Of the elm there are two species, the English or narrow-leaved elm, Ulmus campestris, *L.*, and the Scotch or broad-leaved elm, Ulmus montana, *L.* Between these two species there are several varieties, or hybrids, such as the Dutch elm and the Huntingdon elm, the latter by far the most valuable timber-tree of the genus. The narrow-leaved elm can hardly be considered as a timber-tree in Scotland, but in the central districts of England its rapid growth, straight trunk, and ample spreading head, constitute it a magnificent tree; and the timber is useful for some important purposes in ship-building, as well as in the construction of machines and agricultural buildings. The Scotch elm is a hardy tree, of rapid growth; but, unless planted in masses, it seldom produces a straight handsome trunk. Its timber is much more durable than that of the English elm, or of any of the hybrids between the species. It was formerly much used in agricultural carpentry, in rural machinery, and in common household furniture. The Scotch elm produces abundance of seeds, which, if sown as soon as they are gathered, often come up the same year; but the English elm and the hybrids produce seeds very sparingly, and are almost always propagated by layers, or by grafting on the Scotch elm. One remarkable difference between the English and Scotch elms it may be useful to notice, viz. that the latter never throws up suckers from its roots; and it is therefore peculiarly valuable as a stock for the English elm, and for those varieties or hybrids between the species which do throw up suckers. There are some other species and varieties of European elms, and several kinds of American elms, but none of them are deserving of culture in Britain as timber-trees.

The beech, Fagus sylvatica, *L.*, acquires a large size, particularly on chalky or sandy soils. It is a very handsome tree in every stage of its growth, but the timber is not remarkable either for strength or durability. It was formerly much used in mill-work and turnery; but its principal use at present is in the manufacture of chairs, bedsteads, and a variety of minor articles. It is a native of England, and of various parts of the continent of Europe. There are some varieties, particularly the purple beech; and there are one or two species natives of North America, but none of them deserve notice as timber-trees. It is propagated by its mast, which it produces plentifully in fine seasons.

The hornbeam, Carpinus Betulus, *L.*, is an indigenous tree, which attains the same height, but not the same diameter of trunk, as the beech, to which it bears a general resemblance, but is in every respect greatly inferior. It is propagated by its nuts, which it produces in abundance. This tree and the beech were formerly highly valued for making lofty hedges, on account of their retaining their leaves great part of the winter.

The sweet chestnut, Castanea vesca, *Gærtn.*, is generally ranked next to the beech as a timber-tree; but in that character it has little or no merit. The tree is magnificent in appearance, rivalling, when full grown, the British oak; but it differs essentially from that tree in its timber not increasing in value as it increases in age. In Britain, and also in France, it was formerly believed that the roofs of the oldest cathedrals, and of Westminster Hall and other buildings, were of chestnut; and it was thought, in consequence, that the tree had formerly been more abundant, both in Britain and on the Continent, than it is at present. Subsequent inquiry, however, proves all this to be a mistake; and Daubenton and various others have shown that the timber called chestnut in old buildings is referable to the chestnut oak, Quercus Robur sessiliflora, *Arb. Brit.* It is worthy of remark, that some of the ancient writers describe a grove of chestnuts as extending northwards from London, and abounding in wild beasts; and that the remains of the indigenous woods at Hampstead, in the Earl of Mansfield's grounds, are of the chestnut oak. The timber of the sweet chestnut, when not more than of forty or fifty years' growth, forms very durable posts for fences and gates; being, according to some, more durable in this capacity than oak itself; but whenever the trunk of the tree becomes of larger dimensions than six or eight inches in diameter, the timber is found to be shaky; and at eighteen inches or two feet in diameter it has already begun to decay at the heart. In a young state, when the stems are not above two inches in diameter at the ground, the chestnut is found to make durable hoops for casks and props for vines; and of a larger size it makes good hop-poles, though the stem tapers rather too much for that purpose. It is a native of Asia, the north of Africa, and of North America; and some think it a na-

tive of Britain. In the south of England, in fine seasons, it ripens abundance of fruit, from which plants are easily raised. There are a number of varieties, both in Britain and on the Continent, which are highly valued for the qualities of their fruit; but none of these, nor any of the American kinds, are worthy of being cultivated for their timber.

The common sycamore, Acer Pseudo-Platanus, *L.*, is a tree of the second rank, seldom attaining the height of any of those that have been hitherto mentioned. It has, however, the merit of withstanding the sea and mountain breezes better than most other timber-trees; and its wood is valued in turnery, and for a variety of minor purposes. It produces abundance of seeds, which, like those of the ash, are called keys, and it is easily raised in the nursery; but it does little good in plantations, unless the soil be good and tolerably dry. It will neither thrive on very stiff clays, nor on dry sands or chalks. There are several species of Acer, natives of Europe and North America; and that which comes nearest to A. Pseudo-Platanus, as a timber-tree, appears to be the A. obtusatum, *Arb. Brit.*, a native of Hungary and Calabria, but it has not yet been tried in plantations made with a view to profit. The Norway maple, A. platanöides, *L.*, is a hardy and very interesting tree; but neither it, nor any of the other species, either from America or Europe, seem to deserve cultivation for their timber. If we made any exception, it would be in favour of the common field-maple, Acer campestre, *L.*, which forms a very curious wood for the cabinet-maker.

The common birch, Betula alba, *L.*, is another tree of the second rank, which is worthy of culture in inferior soils and situations, more especially as coppice-wood. The spray, in some parts of the country, is sold to the besom-maker, and makes a valuable return. The tree seeds freely, and is in every stage of its progress easy of management. There are several species of birch, natives of North America, which attain the size of timber-trees, and all of them have been introduced into this country, and tried in British plantations; but there is not one of them which can be considered otherwise than as an ornamental object, or as one of botanical interest.

The false acacia, or locust, Robinia Pseud-Acacia, *L.*, may be placed amongst the timber-trees of the second rank. It is of unquestionable beauty, and much has been said of the value of its timber. When of a certain age, this is of great hardness and durability, and it lasts a long time as posts, or as trenails or wooden pins, for bolting together ships' timbers. For the latter purpose, however, iron and copper are now generally used, both in Europe and America. The false acacia has been much recommended by Cobbett and a host of other writers for hop-poles and props for vines; but though it has been extensively tried in England for the former purpose, it is now utterly neglected, being found rarely to grow straight and clean, and, when used, being much less durable than the ash.

Amongst hard-wooded trees of the third rank, the timber of which is of some use, are the mountain ash, Sorbus domestica, *L.*; the white beam-tree, Sorbus Aria, *L.*; the wild apple, wild pear, wild cherry, and wild plum, the hawthorn, the holly, the laburnum, and perhaps one or two others. We could hardly recommend a plantation to be made solely of any of these trees; but when a few are introduced by way of variety or ornament, it is useful to know that their timber is of some value. The laburnum, the holly, the yew (which last we have included under the needle-leaved trees), are by far the most valuable of the trees of the third rank. The heart-timber of the laburnum is almost as dark and hard as that of ebony, and that of the holly is of a beautiful white. The timber of the yew is veined, and its beauty may be increased by judicious staining. The roots of the thorn, the yew, and of most of the third-rate trees, are often beautifully veined, and employed in cabinet-making and veneering.

Soft-wooded Trees are distinguished by the comparative rapidity of their growth, and the softness of their wood, its whiteness, and its limited duration. The principal of these worth cultivating in Britain as timber-trees, are the poplar, the willow, the alder, the lime, and the horse-chestnut.

The poplar, Populus, *L.* There are several species of this tree, which well deserve culture with a view to their timber, where the soil is good and deep, and where the roots can reach water without being saturated by it. The white and gray poplars, Populus alba, *L.*, and P. canescens, *L.*, are hardy, of very rapid growth, attaining a height of thirty or forty feet in most parts of Britain in ten or twelve years, and producing a beautiful, smooth, compact, white timber, well adapted for flooring bed-rooms, and for a great many minor purposes, either in its native colour, or stained black in imitation of ebony. The black Italian poplar, P. monilifera, *Dec.*, is an equally rapid-growing tree with the white poplar, and produces a beautiful pale-yellow timber. The common black poplar, P. nigra, does not grow so rapidly as the last, and seldom produces a straight trunk; but its timber is homogeneous, of a yellowish white, and takes a fine dye. The aspen, or trembling poplar, P. tremula; and the Athenian poplar, P. Græca, are of slower growth than the white or black poplars, and they have a beautiful, smooth, homogeneous, white wood. There are a number of other species of poplar, chiefly natives of America, and the Lombardy poplar, which is a native of Persia; but none of these are worthy of being planted as timber-trees in the climate of Britain.

The white willow, Salix alba, *L.*, is a rapid-growing tree, and produces a great bulk of timber in a short period. The wood is white, soft, and sometimes slightly veined with blue. When kept dry, and well ventilated, it will last a long time, and has been found in buildings which have existed upwards of a hundred years, in a perfectly sound state. The Bedford willow, Salix Russelliana, *L.*, grows with about the same rapidity as the white or Huntingdon willow, and its timber is of the same quality. The crack-willow, Salix fragilis, *L.*, is a tree of a smaller size, but its timber is useful for a variety of purposes; and the bark of this, and of most of the other species, may be used in tanning. There are a great many species and varieties of willow natives of Europe, or of North America and Asia; but, excepting the three above mentioned, we do not consider any of them as worth cultivating for timber.

The alder, Betula Alnus, *L.*; Alnus glutinosa, *Dec.*, is an indigenous tree, of smaller size and much lower growth than the poplars, or tree-willows; but its timber is more valuable from being more compact, less liable to twist, and having a fine mahogany tinge. The tree is a native of Britain, and of most parts of Europe, on moist soils by rivers; and it is readily propagated by seeds. There are some other European species; and two, Alnus incana, and Alnus cordifolia (the latter lately introduced from Naples), may probably prove useful as timber-trees, as they both grow on dry soils; but, from the experience which has yet been had respecting them, they can only at present be recommended as ornamental.

The lime-tree, Tilia Europæa, *L.*, is a well-known soft-wooded tree, of some value for its timber, which is used by musical-instrument makers and carvers. It is a native of Europe, and is generally propagated by layers. The blossoms produce the whitest and most delicate honey in the world. There are some American lime-trees, but they scarcely attain the size of timber-trees in England.

The horse-chestnut, Æsculus Hippocastanum, *L.*, is a rapid-growing tree in good soil; but its timber is perhaps the least valuable of the class to which it belongs, as it has

little strength, and, unless kept dry, is far from being durable; but it is useful for some husbandry purposes, such as linings to carts, wheel-barrows, &c.; and it takes a ready dye as a substitute for ebony.

The only soft-wooded trees that can be recommended for culture with a view to profit, are the white, gray, black Italian, and common black poplars, and the white and Bedford willows.

Hedge-trees and Shrubs.—Plants which are useful for forming hedges are of as great importance to the planter as those which are valuable for their timber. Almost all trees planted in rows, with the free admission of air and light on every side, will become clothed with branches from the ground upwards; and if these are occasionally cut in, they will form gigantic hedges, more or less compact; but some trees are much better adapted for this purpose than others; and among those of the first class, the best are the beech, the hornbeam, the elm, the lime, the Lombardy poplar, and the spruce fir. The best of the second class are perhaps the common birch, Sir Charles Wager's maple (Acer eriocarpum), and the evergreen oak; and the best of the third class are the common thorn, the crab, the sloe, the wild plum, the buckthorn, the barberry, the holly, and the yew. By far the best of these for British field-hedges is the common hawthorn, and the next best is the wild crab. The sloe or black thorn makes an excellent hedge; but it throws up so many suckers, that it requires constant attention to keep it within bounds. It forms, however, an excellent barrier for picturesque plantations, where it is allowed to spread itself in every direction. The holly, were it not for the slowness of its growth, would form the best of all hedges, both for gardens and fields, as its leaves are little liable to be injured by insects; and, being an evergreen, it neither harbours weeds nor vermin at its roots. Birds are also much less apt to build in it than they are in deciduous hedges. It has only two disadvantages that we are aware of, viz. the slowness of its growth, and its imperviousness to wind in the winter season. On this last account, when on damp clayey soil, it has a tendency to prevent the drying of arable lands in spring. Were holly hedges occasionally introduced among those of the common thorn, they would add very greatly to the beauty of the country in the winter season; and, on dry uplands, they would form excellent shelter for stock. The common furze sown on the top of a high bank forms an effective hedge in a short period, but it is of no great duration. On moist soils fences may be made for planting rows of willows or poplars, and in situations exposed to the sea-breeze the elder may be planted; but such fences can be hardly considered as hedges, from their want of compactness and density of foliage.

Trees and Shrubs suitable for Coppice-wood and Undergrowth.—One property required for all these plants is, that they should stole or spring up from the collar or stool when they are cut over; and the true undergrowths are only to be found among such shrubs as will grow under the shade of trees. There are a great many woody plants which may be cultivated as coppice-wood; indeed there are few of the broad-leaved trees and shrubs which will not answer for this purpose, but the locality must determine the preference. In soft, wet soils, the birch, the alder, and the apple-leaved willow, are amongst the most common and useful trees. In drier soils, the ash forms a most valuable coppice-wood, supplying handles for agricultural implements, stuff for hurdles, hoops, wattles, and a great many other useful articles. In good, deep, loamy soil, the oak forms an excellent underwood; and if the situation be at a distance from a market, it is by far the most valuable that can be employed, as the bark alone will produce a sufficient profit, and, from its portable nature, it can be sent to a greater distance than timber.

Ornamental Trees and Shrubs include by far the greater number of woody plants in cultivation; though many, perhaps the whole of them, produce wood which, when it can be obtained of sufficient size, may be applied to some useful purpose. As already observed, we exclude altogether from consideration in this article, flowering and fruit-bearing trees and shrubs. We also exclude all those that are rather delicate, or require particular kinds of soil; and shall confine ourselves to trees and shrubs which are considered ornamental from their general form, and which may be introduced into the margins of ordinary plantations in most parts of Britain. We shall arrange these under the heads of evergreen and deciduous.

Evergreen ornamental Trees and Shrubs.—The most ornamental of these, and one which will thrive in every part of Great Britain, is undoubtedly the cedar of Lebanon. It is somewhat delicate when young; but, if brought forward in pots, placed where it is finally to remain when of the height of eighteen inches or two feet, and carefully planted, and protected from cattle and vermin, it soon makes a vigorous growth, and becomes a handsome tree, even in the Highlands of Scotland. The seeds of the cedar of Lebanon, when left in the cones, retain their vitality for a number of years; the cones are sometimes imported from the Levant, but more generally obtained from English trees. Where proper care can be bestowed on the seeds and the soil, it would be an improvement to sow them where they are finally to remain; because the cedar, and all the pine and fir tribe, depending principally on their surface-roots, suffer more from confinement in a pot, or transplanting from the open nursery, than trees having powerful tap-roots. The Deodar cedar differs in general aspect from the cedar of Lebanon, in having foliage of a whitish or glaucous hue. It appears to be as hardy as the other, and will probably soon become as common. Cones are imported from the Himalaya Mountains, where the tree is indigenous; or it may be grafted on the common cedar, or raised from cuttings. All the pine and fir tribe may be described as highly ornamental, and a great many of them will endure the open air in the coldest parts of Britain. The Weymouth pine, Pinus Strobus, is a very hardy ornamental tree; and still more so is the Pinus Cembra, which is of slow and erect growth, and retains the beauty of youth longer than any other pine. The Pinus excelsa is a very hardy and very ornamental species, but it is at present rare. Pinus Banksiana, and P. inops, are curious and very ornamental species. Some of the Californian pines, particularly P. ponderosa and P. Sabiniana, appear to be quite hardy. Among the ornamental spruce firs may be mentioned Abies Smithiana (A. Morinda, *Hort.*), a native of the Himalayas, which closely resembles the common spruce, and is apparently as hardy; it is readily propagated by cuttings, and by herbaceous grafting on the common spruce; and the trees already planted will probably very soon produce cones. The largest tree of this species in Britain is probably that at Hopetoun House, near Edinburgh. The Douglas fir, Abies Douglasii, is a very handsome tree, apparently as hardy as the common spruce, but differing in the dark-green colour and somewhat two-rowed disposition of its leaves, from which it appears intermediate between the common spruce and the silver fir. It has already attained the height of eighteen or twenty feet in different parts of Britain, and has produced cones. The Cephalonian fir, Abies Cephalonica, *Arb. Brit*, is a very handsome tree of the same kind, and of recent introduction; and which, having withstood the winter of 1837–38, is probably hardy enough to become an ornamental British tree. It is very readily propagated by cuttings, and cones might doubtless be imported from Cephalonia. The black and white spruces of North America are well known ornaments in our shrubberies; and there are some Californian species, such as Abies

Menziesii, which will probably soon be added to their number. The hemlock spruce (Abies Canadensis, *Mich.*) is one of the most ornamental of fir-trees; it is very hardy, and ripens seeds in different parts of England. One of the finest specimens is at Strathfieldsaye, in Hampshire, the seat of the Duke of Wellington. Among the ornamental silver firs, the first in point of grandeur is the Picea Webbiana, *Arb. Brit.*; but, even in the climate of London, it suffers so much from the spring frosts, that it is doubtful whether it will ever become a very ornamental tree in England. Nevertheless, though the severe winter of 1837–38 seriously injured this tree, it did not kill it; and probably, as it increases in age, it may be later in protruding its young shoots, and thus be more likely to escape the spring frosts. Even the silver fir, which attains the height of 100 feet and upwards in many parts of Britain, is yet frequently injured by frosts during the first twenty years of its growth. Picea pichta Fraseri, and some other species and varieties, natives of Siberia or North America, are as hardy as the balm of Gilead fir, Picea balsama, *Arb. Brit.* The Chili pine, Araucaria imbricata, is a noble tree in its native country, and appears to be much hardier in the climate of Britain than has generally been imagined. Young plants which have been two or three years established in the open ground passed the severe winter of 1837–38 without any injury, which renders it not improbable that it may ultimately prove as hardy as the common cedar. The evergreen oak, Quercus Ilex, *L.*, is a hardy evergreen tree, of which there are several varieties. It is readily propagated from its acorns, which are ripened in abundance in this country, or may be imported from the Continent. It will thrive in any deep dry soil, and forms excellent hedges, or shelter to a dwelling-house. The cork-tree, Quercus Suber, *L.*, is of a corresponding character, but rather more tender. The holly, the common yew, the Irish yew, and the box-tree, are evergreens universally known and admired. They are perfectly hardy in every part of Britain, and deserve a place in every plantation.

The Portugal laurel and the common laurel form very ornamental trees, or large shrubs; and, from their glossy foliage, they are particularly beautiful in winter. The alaternus and the phillyrea form large bodies very ornamental. The arbor vitæ, of which there are two species, is very hardy, and forms a permanent fastigiate low tree. The red cedar, Juniperus Virginiana, *L.*, the Phœnician juniper, and some other species of juniper, are at once hardy and ornamental. The cedar of Goa, Cupressus lusitanica, *L.*, is a beautiful evergreen, with glaucous foliage, but somewhat tender; nevertheless, in Ireland it has attained a great size. The common cypress, Cupressus semper virens, *L.*, grows vigorously in the central districts of England, but scarcely thrives in the northern counties. The Arbutus is one of the handsomest of evergreens, and is admired for its flowers and fruit, no less than for its foliage and general form. There are several varieties and species which endure the open air in the climate of London, but which are found rather tender farther north. The sweet bay, Laurus nobilis, *L.*, forms a bushy low tree in the climate of London, and in the south of England has attained the height of sixty feet; but it suffered much from the severe winter of 1837–38, and may be considered, on the whole, as rather tender.

Sub-evergreens are trees which retain their leaves through the winter in a green state, and drop them late in spring, immediately before the development of the new leaves. The principal British trees of this description are certain varieties of the Turkey oak, and more especially the Fulham oak, and the Lucombe oak. These are trees of the first rank, and in the central districts of England become magnificent objects. Turner's oak, Quercus Turneri, is also sub-evergreen, and forms a handsome tree of the second size. Quercus virens, the live oak of America, forms a sub-evergreen tree in the climate of London, but farther north it is to be feared that it will be found rather tender.

The common privet, especially when cultivated in good soil, becomes a sub-evergreen bush, and, when trimmed to a single stem, a handsome small tree; and to it might be added some others, such as Cratægus Mexicana, Photinia serrulata, Berberis aristata, Aristotelia Macqui, and Cotone aster frigida, affinis, acuminata, and nummularia, all of which are quite hardy in the climate of London, and also in Ireland, but rather tender in the north of England, and in some parts of Scotland.

Deciduous ornamental Trees and Shrubs.—We shall notice the hardiest of these in the order in which they occur in the natural system. Magnolia acuminata is perhaps the only species of Magnolia that can be considered truly hardy in most parts of Britain; and, from its large leaves, and curious greenish-blue flowers which afterwards change to yellow, it well deserves a place either on the lawn, or in the margin of plantations. M. cordata, tripetala, and conspicua, are quite hardy in moderate climates; but M. conspicua flowers so early that it is apt to be injured by spring frosts. The tulip tree, Liriodendron Tulipifera, *L.*, forms a tree of the first rank in the climate of London, and attains a considerable size in the milder parts of Scotland; for the beauty of its foliage, independently altogether of its flowers, it deserves a place in every collection. The Hungarian or white-leaved lime-tree, Tilia Europæa alba, *Arb. Brit.*, is a tree of the second rank, of very great beauty, and nearly as hardy as the common lime-tree. From the effect of its mass of white foliage among the green leaves of other trees, it becomes useful for breaking formal lines, directing attention to particular objects, or harmonizing white buildings with verdant scenery. The red-wooded and yellow-wooded lime-trees are very ornamental, and also the cut-leaved variety. The American limes are sufficiently hardy to attain the size of trees in the climate of London, and, from their leaves being much larger than those of the European limes, they are very ornamental. The maple, Acer, *L.*, is a genus which contains some of the finest ornamental trees that occur in British plantations. They are all valuable for coming early into leaf and early into flower, as well as for the many angled forms of their leaves, and the beauty of their buds. The variegated leaved varieties of the common sycamore form very ornamental objects, but, like all variegated leaved trees, their greatest beauty is in spring, when the leaves first expand. The variety with white striped leaves is well known, and is very generally planted; but the yellow-leaved variety, or Corstorphine plane, though by far the most beautiful, is scarcely known, except in the neighbourhood of the original tree. The purple-leaved variety is a very striking one, having the under surface of the leaves, more especially when they first come out in spring, of a dark purple. The hairy fruited, or Sir Charles Wager's maple, Acer eriocarpum, is a very elegantly shaped tree, with beautifully cut leaves, and conspicuous reddish flowers, which appear in February; it ought never to be omitted in plantations having the slightest pretensions to ornament. The red flowering or scarlet maple, A. rubrum, resembles the last tree in foliage; but its flowers are of a much darker red, and the tree is of less vigorous growth. In autumn the leaves die off of an intensely deep red, insomuch that the tree attracts attention even at the distance of a mile or two. Where it thrives, it may certainly be considered as the most ornamental of all the maples. A. Tataricum and spicatum are low trees, the first a native of Tartary, and the last of North America; they are remarkably hardy, come early into flower, and their keys and leaves die off of a fine yellow or red. The snake-barked maple, A. striatum, is a beautiful tree, whether

we regard its leaves or its bark; it is a native of Pennsylvania, and therefore quite hardy in Britain. A. macrophyllum, the large-leaved maple, is a remarkably fine tree, with leaves sometimes nearly a foot in diameter; it appears to be as hardy as the common or the Norway maple, and its growth when young is very rapid; though, having been only lately introduced from North America, it is as yet scarcely known in Europe. The Norway maple, A. platanöides, is so hardy that it might almost be considered as a timber-tree; but being inferior in this respect to the common maple, it, and its different varieties, are more generally to be ranked as ornamental. The sugar maple, A. saccharinum, in Britain, is one of the most tender North American maples; it bears a close resemblance to the Norway maple, and, like it, its foliage dies off of a very rich yellow. A. obtusatum, a native of Hungary and of Calabria, is a remarkably fine vigorous-growing tree, bearing a considerable resemblance to the sycamore, Acer Pseudo-Platanus. A. Opalus is a very handsome small tree, with round, coriaceous leaves, finely cut at the edges; this tree is little known and seldom planted, though few objects are better adapted for a small lawn. The round plaited-leaved maple, A. circinatum, is a rare species from North America; but one of great beauty of foliage, and apparently quite hardy. A. Monspessulanum is a small tree of great beauty, and in some situations sub-evergreen. The common or field maple, A. campestre, is one of the hardiest and most beautiful of small British trees: the most ornamental tree of this species is the Austrian variety, A. campestre Austriacum, *Arb. Brit.*, which forms a beautiful single object on a lawn, and also very good garden hedges. The Negundo, or box-elder, Negundo fraxinifolium, *Dec.*, a native of North America, is a beautiful tree, with its leaves cut in the manner of those of the ash, and a fine, smooth, dark-green bark. The foliage, when it first appears, is of a fine yellow, and when mature it is of a pale green. It is a desirable object, as a single tree, or in the margin of plantations. The different species or varieties of the horse-chestnut are all trees remarkable for the beauty of their foliage, but more especially for that of their flowers. The common species is known to every one, but the scarlet and red flowered varieties, and the yellow and pale flowered kinds, all comparatively of recent introduction, only require to be seen to be ardently desired by all lovers of trees. The pavias, or smooth-fruited horse-chestnuts, are much smaller trees than the rough-fruited kinds, and they are all extremely beautiful. P. rubra, flava, discolor, hybrida, neglecta, macrocarpa, and macrostachya, deserve to be in every collection. Kœlreuteria paniculata, a native of China, is a hardy tree, very ornamental from its foliage as well as its flowers. There are fine specimens both in England and Ireland, yet the tree is not generally met with in pleasure-grounds. The toothache-tree, Xanthoxylum fraxineum, is a small tree or large shrub, a native of North America, hardy and ornamental both from its foliage and flowers. The same may be said of the shrubby trefoil, Ptelea trifoliata. The ailanto, Ailantus glandulosa, is a native of China, but perfectly hardy in most parts of England. It forms a stately tree of the first rank, with a straight trunk, ample head, and magnificent foliage, the leaves, which are compound, being sometimes three feet in length. In some parts of France it is planted as a timber-tree, and is found to thrive particularly well on chalky soils. The bladder-nut tree, Staphylea, *L.*, is a hardy bush, which may be trained to a very handsome low tree, ornamental from its foliage, its white flowers, and its curious bladder-like capsules. There are two species, S. trifoliata and S. pinnata, both deserving a place in the shrubbery. The spindle-tree, Enonymus, *L.*, is a genus of which there are several species, quite hardy, and singularly ornamental when in fruit. The common spindle-tree, E. Europæus, and the broad-leaved spindle-tree, E. latifolius, are the handsomest hardy species of the genus, and, when trained up to single trees on a deep loamy soil, with ample space, they form in autumn, when their capsules are ripe, objects altogether unique in the arboricultural world. Though these species are commonly seen as shrubs drawn up among others, or growing in hedges, and forming bushes perhaps not more than six or eight feet in height, yet, when properly treated, they will form trees thirty feet high, as may be seen in some of the London gardens, and even as far north as Forfarshire, where the spindle-tree produces a timber much sought after by coopers. The different varieties of the common holly are so well known for the beauty of their foliage, that the reader only requires to be reminded of them. The Minorca holly, Ilex balearica, and the opake-leaved holly, I. opaca, are very handsome kinds, which ought not to be forgotten. The winter-berry, Prinos, is a deciduous shrub, a native of North America, which, like the holly, produces fine scarlet berries, and retains them through the winter. There are several species, all quite hardy, and one or more of them deserve a place in every collection. Christ's thorn, Paliurus aculeatus, is a native of Asia, and is used as a hedge-plant in the north of Italy. It is altogether a most elegant bush or tree, there being something quite unique in its branches, bark, and thorns, which are very numerous; and in its leaves, flowers, and seeds. The buckthorn, Rhamnus, is a hardy genus of shrubs or low trees, of which there are many species; but we shall confine ourselves to those which are decidedly hardy. Rhamnus Alaternus is a well-known evergreen, of which there are varieties having broad and narrow leaves, and leaves blotched or variegated with yellow, and also with white. R. hybridus, a native of France, is a sub-evergreen, resembling the alaternus. R. catharticus, the purging buckthorn of Britain, and the white thorn of the modern Greeks, forms a very hardy and handsome small tree. R. alnifolius, alpinus, and frangula, are also very handsome small trees; and there are several other species which, if they can be procured, well deserve a place in the shrubbery. R. latifolius, a native of the Azores, is a very handsome kind, and quite hardy both in the gardens of London and Edinburgh. The different species of rhus are very hardy and very ornamental. R. Cotinus is a particularly interesting object when its seeds are ripe. R. typhina, viridiflora, and glabra, are curious from the stag's-horn appearance of the ends of the branches; and their leaves, before they drop, assume a fine yellow, rich scarlet, or dark-red hue. Sophora Japonica forms a splendid tree in the climate of London, and there is a pendulous-branched variety which is very ornamental. One property of this tree is, that in dry and warm seasons, when the leaves of most other trees become of a paler green than usual, those of this tree assume a darker hue. Virgilia lutea is a North American tree, with fine large foliage, hardy in most parts of Britain; and, in America, valued for the yellow colour of its wood. The laburnum has already been mentioned both as a useful and an ornamental tree. The purple laburnum is a hybrid between the Scotch laburnum and the Cytisus purpureus, of vigorous growth, but more curious than beautiful. Robinia viscosa is a variety of the false acacia, or locust-tree, with a glutinous bark, and flowers slightly tinged with pink. It is a beautiful object, both in foliage and when in blossom, and is as hardy as the common robinia or locust. There are a number of other varieties of Robinia pseud-acacia, and in particular the parasol-acacia, all of which are very ornamental. The rose-acacia, Robinia hispida, of which there are several varieties, is highly prized for its rose-coloured flowers. The Siberian pea-tree, Caragana arborescens, and a number of other varieties or species of Caragana, are all very ornamental, and quite hardy; and the same may be said of the salt-

tree, Halimodendron, and of the different species of Colutea, or bladder-senna. The three-thorned Gleditschia, or honey-locust, Gleditschia, *L.*, is a genus of which there are seven species in cultivation in British nurseries, besides varieties. Some of the Gleditschias attain the size of trees of the first rank, and others are middle-sized or small trees; but they are all deserving of culture, on account of the beauty of their foliage, and their very remarkable spines. The Kentucky coffee-tree, Gymnocladus Canadensis, is a curious-looking object in winter; but in summer it is clothed with a magnificent foliage. It is a native of Canada, easily propagated by cuttings of the roots, and consequently hardy enough for any part of Great Britain; though, strange as it may appear, it is far from being common in collections. The Judas trees, Cercis Siliquastrum and Canadensis, are very handsome small trees, both when in leaf and in flower; the flowers have an agreeable acid, and they are used in Paris in salads, and fried in batter for fritters. The almond, the peach, the apricot, the plum, and the cherry, in their single or comparatively wild state, and also the varieties of these species having double flowers, are fine ornamental objects in plantations or on lawns, and are quite hardy. Cerasus semperflorens and serrulata, the Allsaint, and Chinese double-blossomed cherries, are very desirable ornamental trees. The perfumed cherry, Cerasus mahaleb, is a most valuable tree, coming early into flower, diffusing its odour in every direction, and soon afterwards becoming covered with berries, which are generally of a glossy black, but in some varieties yellow. The bird-cherry, Cerasus padus, is a native of the woods both of Scotland and Sweden, and one of the most ornamental of low trees when in flower. Its beautiful spikes of white blossoms are succeeded by black or red fruit, which is very ornamental while it remains on the tree, but when ripe is soon devoured by birds, by whom it is greedily sought after. The Cornwall bird-cherry, Cerasus padus rubra, and the pendulous branched bird-cherry, Cerasus padus bracteosa, are interesting varieties. C. Virginiana, serotina, and capollin, are species of bird-cherry resembling one another, surpassing the European bird-cherry in the smoothness and glossiness of their foliage, and equaling it in the beauty and profusion of their flowers. C. Virginiana is so hardy, and produces fruit in such abundance, that in some parts of England it may be considered as naturalized, having come up in the native copses from seeds carried thither by the birds from artificial plantations. There are about twenty other species of Cerasus, all quite hardy; and though some of them are of very humble growth, and adapted for planting on the faces of rocks, rather than amongst other shrubs, yet they are all deserving of culture.

The genus Cratægus consists of twenty-eight species, and about double that number of varieties, each of which forms a beautiful small tree. There is not perhaps any other genus of hardy ligneous plants in which so many beautiful small trees are to be found. They are all remarkable for having an irregular, picturesque character of outline, and for assuming this character at the growth of even five or six years. They all come into flower at an early age, produce flowers profusely, and all ripen abundance of fruit. The flowers are, for the most part, white and fragrant, but in some varieties they are tinged with red and purple; and in one, the scarlet hawthorn, C. oxyacantha rosea, they are of a fine rose colour. The flowers appear at various periods from March till the middle of July; and one variety, the Glastonbury thorn, often comes into bloom at Christmas. The earliest flowering species are Cratægus purpurea and nigra, and the latest C. cordifolia and Virginica. The colour of the fruit is for the most part red, as in the common hawthorn; but in some it is yellow, as in C. Aronia; black, as in C. nigra; or greenish-yellow, as in C. Mexicana. In C. coccinea the fruit is large, and of a scarlet colour. In C. Douglasii it is of rich glossy purple-black; and in C. orientalis sanguinea, *Arb. Brit.*, it is of an intensely deep port-wine colour. Of the common hawthorn of our hedges, C. oxyacantha, *L.*, there are no fewer than thirty recognised varieties, each of which would form a very beautiful and distinct tree. One of the varieties has the fruit white, another has double white flowers, another, C. oxyacantha phœnicea flore pleno, double red, another a fine single pink. One has black fruit, another yellow, and a third white. In one the entire tree takes the upright narrow form of a cypress, and in another the branches are pendulous, like those of the weeping willow; one has leaves like those of the oak, another leaves like those of the fern, and so on. All the species of Cratægus may be readily propagated by grafting them on the common thorn, by which means, when stocks standard high are used, they become trees fit for planting out where they are finally to remain, at the end of the third season. The species may be propagated either by grafting, by seeds, or by cuttings of the roots. Much ornament might be conferred on the country, and especially on the roads which pass through a hedged estate, if the proprietor were to allow some thorns in his hedgerows to grow to the average height of two or three feet above the top of the hedge, and at that height to bud, or graft these with some of the more tree-growing of the ornamental species. Cotoneaster frigida, affinis, acuminata, and nummularia, are Nepaul small trees of very great beauty, both on account of their foliage and their fruit; so much so, that though we have already mentioned them under the head of sub-evergreens, we have here repeated their names. Amelanchier vulgaris, Botryapium, sanguinea, ovalis, and florida, are very beautiful low trees, which bear a profusion of white flowers early in spring, and are succeeded by brown or black berries, which, though commonly left to the birds, are not disagreeable to eat. The common medlar, and Smith's medlar, Mespilus Smithii, *Dec.*, M. grandiflora, *Hort.*, are ornamental trees: the former is valued also for its fruit, and the latter for the profusion of white blossoms with which it is covered in April. There are a great many very ornamental species and varieties of the genus Pyrus, which is now so far extended as to include species formerly considered as belonging to Sorbus, Cratægus, Mespilus, &c. P. nivalis, sinaica, salicifolia, elæagnifolia, and amygdaliformis, may be considered as white woolly-leaved varieties of the common wild pear, and P. sinensis as a distinct variety of the common cultivated pear. P Bollwylliana appears to be a hybrid between the apple or crab, and Pyrus Aria. P. variolosa, a native of Nepaul, is a remarkable tree, with leaves sometimes like those of the common cultivated pear, and at other times cut, like those of Pyrus spuria sambucifolia. Pyrus prunifolia, baccata, and Astracanica, are crab-apples with handsome blossoms and small beautiful fruit; and there are a number of sub-varieties, which may be obtained in the nurseries. Among these, the white astracan or transparent crab of Moscow, the supreme crab, and Biggs's everlasting crab, deserve the preference. P. coronaria, and P. angustifolia, are American wild apples, with sweet-scented flowers. P. spectabilis, a native of China, but quite hardy, is remarkable for its showy pink and white blossoms, which are produced in great profusion. P. Aria, the white-beam tree, and all its varieties, deserve culture, as compact, low, or small trees; P. vestita, a native of Nepaul, is remarkable for its large woolly foliage, which dies off of a fine yellow. P. torminalis, though indigenous, is a most ornamental tree. Pyrus Sorbus, and all its different varieties, are very ornamental. Pyrus spuria, a native of Kamtschatka, forms a very beautiful little tree, with a profusion of white flowers and black fruit; and Pyrus arbutifolia, Mespilus arbutifolia, *L.* with its varieties, melanocarpa, floribunda, and depressa, are beautiful low shrubs, and, when grafted standard high on the common thorn, form very ornamental objects, whether in blossom, when covered with their fine dark fruit, or when

their leaves are dying off, and have become of an intensely dark red, shaded with yellow and purple.

The common and Chinese quinces form handsome low trees; the former more particularly so when in flower and fruit, and the latter when in full leaf. The Japan quince, Cydonia Japonica (Pyrus Japonica, *L.*), is well known as one of the most ornamental spring-flowering shrubs in cultivation. Hamamelis Virginica, the Wych hazel, is valuable from its beginning to flower in November, and retaining its blossoms till February or March: though rarely seen in collections, it is very hardy, and forms a very handsome small tree. The different species of dogwood are ornamental, and, with the exception of C. florida, quite hardy. C. alba sibirica has the shoots of a fine scarlet colour, and is singularly ornamental in the winter season. The common elder, Sambucus nigra, will thrive, and form a handsome low tree, in a variety of situations, where many other trees and shrubs will scarcely grow: on a mountain side, and in the coal-smoke of cities or factories. There is a very handsome variety with cut leaves, one with white fruit, and another with green fruit. S. racemosa is a native of Spain, which grows vigorously in this country. The leaves are finely cut; and the fruit, with which it is generally profusely covered, is of the most brilliant scarlet: being very little known among gardeners, it is scarcely ever seen in collections. The different species of Viburnum are hardy, and all more or less ornamental, both when in flower and in fruit. The leaves also die off of a fine yellow-red, sometimes tinged with purple. V. Lentago, pyrifolium, prunifolium, and nudum, when trained to a single stem, form compact-growing, neat, little trees. The common wayfaring tree, V. Lantana, and the American wayfaring tree, V. lantanoides, form very neat bushes. V. Opulus is well known as the Guelder rose; and the American variety, V. O. oxycoccos, has fruit as large as the cranberry, which is used in America for the same purpose; as is the fruit of V. O. edule, another American variety. The fly-honeysuckle, Lonicera xylosteum, and the Alpine upright honeysuckle, Lonicera alpigena, are the only two species which are sufficiently woody and large to be noticed in this selection; the other species belong to flowering shrubs. The snow-drop tree, Halesia tetraptera, is one of the hardiest of North American trees, and, when in flower, one of the most beautiful: it ripens abundance of seeds in this country, by which it is readily propagated; so much so, that in some parts of England it is, like the American bird-cherry, naturalized in the copses. It is rarely to be met with in Scotland, though few trees so well adapted for the climate of that country are so ornamental. The date-plum, Diospyros Lotus, though it ripens fruit as a standard in the climate of London, is perhaps rather tender for the northern counties; but where the climate is moderate, it forms a very beautiful small tree. The Virginian snow-flower, or fringe-tree, Chionanthus Virginica, is nearly as hardy as the snow-drop tree; and when planted in a moist soil, and trained to a single stem, its head is ornamental from its large, deep-green foliage, independently of the fine, white, fringe-like flowers which are suspended from the axils of the leaves. The common purple and the common white lilacs, Syringa vulgaris, and S. vulgaris alba, are very hardy, and make very neat small trees when trained to a single stem. The common ash is the parent of several varieties which are very ornamental. One of the oldest of these is the simple-leaved ash, of which there is a variety lately discovered in Ireland, with the leaves variegated. The pendulous-branched or weeping ash is a well-known variety, as are the yellow barked and the striped barked. There are several other varieties not in our opinion worth cultivating, though from these we except F. excelsior parvifolia, F. e. p. argentia, and F. e. p. oxycarpa. The lentiscus-leaved ash, F. Lentiscifolia, is an elegant tree; and there is a pendulous variety of it, which forms by far the most graceful tree of the genus. There are several species or varieties of American ash, very ornamental in their foliage, most of them hardy in the climate of London, but few of them adapted for the northern counties. The flowering ash, Ornus Europæa, is a very handsome tree, nearly as hardy as the common ash, and it ought on no account to be omitted in ornamental plantations. Few trees have a finer effect when standing singly on a lawn. Catalpa syringæfolia is a splendid tree when in flower: it attains the height of thirty or forty feet, and sometimes ripens its seeds in the climate of London; but in the northern counties it seldom does much good. It is one of those trees which will bear an immense deal of cold in winter, provided there has been heat and bright sunshine enough in summer to ripen its wood. The tupelo tree, Nyssa, is nearly as hardy as the Diospyros Lotus, and is more beautiful than that tree in autumn, when its leaves change to an intensely deep rich scarlet. The Oleaster or wild olive, and the Hudson's Bay olive, Elæagnus hortensis and argentea, are handsome silvery-leaved low trees; the former, however, rather tender, and the latter rather shrubby. The sea-buckthorn is a very handsome and a very hardy willow-leaved little tree, which has the great advantage of standing the sea-breeze without injury. Hippophæ salicifolia, a native of the mountains of Nepaul, is of more vigorous growth than the European sea-buckthorns, and appears to be nearly as hardy as they are. Shepherdia argentea, the Missouri silver-tree, is an elegant silvery-leaved tree, a native of North America, where it produces an edible fruit: it forms a suitable companion to Hippophæ and Elæagnus, which are also more or less silvery in their foliage. The black, the white, the red, and the tartarian mulberries, are all ornamental trees, but rather tender in the northern counties. The paper mulberry, Broussonetia papyrifera, is an interesting object, but more tender than the common mulberry. Maclura aurantiaca, the American bow-wood, or Osage orange, is a tree of very vigorous growth in the climate of London; but as it continues growing till late in the season, its wood is often not ripened so far as the points of the shoots, and the tree is therefore probably unfit for those parts of the island where the atmosphere is almost constantly charged with fog. The elm comprises many ornamental species and varieties. Of the English or narrow-leaved elm, those which we prefer are U. campestris viminalis, U. c. foliis variegatis, and U. c. virens. U. c. planifolia, and U. c. chinensis, are very beautiful as elms, but difficult to procure. Ulmus effusa is, in our opinion, by far the handsomest species of the European elms when it is in a young state; but it does not grow up to a handsome tree. The most beautiful variety of Scotch elm is the weeping elm, Ulmus montana pendula, which is remarkable for the vigour of its growth, and the picturesque manner in which its branches are thrown about. There are some American elms which are tolerably hardy in the climate of London, but which cannot be recommended for colder districts. Planera Richardi is an Asiatic tree, and attains the first rank even in the climate of London, where it sometimes ripens seeds; it deserves a place along with the elms, and along with the southern and eastern nettle-trees, Celtis australis and Tournefortii. The common walnut-tree, Juglans regia, though it becomes a tree of the first rank in the climate of London, and is cultivated for its fruit both there and in Devonshire, yet in the north has generally the points of its young shoots blackened by the spring frosts. Of the willow there are a great many species and varieties, all of which are highly ornamental when in flower. Of these we may recommend the almond-leaved willow, S. amygdalina; the sweet-scented bay-leaved willow, S. pentandra; the weeping willow, S. Babylonica; the golden willow, S. vitellina; and the purple-barked willow, S. atropurpurea. The pop-

lar genus contains several ornamental species. The first we shall mention is Populus tremula grandidentata, *Arb. Brit.*, the North American large aspen, of which there is a pendulous branched variety. P. heterophylla is an American poplar, little known and rarely met with in British nurseries. The balsam poplar, P. balsamifera, is one of the earliest trees, which sends out its leaves in spring; and it and the Lonicera Tatarica, in the climate of London, are found clothed with leaves a week or a fortnight sooner than any other tree or shrub whatever. The leaves of the balsam poplar, when they first come out, are of a rich yellow, and they perfume the air with their fragrance for some distance around; as the summer advances, they become darker, till in the autumn they are of a black or bluish green. It may give some idea of the extreme hardiness of this tree to mention, that Captain Franklin found it as far north as the Great Slave Lake; and that the greatest part of the drift-timber which he observed on the shores of the Arctic Sea was of this species. It is one of those poplars that send up suckers, and it is consequently readily propagated by cuttings of the roots. It prefers a moist soil, and though the Cree name for this species means ugly poplar, yet when full grown on such a soil, it forms a very massive round-headed tree, which at a distance might be mistaken for an oak or a chestnut, as is proved by two fine specimens in the grounds at Syon. The Ontario poplar, P. candicans, bears a close general resemblance to the balsam poplar; it has the rigid fastigiate habit of that tree, the same habit of sending out its foliage before all other poplars, its fine fragrance, and its property of throwing up suckers from the roots; but it differs from the balsam poplar in having very large heart-shaped leaves. It is rather more difficult to propagate than the balsam poplar, and, in British nurseries, is commonly raised from layers. The genus Alnus, the alder, contains some very ornamental trees. A. glutinosa laciniata has finely-cut foliage, and, what is remarkable, is in general a more free-growing tree than the species. A. cordifolia is a native of Calabria, and by far the handsomest species of the genus. We have already mentioned it as probably fit to be grown for its timber. A. incana, the hoary-leaved alder, is a very handsome tree, and has the advantage of preferring dry soil. A. oblongata, serrulata, undulata, and viridis, are low trees or large shrubs, quite hardy, and deserving of introduction into collections. The birch is a genus of which the greater number of species are natives of North America; and, though they are valuable timber-trees there, none of them in this country have yet proved anything more than ornamental. The finest American species is B. nigra, distinguished by the beautiful paper-white of its bark, which cracks, separates into thin laminæ, and rolls up, even when the tree is young and only two or three inches in diameter. B. populifolia is a handsome species, very much resembling the common birch, and in our opinion only a variety of it, as are B. pubescens, urticifolia, pontica, Dalecarlica, and others. There is a cut-leaved, pendulous variety of the common birch, which is very ornamental. The paper-birch, B. papyracea, is a fine tree; as are B. glandulosa and B. Däurica. B. fruticosa, pumila, and nana, are shrubs.

Of oaks there are upwards of forty species introduced into British gardens; the greater number of them, with many varieties, being purchasable in British nurseries. All these, with the exception of the two varieties of the common oak and the Turkey oak, may be considered as solely or principally ornamental. Of the common oak, Q. pedunculata, there are three varieties, very distinctly marked, viz. the cypress oak, Q. p. fastigiata; the weeping oak, Q. p. pendula; and the cut-leaved oak, Q. p. heterophylla. These three varieties often ripen acorns, and of the plants raised from them a number are found to have the same habit as the parent. There are several varieties of Q. sessiliflora, which differ in the size of the acorns, in the size of the leaves, in the greater or lesser degree in which these are cut, and in the presence or absence of pubescence; none of these varieties, however, have yet been propagated by the nurseryman, excepting Q. s. pubescens. The Pyrenæan oak, Q. Pyrenaica, is a very handsome and distinct species, of low growth. Q. Apennina is also a low tree. Q. Esculus, the Italian oak, is a tree under the middle size, which thrives well, and ripens its acorns in the climate of London: there are fine specimens at Whitton Park. Of the Turkey oak, Quercus Cerris, there are ten or twelve very distinct varieties. The first of these is the pendulous variety, the next the Austrian, then the Ragnal, the Fulham, and the Lucombe. Of the latter there are five very distinct sub-varieties, all sub-evergreen, and all well deserving of culture wherever the common Turkey oak will thrive. Quercus Ægilops, the Velonia oak, thrives in the climate of London; but is probably too tender for the northern counties. The American oaks, which are deciduous, may be classed as the white, red, black, and willow oaks. The white oak best worth cultivating in Britain as an ornamental tree is Q. alba; but Q. olivæformis and macrocarpa are remarkable for their fruit, and Q. obtusifolia and lyrata for their leaves. The chestnut oak, Q. Prinus, and its several varieties, also deserve culture: the leaves of these oaks resemble those of the sweet chestnut, and the species is to the other deciduous American oaks what Q. sessiliflora is to the deciduous oaks of Europe. Q. alba bears the closest resemblance to Q. pedunculata, and may be considered as being the American form of that species. All the red oaks are beautiful in the form and colour of their foliage; and some of them attain the size of timber-trees in Britain, though their wood is of little value either here or in America. Q. rubra, and coccinea, and tinctoria (the Quercitron), are perhaps the most ornamental; and Q. palustris is the hardiest, the most rapid growing, and the handsomest in point of general form. The black American oaks are all remarkable trees. The black-jack oak, Q. nigra, *L.*, is the most extraordinary species, from the very singular form of its leaves; and next to it is Q. aquatica. Q. ilicifolia, heterophylla, and agrifolia, belong to this division. The willow oaks, Q. Phellos, imbricata, and laurifolia, have entire leaves, which die off without changing colour; and this group may be considered the least ornamental of the American oaks.

The American hornbeam, Carpinus Americana, and the common and Virginian hop hornbeams, Ostyra vulgaris and Virginica, deserve a place in collections, more especially the hop hornbeams, from the singular appearance of their fruit. Of the common hazel there are some ornamental varieties, such as that with purple leaves, and another with cut leaves. The Constantinople hazel, Corylus Colurna, forms a very handsome middle-sized tree; and C. rostrata and Americana are hardy, and well deserving a place in ornamental plantations. The oriental and occidental planes are highly ornamental trees of the first rank, and Platanus Orientalis acerifolia, *Arb. Brit.*, and P. O. cuneata, *Arb. Brit.*, are fine varieties, the latter forming a curiously-twisted low tree. The Liquidambar is a splendid tree, remarkable for the beauty of its foliage and its refreshing fragrance. Liquidambar imberbe is a small tree, also very ornamental. The Ginkgo or maidenhair tree, Salisburia adiantifolia, *Sm.*, is remarkable for the singularity of its foliage: it is a native of China, but is quite hardy in most parts of Britain; and it is propagated without difficulty by cuttings made in autumn. Of the larch there are some species and several varieties, which are chiefly ornamental; those best deserving of culture are L. Europæa pendula, L. Americana pendula, and L. Americana rubra. The deciduous cypress is rather tender in the northern parts of the island; but in the climate of London, when planted where its roots are within reach of water, it forms a magnificent tree of the first rank.

III.—*The Nursery Culture of Trees.*

We have now gone through the whole of the hardy trees and shrubs of Britain, and have indicated those which we think best deserving of culture, where the objects are either timber-produce or general effect, and where no extraordinary care is proposed to be bestowed on the soil. The reader cannot fail to be surprised at the very small number of species which merit to be planted for the sake of their timber, and at the great number which we have enumerated as ornamental. That number would have been more than doubled had we included the flowering shrubs, and such foreign trees and shrubs as will only thrive in the southern parts of the island; but we have confined ourselves as much as possible to those which will thrive both in the climate of London and in that of Edinburgh. It must be recollected that all the ornamental trees produce timber of some sort; and some of them, such as the box, crab, common maple, &c., timber of considerable value. Every ornamental tree, therefore, may be considered a useful tree, even with respect to the wood which it produces; though, from the length of time it takes to produce that wood, it may not be a profitable tree to cultivate for that purpose. Having treated on the trees worth cultivating, we shall now enter on the subject of their cultivation.

The cultivation of trees and shrubs includes their propagation and rearing in the nursery, and their culture and management in plantations.

Nursery Culture.—A nursery is any plot of ground devoted to the propagation and rearing of trees and shrubs. To be perfect, it ought to contain the principal kinds of soil in which trees and shrubs grow, and to possess different climates, according to the countries of which the plants are natives; but as these requisites cannot be always obtained, particularly with respect to climate, all that art can do is to make the nearest approach to them that circumstances will admit. It may be laid down as a general principle, that all seeds will germinate, and all plants grow, in any kind of soil whatever, provided it contain some vegetable matter, be in a state of minute division, and be retentive, to a certain extent, of water. All plants, therefore, may be reared in a nursery containing only one kind of soil; but in such a nursery all will not be equally well reared; for some plants, such as all those which have hair-like roots (as the ericaceæ, including the heaths, rhododendrons, arbutuses, &c.), and in general all that are called peat-earth plants, will only thrive in a peaty-soil; or a soil composed of a mixture of very fine sand, and thoroughly decomposed leaves, or woody matter. Other plants, such as all those which attain a large size, and have strong tap-roots, will only thrive in deep loams or in deep fertile sands, though they will grow for a time very well in peat. A nursery, therefore, that contains the three leading soils of sand, loam, and peat, will suffice for all the purposes for which the most extensive nursery can be required; and, for raising such trees and shrubs as have been treated of in this article, a piece of ground containing sandy loam in one place, and clayey loam in another, or even sandy loam throughout, will be quite sufficient, as far as regards soil. With respect to climate, all the deficiencies which can occur in Britain may be made up by glazed frames, in which the more tender kinds can be raised; and in which those which are grown in pots can be kept through the winter. A nursery may be considered in two points of view: with reference to the nurserymen, and with reference to the climate and soil where the trees are finally to be planted. As matters stand at present, it is the interest of the nurseryman to have his nursery in a fine climate, and in deep, fertile soil, in order that he may raise large vigorous plants in the shortest possible period: but it is the interest of the purchaser to have the plants reared in a climate and soil inferior to that into which they are to be transplanted; because, when this is done, instead of the plants receiving a check from the operation of transplanting, as is usually the case, they will be improved by it. It is the interest of the nurseryman to have his nursery trenched and manured to the depth of two or three feet; in order that it may contain abundance of nourishment, and be retentive of moisture during the summer season, so as to cause the plants to produce long and vigorous shoots. On the other hand, it is the interest of the purchaser that the soil should not be cultivated to more than eight or ten inches in depth, in order that the nourishment and the moisture, and consequently the roots, may be concentrated in a very limited space; so that, when the plants are taken up, the whole of the roots may be taken up with them, which, where the ground has been trenched, is impossible, from the great depth to which they will have penetrated. It is for the interest of the nurseryman that the summer should be moist, in order that the shoots produced may be long and strong; but it is for the interest of the purchaser that the summer should be dry, in order that the shoots may be short, and thoroughly ripened; and that the roots should cease to grow early in the autumn, in order that their spongioles, having had time to harden, which they cannot do till they have ceased elongating, may receive the less injury when the plants are taken up. In short, it is the interest of the purchaser to concentrate all the forces of the plant within such limits as he can thoroughly command, that is, can take up and carry away. The advantages of thin sowing and planting to the planter, therefore, are obvious, though the reverse is for the interest of the nurseryman; as by thick planting the plants are drawn up taller and straighter, and a greater number will grow on a given surface. We are fully aware of the arguments which are opposed to this doctrine by nurserymen; viz. that the stronger a plant is, and the greater the number of its fibrous roots, the more likely will it be to succeed after being transplanted to a new situation; and that this strength of shoot, and abundance of fibrous roots, can only be produced in deep, rich soil. But we deny that this vigorous appearance in the shoots of plants is strength; and assert that, so far from a deep soil being favourable to the production of fibrous roots, it is directly the reverse. The strength of a plant, and its suitableness for being removed from one situation to another, and for growing vigorously after it is removed, consists in all its parts having arrived at maturity, in the thorough ripening of its wood, and in the completely dormant state of its fibrous roots; and these requisites, we assert, can only be obtained by concentrating the nourishment contained in the soil into a limited space, by the soil being compact, and by no more moisture being admitted to the roots than what is absolutely necessary to complete the growth of the season in sufficient time to allow of the thorough ripening of the young wood. If by any mode of culture these requisites can be obtained, together with the long and thick shoots which are produced by growing the plants in deep, rich soil, so much the better; but we contend, that, in the climate of Britain, this is impossible. If the purchasers of plants in nurseries will observe what takes place in the case of layers, as in those of the elm, the lime, the platanus, the white poplar, the vine, &c. they will see the justice of our statement. Such layers made in spring have generally at the end of the season shoots of three or more feet in length, which have continued growing till they were checked by frost; the consequence of which is, that neither the wood nor the fibrous shoots have ripened. The first year after removal, such plants make scarcely any growth; and if they survive the first year, it requires two or three years more before they are firmly established. Nearly the same thing may be said of almost all one-year grafted or budded fruit-trees, which, hav-

ing seldom ripened their wood thoroughly, from being planted in deeply trenched rich soil, and half of their roots having been left in the ground after they are taken up, are consequently obliged to be cut in when planted. These considerations show, as a general principle, the advantage of growing all plants that are to be transplanted, in such a manner as that they may thoroughly ripen their wood and roots, and so that the whole of the roots may be taken up with the plant. On a large scale, the only mode of effecting this is by having the soil shallow and rich, but not too moist. On a small scale, the same end is attained in a very complete manner by growing the plants in pots; and, were it not for the expense, this would be the best mode of growing all nursery articles. The plants, however, should not be kept too long in pots, because, when so treated, many species, after a time, acquire a stunted habit, and the roots, when the tree is transplanted, instead of being in a state to allow of their being unwound from the ball, and stretched out in lines radiating in every direction from the stool, are so long and slender, and the circulation through them is so languid, that they require to be cut off or shortened. In general, it may be observed, that a weak plant, with the wood and roots thoroughly ripened, is much more likely to thrive when transplanted, than a strong one from which a great part of the roots have been cut off; and hence, of two young Huntingdon elms, budded on the Scotch elm, one of which had been grown in a pot, and had its leading shoot only two feet long, and another which had been grown in the free soil, and had its leading shoot five or six feet long, as is often the case—the former, when transplanted where it was finally to remain, would far sooner attain the height of twenty or thirty feet than the latter. We do not expect that all commercial nurserymen will subscribe to these opinions, but private gentlemen who raise their own trees will find it their interest to attend to them. Hence those who plant in mountainous districts will always find it better to have their nurseries on the sides of the mountains than in the valleys.

Propagation.—Trees, like other plants, are chiefly propagated by seeds; but they are also increased by cuttings, layers, budding, and grafting. The timber-trees of all countries are raised from seeds, with the exception of a very few, such as the poplar and the willow, which are raised from cuttings; and some species of elms, limes, and a few others, which are raised from layers, or by grafting. The greater number of ornamental trees and shrubs are raised by some of these artificial methods; because in this country they seldom ripen seeds, and because varieties are always perpetuated by artificial modes. Thus, all the American oaks are, or may be, grafted on the common British oak. Most of the foreign acers and birches are raised by layers, most of the ornamental thorns by budding and grafting, and almost all the ornamental willows and poplars by cuttings. All plants which do not ripen seeds readily are propagated by some of these artificial modes; and that mode is preferred by the nurseryman, which, experience has proved, will produce the largest and most vigorous-looking plants in the shortest time. Thus, though more suitable plants for the planter would be produced by raising the platanus and the white poplar from cuttings, because in that case nature would adjust the tops to the power of the roots; yet, as much larger plants are produced by layers, that mode is everywhere preferred in the commercial nurseries. The lime-tree ripens its seeds in this country, and also the English elm; but large plants are much more rapidly procured in the first case by layers, and in the second by grafting. We do not say that in every case the mode by which the largest plants are most rapidly produced should give way to the slower mode; but merely that, in most cases, it would be advantageous to the purchaser that the slower mode should be adopted. According to some writers, plants which are raised from cuttings, or by any other mode than by seeds, are of less durability than seminal plants; but though this may be true, or appear so, in a few instances, it can never be adopted as a general principle; since, from all that we are taught by physiology, a bud contains as perfect an embryo of a plant as a seed: the only difference being, that the bud is more powerfully imbued with the peculiarities of the individual which produced it than the seed is. This doctrine is confirmed by experience; since the poplar, the willow, the vine, &c., have been propagated by cuttings from time immemorial, and, for any thing that is known to the contrary, possess respectively the same properties now that they did in the days of the Romans.

Propagating by Seeds.—The seeds should be collected from the handsomest individuals of the species, when they are quite mature; and they should either be sown immediately, or preserved in a place where they will undergo few changes in regard to heat or moisture, till the proper sowing season, which, in almost every case, will be the following spring. Nature, it may be observed, sows all her seeds soon after they are fully matured; that is, they drop from the tree upon the ground in autumn, or the beginning of winter, or, in the case of some trees, such as the pines and firs, not till the following spring; but as, when seeds are thus left to chance, the greater part of them are destroyed by vermin, by being placed in a condition not favourable for germination, or by imperfect or premature germination, only a moderate number of them produce plants. It is the business of art, therefore, to study what is favourable and unfavourable in nature's mode of sowing seeds, and to imitate only the former. The result of this study is, that by far the greater number of seeds may be kept with advantage from the time they ripen, till early in the following spring, that is, till February or March, and then be committed to the soil. There are a few exceptions, as in the case of poplar and willow seeds, which ripen early, and which, when sown immediately that they drop from the tree, often come up in the course of a few weeks; whereas, if they are kept till the following spring, the greater number do not come up at all; and also in the case of seeds which lie two years in the ground before coming up, such as those of the hawthorn, the holly, &c. and which may be kept till the second spring after being ripened before they are sown. In order to show the treatment required for the seeds of different kinds of trees, and the plants raised from them in the nurseries, it will be convenient to throw them into groups; and these may be as follow: the pine and fir tribe; the trees producing nuts, acorns, masts, and keys; trees producing pomes with kernels, berries with stones, berries in capsules, small seeds, leguminous seeds, and cottony or papery seeds.

The seeds of the pine and fir tribe ripen from October till January, and if the cones are allowed to remain on the tree throughout the winter, the seeds do not in general drop out till the following April or May; soon after which, such of them as drop into a favourable soil, where there is a certain degree of moisture and shade, come up in five or six weeks. The nurseryman collects the cones of each species immediately after they are ripe (which, with the pinaster, and a few others, is as early as the month of October), and he lays them by in a dry place till he has leisure to extract the seeds. This he does by exposing the cones to the heat of the sun under a glass case, by which the heat is retained, and raised to a higher degree than it would be in the open air; or he subjects them to artificial heat before an open fire, or on a kiln. The seeds, when taken out, are sown in April, in soil dug over, and rendered fine by raking; and over them is laid a covering of soil, which, in general, need not be deeper than the thickness of the seed to be covered, where the soil is loamy;

but it may be twice that thickness where the soil is a coarse sand. In order to retain a uniform degree of moisture on the surface, the beds, after the sowing is completed, should be shaded from the sun, by covering them slightly with the branches of trees, and especially with those of evergreens, such as the spruce fir. In cold moist climates, such as that of Aberdeen, this shading may be dispensed with; but in the climate of London it is, in most seasons, essentially necessary, and may be effected by hoops and mats, by fronds of fern, by straw, or by pea haulm. For greater convenience, the seeds are generally sown in beds, a slight excavation being made in the beds by drawing some of the earth to the sides; and in order that the seeds may be evenly deposited on a somewhat firm surface, the bottom of this excavation is rolled with a light roller. After the seeds are distributed over the beds, at such distances as that the plants, after they have come up, and have grown to the end of the season, may not touch each other, the beds are again rolled, and afterwards the covering of earth is thrown over them which was drawn off before rolling and sowing. It may be observed here, that the rolling in of the seeds, by bringing them in close contact with comparatively firm soil, renders a much thinner covering of earth necessary than if the seeds had been sown on a loose surface. It is also more favourable to the vegetation of the seeds; it being found that close contact with the soil, both in the case of seeds, and the spongioles of the roots, is a powerful stimulus to vegetation. Some of the more tender species of pines and firs, such as the stone pine, the cedar of Lebanon, the cypress, &c. are commonly sown in pots, or in flat earthen pans, for the convenience of making them germinate under glass, and in order to facilitate future transplantation; but the process of preparation, sowing, and covering, is exactly the same as when the seeds are raised in beds. The plants, after they have come up, require nothing but the usual routine culture of the nursery for two summers; at the end of which period they should be taken up, and, if possible, transplanted where they are finally to remain; but as this cannot always be done, the next best practice is to plant them in the nursery, either in lines, which is the most convenient mode, or scattered over beds; in either case keeping the plants so far apart that there may be a clear space round each plant, of from three to six inches, according to its height and the length of its leaves. Thus, for the Scotch pine and the spruce fir, which grow slowly when young, and have comparatively short leaves, three inches will be sufficient; whilst for the larch, which grows rapidly the second year, and for the pinaster, which has long leaves, six inches will be required. Here the plants may remain another two years, and afterwards be transplanted on the same principle; unless they are in the mean time removed to where they are finally to remain. Unless this has been the case, they will have little chance of doing good as timber-trees; for experience has proved, that after two years' growth, or at most four years', all the pine and fir timber are materially checked by transplanting; and that this check is of a kind which cannot, like that given to broad-leaved trees, in a similar case, be counteracted by cutting them down to the ground; but, on the contrary, remains for many years, and materially affects the future growth and habit of the tree.

Trees bearing Nuts, Acorns, Masts, Keys, &c.—These, on British timber-trees, ripen from October to December. The greater part of oaks ripen their acorns in November; but the beech, the horse-chestnut, the walnut, and the hazel, ripen their mast and nuts in October; and most of the sycamores and maples their keys in September. All these seeds ought to be gathered as soon as they are ripe; because, as they form an important part of the food of wild animals, the best are liable to be picked up by them as soon as they drop. They may either be sown immediately or kept till February, as in neither case will they come up till April or May. They should be sown in a sandy loam, in drills, the seeds being deposited at such a distance from each other, that the leaves of the plants springing from them may not touch at the end of the first season; they should be trodden into the drill with the foot, or pressed down with the back of a wooden rake; and they may be covered to the depth of twice or thrice the thickness of the seed. The reason why drills are recommended for this description of tree-seeds is, that in the intervals between the rows, a spade may be inserted obliquely, so as to cut through the tap-roots of the plant, and force it to throw out lateral roots. This operation is commonly performed early in the spring of the second year: it does not prevent a second tap-root being formed from the mutilated extremity of the first; but it throws a greater proportion of the energies of the plant into the lateral roots, which, by increasing these and their fibres, renders the tree better adapted for transplanting. At the end of the second year, plants so treated may be taken up, and either planted where they are finally to remain; or, their tap-roots being shortened, they may be transplanted into nursery lines, at distances adjusted according to the principles laid down for transplanting the pine and fir tribe. In this situation they may remain two years longer, and then be taken up and again replanted in the nursery; because all broad-leaved tap-rooted trees differ from needle-leaved trees in this important particular, that the larger and stronger they are, up to a certain point, before they are removed from the nursery, and planted where they are finally to remain, the more vigorously will they grow there. The point or limit to the size which they may be allowed to attain in the nursery must be regulated by the condition of the soil into which they are to be transplanted, relatively to moisture. If this be abundant, so as to supply all the fibrils with water during the first summer, even if the removed plant has a stem an inch in diameter, so much the better; it being clearly understood that it has been transplanted in the nursery every two years, and is consequently abundantly supplied with fibrous roots, and has all its wood perfectly ripe. If, on the other hand, the soil into which the plant is to be transplanted is naturally dry, and perhaps also thin and poor, the plants should be removed from the nursery thither at the end of the second year. The reason is sufficiently obvious; such plants, being of small size, have few leaves to exhale moisture, and before they grow large they will have adjusted their roots and annual growths to the locality.

Trees producing Pomes with Kernels.—This class includes the genera Pyrus, Cydonia, Amelanchier, Cotoneaster, Viburnum, &c. The fruits of the different species of these genera ripen at various periods from September to November. They should be gathered when ripe, and each kind should be mixed with sand, and laid up in a heap, in order to rot away the pulp. This heap may be turned over several times in the course of the winter; and in the month of February it may be sifted, and the seeds separated from it, and sown in beds, exactly in the same manner as is done with the seeds of the pine and fir tribe. After the plants have been two years in the seed-bed, they may be transplanted into nursery lines, on the same general principles as already described.

Berries having Stones.—This class includes the genera Cratægus, Ilex, Taxus, Prunus, Cerasus, Rhamnus, and some others. The fruit ripens from August (as is the case with some species of Cratægus) to December. It should be gathered as soon as it is thoroughly ripe; and after having been mixed with sand or sandy soil, the mixture should be laid up in moderate-sized heaps, exposed to the weather, and turned over frequently for two years, after which it may be taken, along with the sand, and sown in beds; and when the plants come up, and have grown two

years, they may be transplanted, and treated like the others. In general, all the plants belonging to this class, whichever way the seeds may be treated, whether they are sown immediately that they are ripe, or kept in a rot-heap two summers, will not come up till the spring of the third year; but there are some positive and some accidental exceptions. Amongst the former are the yew, the berries of which generally come up at the end of the first year, and the wild cherry, which, if sown in July, immediately after the fruit is ripe, will come up the following spring; whereas, if kept till August before it is sown, it will not come up for two years. As casual exceptions, we may mention that the holly and hawthorn, when the berries are macerated in water as soon as they are gathered, and sown immediately afterwards, will, in some seasons, come up the following spring in considerable numbers; though the same treatment in other seasons, in the same nursery, will not be attended with the same results.

Berries and Capsules having small Seeds.—This class includes the elders, the privet, the spindle-tree, the barberries, and some others. The fruit may be treated like the pomes; and great care should be taken, after it is rotten, either that the seeds are completely separated from the sand before they are sown, or that the sand and seed, when sown together, should be so distributed over the bed as that the plants may come up at regular distances, and sufficiently far apart. The covering of soil should be very thin, more especially if the seeds are rolled in; and the beds should be shaded by branches or matting till the plants are fairly above ground. At the end of the second season they may be transplanted into nursery lines as before.

Leguminous Seeds.—These include the genera Cytisus, Robinia, Gleditschia, Caragana, &c. The pods generally ripen in September or October; but some of them, such as the Gleditschia, not till November or December. The seeds may be kept in the pods till February, and then taken out and sown in beds, on the principles before laid down. At the end of two years the young trees may be transplanted as before.

Cottony, Papery, Feathery, and other soft Seeds.—These include the genera Populus, Salix, Alnus, Betula, Ulmus, &c. The seeds ripen from May to November; all the poplars ripen their seeds in May; all the willows and elms in June; the alders in November; and the birches in October. The seed of the alder and the birch may be kept in a cool, dry, airy situation till the following spring, or it may be sown immediately after it is gathered. In either case it comes up in the May or June following; but it is preferable that the seeds of the elm, the poplar, and the willow, should be sown immediately, because in that case they are much more certain of coming up. Many of these seeds will come up the same autumn, and the remainder the following April and May. The seeds may be dried and preserved in bags for a year; but in this case the greater part of those of the poplars and willows will not vegetate. The reason may be, that the seeds, when preserved, are kept too warm; which must necessarily deprive them of their moisture, through the absorption of the cottony substance with which they are enveloped. Poplar and willow seeds require to be sown on a surface rendered quite even, and slightly firm, by rolling. Afterwards the seeds should be evenly distributed over it, and they should be covered with very light, sandy soil, or peat or vegetable mould, if either can be procured, no thicker than barely to conceal the seed from the eye. After this the beds should be watered, and effectually shaded, by being hooped over and matted; and they should be kept in a uniform state of moisture, by occasional supplies of water, when the plants make their appearance. Of all the seedling trees raised in British nurseries, none come up and grow with so much vigour, the first year, as the common broad-leaved elm; and, therefore, the seeds of this tree require to be placed at a greater distance from each other in the seed-bed than those of any other kind. The seeds of the elm also keep much better till the following spring than those of the poplar and willow, and they are generally so kept by Scotch nurserymen.

IV.—*The Culture of Trees in the Plantations. The Formation and Management of Plantations.*

Whether plantations of forest-trees should be sown or planted, is a question which has been agitated and discussed by different writers. It is readily allowed, that sowing is the natural mode; but it is the business of art to improve upon nature, and to attain the same ends which she does, by more definite means. If this general principle be correct, it affords at once a decisive answer as to the respective eligibility of sowing or planting; unless, indeed, it can be shown, which some have attempted to do, that the timber of transplanted trees is never so valuable as that of sown ones. The only reason alleged for this is, that the transplanted trees have lost their tap-roots; and although a more frivolous one could hardly be imagined, yet it has been maintained by a number of writers, and is still insisted on by a few. On examining the roots of full-grown trees, however, either in natural forests or artificial plantations, no tap-root is ever found; on the contrary, those roots which proceed either directly or obliquely downwards from the base of the trunk, are uniformly found much smaller than those which proceed from the base of the trunk horizontally, at a few inches distance under the surface of the ground. The tap-root, therefore, is chiefly of use to the tree whilst in a young state; and if we trace a seedling oak through the first ten years of its progress, we shall find that, in the first year, the tap-root is larger in proportion to the part of the plant above ground, than it is in any succeeding year; and that as the top of the tree and the lateral roots increase in size, the tap-root ceases to increase, till at last, even at so short a period as ten or twelve years' growth, it is found to be the smallest of all the main roots of the tree. We assume it, therefore, as agreed on by the most intelligent planters, that a transplanted tree, other circumstances being the same, is in all respects as good as a seedling one. Hence we conclude, that all artificial plantations ought to be made by planting the trees, and for a similar reason we would plant these in rows at regular distances; and, in short, treat them, as far as is practicable, like a crop of herbaceous vegetables, when reared in the kitchen-garden or in the field. We would prepare the soil, and even manure it for the trees, with as great care as we would for a crop of turnips or cabbages; and we would stir the surface afterwards for two or three years, till it began to be covered with the branches of the trees; in which state we should leave it during the whole period of the growth of the plantation, only taking care to remove large weeds. We admit, however, that this kind of tree culture can only take place with advantage on a tolerably even surface, and where the soil is of the same nature throughout; but we think it right to lay it down as a general principle of guidance, in so far as it can be followed, for planters in all other soils and situations. With the exception of the ground destined for ornamental plantations about country houses, the great majority of cases in which plantations are to be formed with a view to profit must necessarily be on hilly and irregular surfaces; and where there is probably a considerable variety of soil, even in a very limited space. The only preparation that in cases of this kind can be given, is under-draining; for to dig or trench the surface would render it liable to be washed away by heavy rains and thawing snow. Plantations under such circumstances must be formed by digging pits for each particular tree, and by making use of such

kinds as are thought to be best adapted to the particular soil and situation. This will frequently occasion the use of a considerable variety of trees in the same plantation; but the effect will be as much more interesting in point of beauty, as the result will be advantageous in point of timber produce. We have already stated, that needle-leaved trees should, if possible, be transplanted when they are not older than two years; but that broad-leaved trees may be transplanted at four, six, eight, or ten years' growth; provided they have been removed every two years in the nursery, and that the soil in which they are placed is sufficiently deep and moist to bring all the fibrous roots into full action the first summer. In the planting of irregular surfaces, which cannot be done by digging, when strong plants of this kind are used they overcome the natural herbage immediately; and, if carefully planted, not one in a score will fail. Smaller plants, on the other hand, are apt to be choked by the grass or herbage, and to have their leaves and young shoots injured by the insects which never fail to abound in such situations. When such surfaces have naturally a very dry soil and subsoil, plants with such a mass of roots as those which we have mentioned cannot subsist on them the first year; and therefore smaller plants, or such as have been only once transplanted, are preferable.

Notwithstanding these arguments in favour of planting instead of sowing as a general practice, there are circumstances under which sowing is either the preferable, or perhaps the only mode, that can be adopted. In every case of making plantations of the pinaster, or of the cedar of Lebanon, unless we could procure a sufficient number of plants of two years old in pots, we should prefer sowing a patch of seeds in every place where a plant was intended finally to remain. Three seeds in a patch would be sufficient; and if more than one came up, the rest should be removed the second or third year. In cases of this kind the plants require to be looked over two or three times every year, to prevent the surrounding herbage from choking them. When steep rocky cliffs, or the sides of hills, consisting of loose naked stones, are to be covered with wood, then sowing is the only mode that can be resorted to. The kind of rock having been ascertained, in order to discover the nature of the debris or soil collected in its clefts, or under the loose stones, the kinds of seeds to be sown may be selected accordingly. Where the soil is good, acorns, ash-keys, maple and sycamore keys, and beech mast, may be introduced; but where it is poor, the safer mode will be to sow seeds of the Scotch pine, the larch, the birch, the mountain ash, the white-beam tree, and the elder. Where there is no visible soil, each seed, or two or three seeds, may be enveloped in a composition of common green moss, cow-dung, and loam, and these balls being deposited in clefts or crevices, or among loose stones, and left to be acted upon by the rain, will swell and burst, and the seeds which they contained will vegetate, and find nourishment in the fragments of the ball in which they were enveloped. When the object is to cover drift sand with wood, the practice followed in the downs or landes of Bordeaux may be adopted, with suitable variations. A zone of the downs, or sandy surface, on that side from which the prevalent winds blow, is first to be sheltered by a fence of boards three or four feet in height. This will protect a zone of twenty or thirty feet in width; that is, it will prevent the drifting sands from covering this space to any great thickness. On this zone the seeds of broom, as being a plant that will grow on the poorest soil, are to be sown; and, among these, the seeds of the tree which is considered the most suitable for the particular situation. Near the sea this will generally be found to be the pinaster; but in the interior of the country, where the sands are not deep, perhaps the birch or the Scotch pine may be found eligible.

Two of the most important points connected with the formation of plantations, are the distance at which the trees ought to be planted from each other, and the introduction or non introduction among them of nurse-trees. When both these points were first settled by professional planters, the important uses of the leaves of plants were not at all understood by practical men. Hence they gave directions for planting the trees at such distances as that they might draw up one another; without considering the loss of the leaves on the sides of each plant which this drawing up will produce. As the strength of every plant depends on the number of its leaves, and on the full exposure of these to the light, it follows that the strongest young trees will be those which are clothed with branches and leaves from the ground upwards, and which have their leaves fully exposed on every side to the perpendicular light. In regard to the distance from each other at which trees can be planted in a plantation, we should say, begin by planting at a greater or less distance, according to the size of the plants and the nature of the soil and situation; but do not neglect to cut down, or thin out, the moment the lower branches of the plants interfere with one another. Continue this practice year after year, till the lower branches begin to show symptoms of decay at their extremities; when, instead of thinning out the trees, the process of pruning them may be commenced. The lower tier of branches may then be cut off close to the stem, it being understood that such pruning shall take place before the branches are more than an inch in diameter at the point where they join the stem, even if the extremities of the branches have not begun to decay. The trees may then be left to grow, either till another tier of branches begins to show symptoms of decay, when, of course, that tier must be cut off immediately; or till the points of the healthy branches interfere with those of the healthy branches of the surrounding trees, in which case thinning must be resorted to as before. In this way the process of thinning and pruning ought to go hand in hand, till the trees have attained their average height; by which time the different species will be found standing at distances differing according to the height of each tree and the nature of its branches. Thus those trees which will be found standing closest together when full grown, will be the pine and fir tribe; because in them the branches never attain a timber size, and the lower tiers begin to decay at their extremities sooner than in any other trees. On the other hand, the oak has more widely-spreading and durable branches than any of the other broad-leaved trees; and hence, when plantations of this tree are fully grown, the individuals will be found at a greater distance apart than those of any other species of broad-leaved tree whatever. What this distance will be must depend on the soil and situation; because in some localities the common British oak will attain double the height and breadth of head which it does in others. Our business here is to illustrate a principle; and we shall leave it to planters who approve of it, to deduce the rules from it which will apply to their particular cases.

The next point which we have to discuss is the advantage or disadvantage of introducing nurse-plants into plantations. That these have a tendency to accelerate the growth of trees in an upward direction for a number of years after the plantation is made, there can be no doubt; but this is always at the expense of the side-branches and side-leaves, and consequently of the thickness of the trunk of the tree to be nursed. The question, therefore, is, what is gained by the nursing? Is there any advantage in having a young tree with a tall, slender stem, and few or no side-branches, rather than a tree of half the height, with a short, stiff stem, clothed with branches and leaves from the ground upwards? We admit that evergreen nurses, such as the Scotch pine and the spruce fir, considerably improve the climate of a plantation, by preventing the radia-

tion of heat from the ground; and that, provided they did not do injury in other respects, in this respect they would do good. The question as to nurses or no nurses may, we think, be satisfactorily answered in the following manner:—Suppose we adopt the principle already laid down, that all trees in plantations intended to produce timber should be kept at such distances, by thinning and pruning, as that the extremities of their lowest branches should never interfere. Then, having fixed on the kind of tree the growth of which is to be the main object of the plantation, and the number of these that, when full grown, can stand upon an acre or any given surface, plant them in their proper places, and fill up the intervals with the trees intended to serve as nurses. As the nurses increase in size, and their branches touch their principals, let them be pruned or thinned; so as in no way to prevent the principals from being clothed with branches from the ground upwards on every side, or to prevent the leaves on these branches from being fully exposed to the sun. In this way the climate of a plantation will be improved by evergreen nurses; and the nurses will protect the trees from high winds till they have attained to such a size and vigour of growth that the annual shoots produced on the top of the tree will be so short that they can be ripened in a colder climate than would be required to ripen a longer shoot produced by a young tree. This mode of nursing trees, it may be observed, is widely different from the practice of letting nurses and principals draw up one another, in which case both will be alike without side-branches; and consequently, when the nurses are removed, the principals, weakened by having their stems, unprotected by branches, exposed to the cold in winter and to the heat in summer, will remain stationary a number of years; in some cases dying away altogether, and in others making so little progress that nearly as much would be gained in the produce of timber by cutting them down, and training up a single shoot from the stools, or by trenching the ground and replanting, as by letting them grow.

We have now taken a cursory glance at the principal points which require to be considered in the culture of trees, and in the formation and management of trees; but the subject is of very great extent, and could not be entered into in all the requisite details in even double or treble the space which can be allotted to this article. Our object in writing it has been rather to direct attention to general principles than to lay down specific rules; satisfied as we are that, in every department of agriculture and gardening, too much deference is paid to routine practices, and too little recourse is had to the principles on which these practices are founded. Above all, planters do not seem sufficiently aware of the important agency of leaves and light, not only in the production of quantity of timber, but of quality also.

(The botanic names in this article are generally those adopted in Loudon's *Arboretum et Fruticetum Britannicum*, to which work we would refer for more ample information.) (C. J. L.)

V.—*Landscape Gardening.*

We now come to landscape gardening. This treats planting as a means of decorating grounds, and combines with it every other operation requisite to embellishment. It does not exclude the growing of trees for the market value of their timber, but it subordinates this to the improvement of scenery. Its entire object is to convert all the land around a residence into an assemblage of pleasing pictures. It is a subject for the exertion of fancy and taste; and expatiates on at once the simplest, the noblest, and the most beautiful scenes of nature. Its business is not confined to what is popularly called a garden, but also regulates the disposition and embellishment of a park, a farm, or even a forest. A landscape gardener selects and applies whatever is great, elegant, or characteristic in any of them; he discovers and brings to view all the advantages of the place on which he operates; he supplies its defects, corrects its faults, and improves its beauties.

The ground selected for a landscape garden may comprise broken surface, lawn, or swamp; it may be a height, a valley, a plain, or a composition of swells, dips, and levels; but it suits best to be all a tract of moderate elevation, with flowing outlines, free from angular points or great irregularities, commanding a good view, enjoying good natural shelter, and possessing a dry, deep, friable soil. All its essential characters are natural. An artist may afford important aid in selecting it; but if it be naturally ill-conditioned, he can do little or nothing to improve its general expression, and must confine his efforts to the correcting of slight inequalities, and the handling of wood and water.

Wood, in landscape gardening, is classified into woods proper, groves, and clumps. A wood proper is a large mixed plantation of both trees and shrubs, or of forest-trees and under-wood, and may comprise any amount of diversity of species, or present any variety of disposition or outline. Its prevailing character is grandeur. A grove consists of trees without shrubs, and pleases the eye not only as seen in mass, but by the individual forms of its component trees. Its prevailing character is beauty. A clump is a small separate patch of either wood or grove: it is either close or open; and in the former case it is sometimes called a thicket,—in the latter, a group of trees. Its prevailing character is gracefulness or finish.

A wood seen from the stand-point ascending the side of a hill, and terminating on the horizon, is one of the noblest objects in a landscape. It fills the eye, occupies an entire space, soars to the clouds or to the sky; yet seems all distinct, all at hand, all a part of the home scene. But if its extremity do not go quite to the sky-line, unless the characters of the hill-top above it be of a peculiar and striking character, the effect will be greatly marred. A wood seen from below, covering even a small hill to the summit, generally looks grander than one covering a much larger hill only to the shoulder. A wood seen from the stand-point spreading down a slope is still less effective. This may form only a small part of the scene, and will then be deficient in its essential character of grandeur; or it may wind out of sight or become lost in the horizon, but will then want distinctness of surface and firmness of outline. A wood on very broken ground, in a deep, winding ravine, or in any similar situation, though incapable of expansive greatness, may fully atone for it by rude magnificence and romantic force.

Varieties on the surface of any wood are essential to its effect. One variety arises from the different forms of its different kinds of trees; another from the differences in their rapidity and mode of growth; another from differences in their hues of green; another from their shadows; another from the groupings and contrasts in their order of arrangement; and another from the inequalities of the ground, and from breaks in the planting. In forming a new wood, an artist has all these varieties completely under his power, so that he can give it the best possible surface; and in improving an old wood, he may so operate on many spots, by thinning or thickening, by removing some trees or supplying others, as to render its surface scarcely inferior to that of a new one. Care must be used to render the varieties distinct, to make the groups and the masses broad, and yet not to destroy the unity of the wood, or to dissever it into contrasted parts. A single tree, or a small cluster of trees, in the midst of an extensive wood, makes no sensible variety; while a number of masses, contrasted to one another in character, standing mutually adjacent, without intermediate blendings, constitute not properly one wood, but a confused collection of several. A wood on a hill,

seen from below, requires to be thick, in order that it may not appear meagre, and must derive the variety of its surface mainly from the tops of its trees; but a wood on a slope, seen from above, suits well to be thin, showing its trees almost in the manner of a grove, and admits a large play of variety in their differences of species, habit, hue, and shadow. A wood in a broken ravine, or in any other ground with strong and salient inequalities, admits of the widest diversities and of the nearest contrasts. A deep hollow in it may be filled with trees of the darkest green; an abrupt bank may be occupied by trees rising above one another, like the tiers of an amphitheatre; and a sharp ridge may be crowned by a narrow line of cone-shaped firs or pines.

The outline of every wood also demands attention. This is completely under control; it can generally be determined by mere taste or will, without impediment from the ground; and it often produces stronger effects than any which arise from the character of the surface. The outline must be irregular: not a series of straight lines or easy curves, but a bold and various combination of sweeps, angles, and breaks. Its main diversities must be either projections or recesses, all differing from one another in length and breadth, and all rather long than broad, and narrowing to a point. These, besides being features in themselves, give peculiar force to the general outline, and have the effect of enlarging the apparent extent of the wood. Several projections from a narrow wood, or hill, or slope, will make it look grander than a much larger one of compact outline; and a deep recess in an extensive wood on a flat, penetrating beyond reach of the eye, and winding inward to a concealed extremity, produces some of the same kind of impressions as a profile scene in a great natural forest. Some parts of the outline, especially across the entrance of recesses, may be materially aided in force and elegance by a thin sprinkling of individual trees. A main rule in the forming of a wood is to modify its grandeur, to blend graces with its greatness, to diversify its uniformity, and to give strong, diffusive, intricate effect to its masses.

A grove differs from a wood, not only in containing no thicket, and in being characterized by beauty instead of grandeur, but in aiming to please the eye rather by its interior arrangement than by its outward form. It is an assemblage of trees to be seen in detail, and admired in all its parts. Its trees are so arranged, singly and in groups, that they may please the eye both by their individual elegance and by their combined effects. The surface and the outline of a grove are of much less consequence than its inner depths. An observer goes into it to walk through it, to stroll in it, or to sit; and he reserves most of his expectations from it to what he shall see in its interior. Main care, therefore, must be given to the choice and disposition of its trees. Varieties of species must be selected in every style of elegance, from the light to the massive, from the graceful to the romantic, from the bushy to the aspiring, in order at once to exhibit a large amount of loveliness in the individual forms, and to intensify and multiply this by comparisons and contrasts. Other varieties must be chosen in every style of habit; some with density of growth, some with large but few branches, some with light thin boughs and leaves, in order to produce every degree of light and shade, from a glare to obscurity. Differences in hue are of less consequence, and ought sometimes to be avoided. The disposition should be a mixture of irregularity and order, free from both uniformity and confusion. The trees should stand in groups or form irregular lines, and describe a variety of figures. The groups and the lines should be so contrived as to show to advantage the characters of the individual trees. The intervening spaces should vary in extent and form; some large and open to the sky, some over-arched with branches or contracted to a mere passage, and all so arranged with relation to one another as to afford frequent transitions and contrasts. The disposition of a new grove may be twofold,—first, with reference to its effect while all the trees are young and small; next, with reference to its matured condition, when the majority of the trees have been removed by thinning.

A clump with shrubs is formed essentially like a wood, and a clump without shrubs essentially like a grove. Clumps, however, as compared with woods and groves, are small objects, and they must be treated according to their dimensions. Sometimes also they stand in an isolated manner, and then must be treated with reference only to their own beauty; but oftener they stand in a relative position, connected with one another or with an adjacent wood or grove, and then they must be treated with reference to the character of the entire scene. Isolated clumps are most in request for relieving an expanse of lawn or breaking a continuous line of hill or slope; but unless designed by a very skilful artist, they may prove rather deformities than ornaments, remarkable for ostentation or clumsiness, and looking like large blots in the landscape. A single one, in almost any view, looks better than several; and one of the best is an open one at the point of an abrupt hill, or on a promontory in lake or river. Related clumps do best to be related to one another throughout an extensive lawn, to control its entire shape, and form beautiful glades; and either in that position, or when related to an adjacent wood or grove, they produce their desirable effects less by their own forms than by their connections and their contrasts.

Water is an important material in a landscape garden. An arm of the sea, or the sea itself, may fill more of the view than the entire ground; and a river or lake may figure as largely as hill or lawn. These in general can be improved only on the margin, and chiefly by planting; but they often admit of improvements there so extensive, rich, and varied, as to give a new character to all the landscape. What these improvements precisely are must be determined by the conditions of shore or banks, but usually appear so obvious that they need not be described. Lakes of a beautiful or picturesque kind can often be formed within the grounds; small streams also, if they have a good fall, through plantations or lawns, may sometimes be greatly changed; and these two forms of water make large demands on the care of the landscape gardener.

The proper situation of an artificial lake is a vale or hollow traversed by a little stream. The particular spot must be carefully chosen with reference both to its own limits and to the features of the surrounding ground. The bottom and sides may be either under-drained, puddled, or otherwise prepared, to prevent any contraction of foulness. A dam of an ornamental kind must be raised across the lower end, to stem the water and to form the lower boundary. The traversing stream must consist of limpid water, must not be subject to muddy freshets, and ought, if possible, to be sufficiently large and constant to maintain the lake in constant purity. Everything in the banks and in the encompassing vegetation must be avoided which would lead to marshiness or putridity. The depth of the water need not exceed five or six feet. The slope of the banks must not be too steep, and ought to blend well with the surrounding ground. The form of the lake must not be elongated, but expansive, with a breadth in good proportion to the length. Its surface may be broken by one or more islets, or invaded by one or more little peninsulas, yet only of such size and in such circumstances as will not injure the view of it as a whole, or make it appear like a collection of ponds. The outline also may be diversified, and even made intricate, with little bays and promontories, yet must so far approach regularity as to possess appreciable shape. Its immediate margin, to a variable breadth, may consist of clean gravel or rich sward, according to the na-

ture of the ground; but all the rest of the banks must be variously planted with shrubs or trees. Mounds may be thrown up, or cuts made, to increase the diversity of the ground; but all these, as well as the natural surfaces, should receive every decoration which can be given them by the rules already laid down for the making of a grove.

Small streams with a lively current may sometimes be altered, with picturesque effect, throughout most of their course, within a landscape garden. If two or more flow near each other, they may perhaps be advantageously thrown together to form one current. The stream need nowhere be furious except at cataracts or cascades; but neither must it be anywhere dull or stagnant, except at pools, and therefore it may be straitened at dull tortuous reaches to increase its velocity. Cataracts or cascades may be improved or formed at places of sufficient descent, and eddying pools may be created at sudden bends overhung by high banks. Bits or masses of rock ought to project boldly at the falls, and may often take an increase of apparent height and dignity from diggings to expose them, and will generally admit of being picturesquely shagged or romantically diversified with shrubs or trees. The general course of the stream can be variously sown with herbage and planted with wood, in such manner as to allow ferny banks, and narrow, winding, shady walks; and a tortuous reach of it, with sufficiently lively current and of sufficient length, may be crossed and re-crossed by the walks over little rustic bridges, or by means of stepping-stones.

Bits or masses of rock in all kinds of situations often give scope for much improvement. Any appearance of them, indeed, in a meadowy or champaign tract is incongruous, and requires to be hidden by gentle mounding or by planting. But even detached pieces of rock, rough and large, fitted into the ground and partially covered with vegetation, on spots of a bold character, such as at the foot of a wooded acclivity, have often an excellent effect, if not directly on the eye, at least on the imagination. Slight protrusions of rock at the walls of a terrace give an idea of dryness and stability; larger protrusions in remoter parts often afford picturesque aid to the diversities of the ground or to the forms of plantation; and ledges of rock, whether they exist naturally, or can be laid bare by art, form a fine flank to a road, a cross, or a declivity. Large protuberances, cliffs, or other huge masses, are features, or assemblages of features, substantially beyond the reach of art, yet admitting as much change on the surface, by mounding, by digging, and especially by planting, as largely modifies or alters their expression. Their prevailing character ranges from savageness to dignity; and when disagreeable, it may be concealed; when imperfect, it may be improved; when pleasing, it may be magnified. Rocks of a disagreeable appearance may generally be concealed by wood; rocks deficient in apparent or relative height may be improved by the removal of earth from their base, and the planting of a line of wood along their summit; rocks standing apart from one another at intervals which destroy or mar their picturesque effect, may be woven into one scene by means of shrubs and trees planted partly on their skirts and partly in the intervals; and rocks of lofty stature and irregular face, soaring, precipitous, rent, and shelving, may be worked into a mingled display of beauty, romance, and grandeur, by the skilful disposition of points, tufts, lines, and masses of wood.

The materials of landscape gardening which we have hitherto noticed—ground, wood, water, and rocks—are natural; but others requiring notice—small in value compared with the natural, but equally indispensable—are factitious. These consist of fences, walks, roads, bridges, seats, and buildings.

Boundary fences do not belong properly to the landscape garden itself, but ought to be well concealed from its walks by masses of shrubs and trees, and may be constructed in any style of security which comports with neatness. Even interior fences have a place in the garden, not as materials of ornament, but as matters of necessity, and do best to be as quiet and unconspicuous as circumstances will permit. Sunk fences are the most desirable, and ought always to be preferred, but are seldom suitable for any situation except between the lawn and the park. Light iron fences, or what are called continuous fences, are generally the best in other situations. A neat rustic wooden fence may suit well to protect plantations from cattle or sheep. Hedges anywhere within a landscape garden, especially in its more open parts, are deformities and obstructions, disagreeable in themselves, and damaging to the view; and even around plantations, they give them a hard, stiff outline, and blot out the sweet beauty which belongs to the trail of their branches on the ground.

The walks in a landscape garden are designed both for the exercise of walking and for the disclosure of the scenery. They must be so formed in material, slope, and border, that they can be comfortably used in wet weather. They ought to lead from view to view, to take a variety of levels, to be concealed from one another, and to command at successive spots all the best aspects of the house, of the garden itself, and of the surrounding country. Their direction must be determined by the points to which they lead, and the nature of the ground over which they pass. They ought never to run long in a straight line, but ought to wind hither and thither in continual variety of sweep, neither making abrupt turns, nor setting their curves to any regular radius.

Some roads within a landscape garden, as drives and rides, are designed only for amusement; while others, as the approach to the mansion, are designed expressly for communication. One road may be formed to serve both kinds of purposes; but every road of a specific character ought to have a direction adapted to its specific use; and a road for communication needs to be straighter than one for mere amusement. The principal road is the approach to the mansion. This generally does best to be a waving line, with very easy sweeps, controlled by inequalities of the ground, and passing through a diversity of wooded scenery; but on a flat tract of large extent, leading to a house of pretty regular form, it may all be a straight line, along an avenue of two, four, or more rows of trees. The first view of the house from it should be oblique or angular, and in good perspective; and the concluding view should show the entire façade and the entrance. The terminating piece of gravel for carriages to turn in is sometimes made so large as to have a diminishing and disfiguring effect on the surrounding objects, but need not be of greater breadth than from thirty to forty feet.

Bridges must be at once useful, ornamental, and consistent. They must exist only on spots where walks or roads really need them, and must possess the kinds of character and elegance most in harmony with the scenes around them. A bridge for a footpath over a brawling streamlet in a wood, or over a stripe of lake to an islet, may suit well to be nothing more than a strong rough plank, with wooden props, and a wooden hand-rail; one for a footpath in a more conspicuous situation may still be all of wood, somewhat elaborated, yet light and rustic; while a bridge for a drive, or for the main approach, amid the finest scenes of the garden, ought to be a structure of stone or iron in some of the highest styles of elegance which architectural skill can design. Bridges of any kind, in any situation, must be well supported at their ends with bushes or trees, to relieve the rigidity of their lines, and to make them blend softly with the adjacent ground; and embankments leading to them, if any embankments be necessary, must be well masked with masses of shrubs.

Seats are useful for rest, shade, and conversation. They

should be set down at all points which command good views, but are seldom appropriate in other situations. Their character, like that of bridges, must be in harmony with the scenery. In rude spots the simple trunk, rough from the woodman's hands, and the stools of rooted trees, without any other marks of tools upon them than those of the saw which severed them from their stems, are proper seats; and in romantic or recluse spots, caves, or grottos, natural or artificial, dry within, and commanding fair views, may be suitable; but all must be so formed and finished as to look in keeping with the adjacent ground. In spots near the mansion or among the finest embellishments of the garden, the seats of even the simplest form require to be elegant and of a light colour, and the most conspicuous may have architectural features.

The buildings of a landscape garden present enormous scope for design, and are in a considerable degree the subject of a specific art. They do not belong to architecture alone, or to gardening alone, or to any ready or obvious combination of the two. Even the mansion must not be designed by a mere architect, but requires in many respects, particularly as to site, style, and harmony with surrounding objects, to be determined also by the landscape gardener. Other buildings of a decorative kind throughout the grounds demand a skill which shall combine proficiency in most of the fine arts with power to adapt their designs minutely and variously to effects on landscape. Loose theory, rather than any system of rules, has hitherto prevailed respecting them; even sheer caprice has not seldom taken the place of theory; and whatever taste or judgment may have controlled the theory or the caprice has been subject to extreme change, from fluctuations in architecture, from fluctuations in gardening, and from collisions and repulsions between the two. A passion long reigned, especially on the Continent, for crowding gardens with all sorts of decorative buildings; the tide of taste turned, continued long on the ebb, and seemed about to carry them all away; but again a love for them, of a chastened kind, and under jealous rules, has revived. We cannot more fitly express the best existing cast of opinion respecting them than in the words of Mr Edward Kemp, in the second edition of his work, *How to Lay Out a Garden*, London, 1858. He says (pp. 178–183):—

"Modern tendencies in gardening have been too much away from its character as an art, and the more it is restored to its legitimate position, the more nearly will it be brought into kindred with architecture. On the other hand, the too commonly cumbrous, regular, and unyielding nature of architectural objects, when used for garden decoration, has tended still further to detach two pursuits which are essentially and obviously allied. For, as a house and a garden are naturally and intimately associated, and it is a law of the universe that the boundaries of each domain in the natural kingdom should insensibly mingle and be lost in each other; so it is plain that an unvitiated taste would be most gratified when the province of architecture is extended so as to embrace lightly and harmoniously such parts of the garden as may be most contiguous to the house; while the garden also in these parts rises in character to meet the requirements of the architecture, until either art is so refined and attenuated that it would be almost difficult to say what belongs exclusively to each. Still there is that about gardening which, in the nature of things, and apart from the difference of the materials with which it has to deal, constitutes it a distinctive art. And garden architecture has lineaments of its own so decidedly removed from those of house architecture, and so seldom studied, that the ordinary architectural practitioner is at sea the moment he enters the region of the garden. It is less a matter of rule and measurement. Its effects are more to be judged of by the eye. It comprehends a far greater variety of combinations. It requires a man to be as much an artist (at least in feeling) as an architect, and to be familiar with natural groupings and tones, to take in an entire landscape in the range of his design, and not merely isolated or detached objects. In fact, the garden architect has to make a general picture, and not simply to set a work of art, as it were, on a solitary pedestal.

"The province of garden architecture is, primarily, to supply fitting appendages and accompaniments to a house, so that the latter may not appear naked, alone, and unsupported. If judiciously applied, it will be effective in helping to produce a good outline or group; to carry down the lines of the house; to connect it with other buildings, such as a conservatory, arbour, &c.; to provide a proper basement for the house; to afford shelter and privacy to a flower garden; to extend the façade or frontage of a house; to shut out back-yards, offices, &c.; to enrich, vary, and enliven the garden; to supply conveniences, such as shelter, receptacles for birds, plants, sculpture, &c., with museums for works of art or specimens of natural history, and supports for climbing plants; to indicate refinement, wealth, and a love of art; and otherwise to blend the various constituents of a garden with the house, and harmonize the two by communicating a more artistic tone to the garden. Wing-walls to a house, broken by a conservatory, and terminated by a summer-house, aviary, museum, or sculpture-rooms; corridors, similarly broken and terminated, and glazed or open, so as merely to form covered ways; conservative walls, either glazed or simply protected by bold projecting piers and copings; viaducts, aqueducts, arbours, arches, arcades, tunnels, boat-houses, temples, prospect and flag towers; with an almost infinite number of smaller objects, such as sculptured figures, sun-dials, statuary, pillars, obelisks, terrace-walls, &c., constitute the elements with which garden architecture has to work.

"In its leading traits, it necessarily comes within the same category as house architecture, and is governed by the same principles. Like the house, it should exhibit design, some degree of symmetry, harmony of parts, unity of expression, consistency of style, fitness for the locality, adaptation for the intended purpose, and stability and permanence of appearance. But it should also display a greater amount of lightness and elegance; a comparative absence of regularity; a decorative rather than an exclusively useful purpose; a superior variety of outline; extreme attention to general grouping; a blending of its forms with those of nature; an especial regard for placing its creations where they will have a distinct meaning and object; a leaning to the use of good materials, but somewhat rougher than those employed in the house; a preference rather for a picturesque outline than for mere ornamental details; and, as a most important characteristic, a marked boldness and prominence of parts. Indeed, picturesqueness, such as would be occasioned by changes of level in the ground, by diversity in the heights of walls, by prominent piers, buttresses, or cornices, by broad projecting eaves to the roofs of buildings, and by any arrangement that will yield depth of shadow, should be the ruling constituent of garden architecture.

"Every architectural object admitted into a garden should form part of the general plan of that garden, and fit into its proper place. It will create a serious incongruity if merely put down at random, or not duly established as part of the main design. Smaller architectural ornaments, too, must be adequately connected with and kept in the neighbourhood of the house or other sufficiently important building; otherwise they will be too different from the forms of nature to appear harmonious. A strictly garden building or object, unless very large, should never be obtrusive. It ought always to be quiet-looking, and not violently different in colour from the surrounding vegetation. Hence white, whether in marble, stone, or painted objects, is decidedly

to be avoided, and a warm drab or a darker tint to be preferred. When a terrace or other ornamental wall, whether balustraded or otherwise pierced, or simply devoid of any relief in the way of openings, becomes the principal foreground to a garden or other scene, as viewed from the windows of the house, it will, however much it may be broken up by piers, vases, &c., appear too hard, cold, and monotonous, without some aid from grass and shrubs. In all such cases, therefore, there should be a broad band of grass between the terrace-walk and the wall; and a few clusters of evergreens, rising in broken masses above the line of the wall, or of climbers mantling its summit in occasional patches, will require to be skilfully introduced, otherwise the wall would seem to divorce rather than mingle with the landscape beyond.

"To pass from the consideration of garden architecture, I now return to the subject of architectural gardening. Its distinctive principles are,—a strict observance of rule; a prominent indication or exhibition of art; the maintenance of a decided harmony and connection with the house and other architectural objects; the adoption of regular figures; the employment of rigid, formal, and exotic plants; the necessity for flat and even surfaces, with the use of terrace-banks or extremely regular slopes; and the production of a conspicuous character of dignity and repose. The proper sphere of architectural gardening is the immediate neighbourhood of the house; as an accompaniment to particular styles of architecture, especially the Italian; in connection with detached architectural structures, as temples, plant-houses, &c.; within the circuit of the flower garden, parterre, rose garden, &c.; in the gardens attached to a palace, mansion, or first-class villa, rather than to a small villa or cottage residence; the kitchen garden; and, where the circumstances are favourable, the town garden.

"There are certain incongruities and defects which frequently attend the practice of architectural gardening, and which should be sedulously avoided. Some of these are the mixture of inharmonious styles; the use of rustic or unarchitectural ornaments, except in remote parts, and where they will not be observed as constituents of the general scene; the placing of terrace-walls or other erections on a sloping bank, or where they have shelving ground immediately below them; the extension of a formal mode of treatment into the park; generally the obtrusion of a flower garden into the view from the principal windows, unless it be on a lower level than the base of the house; an avenue or row of trees that crosses any main line of view, or one on the summit of a hill that forms the line of horizon; a curved avenue; a ground-line that is oblique to the basement of the house on either of its chief fronts; diagonal lines of walk on lawns, or walks crossing or starting from other straight walks at any but a right angle; plants trimmed into formal or grotesque figures, unless it be the heads of standards,—plants with naturally appropriate habits, or confined in tubs, being preferable; gravel-walks in flower-gardens that are inaccessible; monograms, or very intricate patterns, in which the beds are too small to admit flowers, for parterres; and the employment of pavements, gravels, or sands, of different colours, in the place of flowers, or merely for producing variety or contrast.

"Among the most characteristic details of architectural gardening, prominence should be given to terraces; broad, flat, and conspicuous walks; extreme smoothness and polish; changes of level, effected by formal banks or walls; raised beds and sunken panels; avenues, vistas, rows of flower-beds; walks and vistas terminating with some proper object, as a temple, obelisk, pillar, &c.; rectangular forms, or those in which various segments of a circle are combined; with a sunk fence and parapet-wall as boundaries to a garden. There are likewise many desirable accessories, of which a few may be noted. These are,—a sufficient breadth of open lawn between the house and the park; a detached flower-garden, with accompanying plant-houses, glass walls, or walls for ornamental climbers, and the opportunity of looking down upon this garden from a raised terrace; a rose garden in a retired spot, with attendant rose-house, or houses for delicate sorts; a winter garden, to be filled exsively with evergreens, the beds arranged in pattern, with a due admixture of specimens, and all the plants selected with reference to their habits and the colour of their foliage in winter; a garden for bulbs, florists' flowers, &c., in some spot which need not be made accessible during the winter; standard or fastigiate plants; plants that blend best with architectural objects; groups or beds of plants, in which one kind or class prevails; and hedges, whether to frame and inclose scenes that it is wished to detach, or in a diminutive state, to make borders and edgings to flower-beds and clumps.

"In practically applying the principles of architectural gardening, it should be remembered that, as extreme irregularity is a merit and a beauty in most kinds of Gothic architecture, the garden accompanying it will also bear to be treated in an equally irregular manner. But, in relation to any variety of Grecian or Italian house, the garden, like the architecture, should be more distinguished by symmetry and regularity. Architectural gardening would further be out of place in connection with a house inferior in design, or destitute of character and style. It is peculiarly suitable for a tame and smooth general landscape; but is quite admissible, for contrast, in a picturesque, bold, and wild region. It specially demands that everything should be good and nicely finished; that the plants shall be of the best and most carefully-selected kinds; the grass evenly laid; the figures, and beds, and edgings of walks neatly and accurately cut; the gravel fine and well laid, and its smoothness (and that of the edgings) not obviously broken by gratings. The edgings, too, should all be particularly shallow, the edges of terrace-banks quite square and even at the top, and the soil in the beds and clumps very slightly raised above the level of the lawn. The spaces for specimens, flower-beds, and masses of shrubs should, moreover, be cut out of the flat lawn, and not have the grass curved up to them, as in the more natural style of treatment. And all the lines, whether of walks or other edgings, ought to be extremely straight or regular, thoroughly well-beaten and level, and the grass be very fine and smooth.

"The practice of employing masses of evergreens to cover changes of level in grounds, to break the transition between a terrace-bank and a natural slope, to fill up the corners of terraces and relieve the hardness and bareness of their walls, and in many ways to reconcile discrepant lines in the form of ground, is one which I have largely and for several years adopted. And I have invariably found it of the greatest possible service, while the result obtained from it is always satisfactory. Indeed this seems to be the only feasible and really thorough solution of a problem which every practitioner who has to direct the shaping of ground about houses must be constantly encountering."

Planudes || La Plata.

PLANUDES, Maximus, a learned Byzantine monk, flourished at the court of Constantinople in the first half of the fourteenth century. His inquisitive, self-confident mind seems to have meddled with many branches of knowledge. He dipped into politics, and was sent in 1327 on an embassy to Venice. He tampered with controversial theology, and was lodged in prison for his leaning towards the creed of the Roman Church. His interest in the exact sciences was also great, as his manuscript work on the *Indian Mode of Calculation* sufficiently testifies. (See Arithmetic.) Nor was time wanting for dabbling in classical literature, and for making Greek versions of Cicero's *Somnium Scipionis*, Cæsar's *De Bello Gallico*, and other Latin works. But it was in the character of an editor of Greek epigrams that Planudes chiefly recommends himself to the notice of posterity. His object was to abridge and re-arrange the scarce *Anthology* of Constantinus Cephalus. Careless and devoid of poetical taste, he blundered along, choosing and omitting at random. Occasionally his clumsy hand expunged whole couplets to make room for stiff and prosaic verses of his own, which his self-conceit imagined to be better. The ungainly collection was completed in seven books, and owing to the scarcity of other anthologies, continued for a long time to be popular, and to pass through many editions. The latest and most perfect edition is that of De Bosch and Van Lennep, in 5 vols. 4to, Utrecht, 1795–1822.

Plassey || La Plata.

PLASSEY, a village of British India, in the district of Nuddea, presidency of Bengal, on the left bank of the Hooghly, 96 miles N. of Calcutta. It is memorable as the scene of the victory that laid the foundation of the British-Indian empire. On the 23d of June 1757, Clive, with a force of 900 Europeans and 2100 Sepoys, crossed the river to attack 68 000 men under Sooraj-oo-Dowlah, soubahdar of Bengal. After much cannonading on both sides, Meer Jaffier, who was in the interest of the British, advised the soubahdar to retreat. Clive immediately advanced, routed the army, and took the camp of the soubahdar, who was dethroned to make way for the traitor Meer Jaffier.

PLASTER, in *Pharmacy*, an external application of a harder consistence than an ointment, and which is, according to the different circumstances of the wound, place, or patient, spread either upon linen or upon leather.

Plaster of Paris. See Gypsum.

PLATA, LA.

The United Provinces of the Rio de La Plata, otherwise called the *Argentine Confederation*, a country of South America, lies between S. Lat. 22. 20. and 40. 56., and between W. Long. 55. 20. and 70. 30.; and is bounded on the N. by Bolivia; E. by Paraguay, Brazil, and Uruguay; S.E. by the Atlantic; S. by Patagonia; and W. by Chile. It extends from the eastern slope of the Andes to the rivers Paraguay and Uruguay, which separate it from the respective countries of these names; and on the S. it is divided by the Rio Negro from Patagonia; but there is no natural boundary on the side of Bolivia. The country thus bounded includes the province of Buenos Ayres, which is at present independent of the Confederation. But as the existing arrangement is merely provisional, it will be included in the general description of the country. The greatest length of the country is about 1260 miles from N. to S., the breadth varies from 500 to 800, and the area is estimated at 786,000 square miles. The country is partly mountainous, but about five-sixths of its area is occupied by immense plains.

Mountains.

The Andes in the southern parts of La Plata are comparatively little known. They consist of two parallel ranges, of which the western, being the more elevated, forms the boundary-line of Chile and La Plata. The general elevation of these mountains is 12,000 or 13,000 feet above the sea; and they are crossed by several passes. North of the 37th degree of latitude the country is better known; the same character prevails, the distance between the ranges varying from 30 to 80 miles. About 33. 30. S. Lat. they approach to about 20 miles of each other, and between them lies the elevated valley of Tunuyan, 7500 feet above the sea. Farther north the mountains again recede, forming the wider valley of Uspallata, on the west side of which rises Aconcagua, the loftiest known volcano in the world. North of the 30th parallel the mountains extend over 120 miles of breadth, and form three parallel chains,—the Andes proper to the west, the Sierra Famatina, and the Sierra Velasco,—none of these ranges being so high as the more southerly ones. North of this point the Andes send out branches far to the east; so that the whole of the N.W. of La Plata, as far as the Rio Vermejo, is a mountainous region. The loftiest part of this region, known by the name of *El Despoblado*, or "The Desert," occupies the extreme N.W. of the country, and is a level plateau 13,000 feet high. From this table-land several mountain chains diverge in different directions,—the principal being the Sierra Ambato and Sierra Ancasta, stretching S.E.; and the Sierra Aconquija, a branch of the Sierra Ambato, towards the N.E. The north-eastern part of La Plata, near the Paraguay, is also mountainous; and in various parts of the country there are ranges of hills and mountains which would be conspicuous anywhere except near the Andes.

Plains.

By far the greater portion of La Plata is low and flat, constituting what are called the *pampas*. These occupy the whole breadth of the country, from the 33d degree of latitude to the Rio Negro; and they are divided by elevated regions into various parts, in which the soil varies considerably in fertility. The eastern and western portions of the plain also differ in their character; and there are three marked belts or regions stretching across the pampas from north to south. For about 180 miles west of Buenos Ayres the ground is covered with clover and thistles alternately. In winter and spring the luxuriant and shaggy leaves of the thistle give the whole region the appearance of a vast turnip field; and in the former season the clover, which is very rich, is grazed on by herds of wild cattle. In summer the thistles rapidly shoot up to the height of 10 or 11 feet, and become so strong and dense as to form an impenetrable thicket. In autumn the thistles wither and die, the dry stems continuing to rattle in the wind until they are laid low by the hurricanes of the region. West of this region an immense plain, covered with long grass, stretches for about 450 miles. There are also lakes of salt water, and salt marshes overgrown with reeds, in this plain, the soil of which is strongly impregnated with muriate of soda, giving even the grass a salt taste. Beyond this a tract of country extends to the foot of the Andes, covered with low thorny trees and bushes, and having a soil which, though arid, sandy, and saline, only requires irrigation to bear the most abundant crops. The western portions of the pampas have been very little explored except along the banks of the rivers; but their character in the northern part of the plain, which is traversed by the road from Buenos Ayres to Mendoza, is well known. The plains of Patagonia, which extend southward from the Rio Negro to the Strait of Magellan, and are claimed by La Plata, are described under

La Plata. PATAGONIA. North of the pampas, between the Sierra Velasco and a parallel ridge of hills called the Sierra de Cordova, there is a level plain, only a few feet above the sea-level, covered with an incrustation of salt, from which it has got the name of Great Salina. But the most remarkable plain in La Plata, next to the pampas, is that called the Gran Chaco, which occupies the N.E. portion of the country, and covers an area of 120,000 square miles. It is very little known, being but thinly peopled, and that chiefly by Indians. The southern part is an arid, sandy desert; while the northern portion is covered with extensive forests. Between the Gran Chaco, which extends as far south as 30°, and the pampas, lies an undulating country of considerable fertility; and the country between the Parana and Uruguay is occupied with hills, forests, and pastoral plains.

Coast. The coast of the country, extending from the estuary of the La Plata to the mouth of the Rio Negro, has few indentations, and is in general low, consisting of sand-hills or cliffs of little elevation. The principal promontory is Cape Corrientes, in S. Lat. 38. 6., which is a high and rather bold headland. Samborombon Bay and Bahia Blanca are the only bays on the coast; the latter contains Port Belgrano, the best and most capacious harbour south of 25. S. Lat., and the nearest point on the Atlantic from which a communication might be established with Conception on the Pacific.

Rivers and lakes. The principal rivers of La Plata are those which fall into the estuary from which the country derives its name. (See PLATA, *Rio de la.*) Besides these, La Plata contains few rivers of any size. The Rio Salado of Buenos Ayres flows through the pampas, and falls into the Atlantic. It is dry in summer, and can be used neither for navigation nor irrigation. Farther south is the Rio Colorado, rising in the Andes, and flowing S.E. to the sea. Its whole length is between 500 and 600 miles, of which it is navigable for about 100. The Rio Negro also rises in the Andes by two branches, and flows at first N.E.; and after receiving the Neuquen from the north, it flows E. and S.E. to the Atlantic. Its whole length is nearly 600 miles, and it is navigable for large boats about 500.

Numerous rivers take their rise in the eastern declivities of the Andes, and after irrigating considerable tracts of country, are either absorbed by the soil or flow into inland lakes. Amongst these may be mentioned the Rio Dolce, which originates in the lofty mountains of Tucuman, and, after watering the capital of the same name, passing near Santiago del Estero, capital of the province so named, and traversing Cordova, is lost in a salt lake situated in that province, and called "lagunas saladas de los Porongos." The Rio de San Juan and the Rio de Mendoza rise in the valley of Uspallata, and flow, the one from its northern and the other from its southern opening, into the lagoon of Guanacache, which is one of a series of lakes between 31. 40. and 32. S. Lat. These lakes are drained by a river called the Desaguadero, which flows S. and E. for 250 miles into another group of lakes, called Belvedero, between 33. 30. and 34. 30. S. Lat. They receive also the Tunuyan from the valley of the same name. Another branch of this river flows south, and, joining the Rio Diamante and the Chadi Leubu from the Andes, flows into the Urre Lauquen, a lake but little known, in 37. S. Lat.

Lakes are distributed over the whole expanse of the pampas, and some of them are of considerable size; but they cannot be said to correspond in grandeur to the other features of this region. The soil is almost everywhere impregnated with salt; and the water of most of the lakes and pools is brackish and disagreeable to the taste. So plentifully is this saline matter distributed, that whole tracts of country are covered with its efflorescence. But a want of water is universally experienced; for notwithstanding the number of lakes and inferior rivers, many of them disappear during the dry season. A growth of rushes overspreads their bottoms, serving as lairs for the pumas, that lie in wait for the cattle, as, perishing of thirst, they fly to the green stagnant water which lies on the marly surface and swarms with myriads of mosquitos.

Geology. The geology of this country presents little variety, and scarcely anything that is interesting. Rocks are seldom seen, except in the mountainous region. Where they do occur, they are generally granitic, covered in some places with quartz. Some gypsum is found in the vicinity of Buenos Ayres, and limestone is said to occur in several places. The stones used in paving the streets or in building are brought from the island of Martin Garcia, at the mouth of the Uruguay, or as ballast in vessels from Europe.

The soil of the pampas is a rich mould, perfectly free from stones, not one being seen on its surface for many hundred miles together. One of the most remarkable features of this region is the number of fossil remains, chiefly of immense quadrupeds, which are found in the soil of the plains.

The mineral productions are gold and silver, copper, tin, lead, and iron (of which large masses are often found), saltpetre, alum, sulphur, marine salt, and bituminous shale; and there are also numerous mineral springs besides the saline lakes already mentioned, from which salt can be procured.

Climate. The tropical climate which prevails in the northern districts disappears more and more towards the south; so that snow and ice are not unknown. Upon the east coast the air is humid, and rain, thunder, and violent storms are not unfrequent; but in the western district the atmosphere is free from vapour, rain is unfrequent, dew never falls, and the drought is often very great. The climate of the pampas is subject to a great difference of temperature in winter and summer, although the gradual changes are very regular. The winter is about as cold as November is in England, and the ground at sunrise is invariably covered with white frost, but the ice is very thin. In summer the sun is oppressively hot; and not only is manual labour suspended during the middle of the day, but even the wild horses and cattle are exhausted by it. The only great irregularity in the climate is the *pampero*, or S.W. wind, which sweeps over these plains with a velocity and a violence which it is impossible to withstand. These periodical visitations, however, produce beneficial effects, the weather being particularly agreeable after they have exhausted their fury; and, taken as a whole, the pampas may be said to enjoy as beautiful and as salubrious an atmosphere as the most healthy parts of Greece and Italy, and without being subject to malaria. With regard to humidity, the atmosphere varies much in different parts of the country. In the provinces of Mendoza and San Luis, or in the regions of wood and grass, the air is very dry, and there is no deposition of dew at night; but in Buenos Ayres a considerable quantity of moisture prevails in the atmosphere, probably from the vicinity of the place to the ocean.

Productions. In some parts of La Plata there are wooded tracts, consisting of palms, cedars, and other trees; but from the Rio de la Plata to the Straits of Magelhaens, as well as throughout the most part of the pampas, we find neither tree nor shrub. In the country north of the Gran Salina tropical productions are raised, such as mandioc, rice, maize, sugar, cotton, and tobacco; while the Paraguay tea plant, the cactus that bears the cochineal insect, the aloe from the fibres of which ropes and cordage are made, and other plants, grow wild here. In the southern regions wheat and maize are principally grown. Cultivation hardly extends beyond the banks of the Parana and the mouths of the other rivers. The N.W. part of the country is chiefly agricultural, while the eastern and southern regions abound in pasture land. The fruits of Southern Europe grow in La Plata

La Plata.

Animals.

This country has long been celebrated for the abundance of its cattle, horses, sheep, goats, asses, mules, and swine. The horses are both wild and tame, and the number of them, as well as of the cattle, is immense. The number of cattle in 1851 was estimated at twelve millions; and the horses, mules, and asses are probably far more than four millions. Amongst the wild animals may be mentioned the jaguar, the puma (which may be said to represent the lion in the New World), the carpincho or water-hog, tajassu, tapir, armadillo, guanaco, monkey, deer, many species of serpents, locust, mosquito, wasp, ant, bee, &c. Amongst the birds of this country may be mentioned the condor, Brazilian eagle, many hawks, emu, crax, guan, wild turkey, parrots, troupiales, woodpeckers, many species of duck, &c. Near the Andes, and on the banks of the Parana, bees are kept, and wax is collected. The cochineal insect is also reared. Of fish, there are various kinds in the rivers; and along the coast whales and seals (which yield train-oil and fish-bone for exportation), sharks and turtles, are found.

Inhabitants

The population of La Plata is very various in its character and origin. It consists of natives, of Spaniards, of races of mixed native and Spanish blood, of Negroes, and of European immigrants. The Indians themselves are not all of the same race, but belong to three different classes. In the mountains and valleys of the N.W. dwells a race of Peruvian origin, speaking the Quichua language; east of the Parana lives a race of Guaranis, who are also spread over a large part of Brazil; and the southern part of the country is occupied by Araucanian tribes. Of the natives but a small proportion are subject to the dominant race, and these are only found in the northern provinces. In some places these natives live in villages separate from the white population. The independent Indians, who inhabit the Gran Chaco and the pampas south of 35. S. Lat., are often at war with the Europeans. With the exception of those tribes who have been taught husbandry by the Jesuits, these people all lead a nomadic life, being almost constantly on horseback, and subsisting on the chase and the produce of their flocks and herds. The tribes of the Gran Chaco, though having no friendly intercourse with the Spaniards, are not constantly at war with them; but those of the pampas carry on their hostilities almost without intermission. They were at one time restricted to the regions south of the 33d parallel; and at present they are by treaty forbidden to cross the Rio Negro without permission, but they pay very little attention to this restriction. They are divided into families, each under a chief, who has very little power except in war. The Spaniards, who are the dominant race, form a very small proportion of the population; but in many parts the bulk of the people is composed of the mixed races. Of these mixed races, the most remarkable are the Gauchos, or rustics of the pampas. They live in huts of osiers and mud; but the greater part of their time is spent on horseback, hunting the wild cattle and horses of the plains. Their dress consists of a coarse jacket and breeches, over which is a poncho or square woollen mantle, with a slit in the middle for the head; a broad straw hat; and boots made of the skin of a horse's hind leg, without a seam. They frequently wear silver buckles, silver-mounted knives, and silver-rowelled spurs. Their peculiar weapons are the *lasso*, or long leather thong and noose, and the *bolas*, or two balls attached to a leather thong. Both these missiles they handle with great dexterity, seldom failing to hit their mark: the lasso they throw round the neck or horns of the animal, the bolas round the legs. There were at one time numerous Negro slaves in some of the provinces of La Plata; and though slavery has been abolished since the revolution, their descendants still form a distinct class among the inhabitants.

Manufactures.

The manufactures of La Plata are few and unimportant, as the great mass of the people are employed in agricultural or pastoral pursuits. The most important manufacture is that of ponchos, which are made of the finest quality at Santiago. Various other woollen fabrics are made for dresses and other purposes. The wearing apparel, knives, spurs, household furniture, &c., of the peasantry are to a large extent imported, and are generally of British manufacture.

Commerce

A large amount of internal commerce is carried on among the different provinces, as most of them produce articles that are not found in the others. There is also some trade by land with the neighbouring countries of Peru, Bolivia, and Chile; and through the Rio de la Plata commercial relations are kept up with other foreign countries. This commerce is chiefly carried on through Buenos Ayres; and since the separation of that province from the other thirteen, through Rosario. Cotton cloth, calico, linen, woollen, and silken fabrics, leather, hardware, cutlery, glass, earthenware, arms, ammunition, &c., are imported from Great Britain; wines, silk, perfumery, jewellery, &c., from France; and various other articles from other parts of Europe, the United States, Brazil, &c. The principal articles exported from La Plata are mules, salt beef, hides, horns, and wool. The annual value of the imports is about L.208,000, and that of the exports L.230,000.

Government.

The provinces of La Plata form a federal republic similar to that of the United States of North America. Each province is so far independent that it has its own constitution, its legislature, and executive; while there is at the same time a federal Congress and a president of the whole confederacy. The Congress consists of two chambers,—the lower one composed of 38 deputies, elected directly by the people; and the upper of 28 senators, named by the provincial legislatures. The authority of the Congress extends to the relations of the republic with foreign states, and the financial affairs of the nation. The president is elected indirectly by the people for the period of six years. The capital and part of the territory are under the immediate government of the president and Congress. The army of the confederacy amounts to 5000 men; and there is a national militia that may be called out in time of war. The national finances are in a very bad condition; the paper currency is very much depreciated; and the debt amounts to a large sum. The annual public expenditure is about L.40,000. The established religion in La Plata is the Roman Catholic, but all others are tolerated. Education is not very far advanced; but in the chief towns it is in a better state than in most parts of South America.

Provinces

The confederation of La Plata consists at present of thirteen provinces, besides the country occupied by the Indians. The provinces, with their area, population, and capitals, are as follows:—

Provinces.	Sq. Miles.	Pop.	Capitals.
Cordova	45,780	150,000	Cordova.
Catamarca	38,150	70,000	Catamarca.
Corrientes	12,720 (with Entre Rios)	84,600	Corrientes.
Entre Rios		50,000	Parana.
Juyjuy	55,100 (with Salta)	40,000	Salta.
Salta		60,000	
Mendoza	47,050	60,000	Mendoza.
Rioja	58,500	40,000	Rioja.
Santiago del Estero	69,620	80,000	Santiago.
San Juan	39,100	40,000	San Juan.
Santa Fé	40,900	32,000	Santa Fé.
San Luis	35,800	40,000	San Luis.
Tucuman	41,960	60,000	Tucuman.
Total	484,680	806,600	

We proceed to describe the several provinces in detail.

Cordova.

Cordova is bounded on the N. by Santiago and Catamarca, E. by Santa Fé, S. by the Indian territory and Buenos Ayres, and W. by San Luis and Rioja. It is occupied in the central and western portions by the Sierra de Cordova and its branches, from which many rivers flow, the principal being the Sercero, an afflu-

ent of the Parana. This is a fine province, the soil being rich and fertile, and well irrigated. It is pretty well wooded, possesses excellent pasturage, and abounds in fine clover. Cordova, the capital of the province, is picturesquely situated in a deep valley, on the Primero, in S. Lat. 31. 15., W. Long. 63. 40. It was founded in 1573, and became a place of considerable importance in the time of the Jesuits. An active trade is carried on through Cordova, between Buenos Ayres and the upper provinces of La Plata Pop. 14,000.

Catamarca.

Catamarca is a tract of country situated near the foot of the Andes, and is bounded by Santiago, Tucuman, and Salta on the N. and E., by the Andes on the W., and by Rioja and Cordova on the S. It consists of a mountainous table-land, but is noted for an extensive and fruitful valley, called the Valley of Catamarca. The climate of this district is of the most genial description, and the country produces cotton of a very superior quality. The city of Catamarca is situated about 180 miles south-west of Tucuman, in Lat. 27. 45. S., and Long. 66. W. It was founded more than a century and a half ago, and stands in the beautiful valley which bears its name. It contains about four thousand inhabitants. The other towns in this province are unimportant.

Corrientes.

Corrientes is situated between the rivers Parana and Uruguay; on the N. it is bounded by the state of Paraguay, E. by Brazil, S. by Entre Rios, and W. by the Gran Chaco. The southern parts of the province are well wooded and fertile, the principal productions being cotton, tobacco, rice, and sugar. The territory of Corrientes is intersected by several rivers, some of which are navigable for a considerable distance Besides the celebrated lake Ybera, which is very shallow, but covers sometimes 1000 square miles, there are in the province numerous sheets of water, by which it is rendered one of the most fertile countries on the face of the globe. Corrientes, the capital, is admirably situated on the banks of the Parana, near its junction with the Paraguay. It is a very ancient city, and contains several public buildings. Its position is very good for commercial purposes. Pop. 7843.

Entre Rios.

Entre Rios is situated between the two great rivers Parana and Uruguay, and is bounded on the N. by the province of Corrientes, E. by Uruguay, S. by Buenos Ayres, and W. by Santiago. It possesses several peculiar advantages, and is one of the most fertile and pleasing provinces in the whole republic. Embraced on all sides but one by the two great rivers just named, it is easily accessible by shipping, and being thus insulated, it is protected from the incursions of the Indians. It is copiously irrigated, the southern part being subject to an annual inundation, and the soil is distinguished for its fertility. Wood is abundant, but small in size. The pastures are extensive; but the wild cattle, which formerly abounded, are much reduced in number. Hides, horns, tallow, and beef are the principal articles exported. Parana or Bajada, the capital of Entre Rios, and the seat of government of the confederation, stands on the left bank of the river Parana, opposite Santa Fé. It is a large town, and contains a hall of representatives, a theatre, and several churches. An active trade is carried on here; and the noise and bustle of the town present a striking contrast to the solitude and silence that prevails on the banks of the river both above and below the town. Parana was founded in 1730. Pop. about 15,000.

Jujuy and Salta.

The provinces of Jujuy and Salta are bounded on the N. and W. by Bolivia, S. by Catamarca and Tucuman, and E. by the Gran Chaco. The western part belongs to the great range of the Cordilleras, and is rich in metals. Here are found gold and silver, copper, iron of various qualities, sulphur, alum, vitriol; and there are also indications of the existence of tin and quicksilver. Many branches of mountains, off-shoots from the colossal chain of the Andes, extend into the province, from which proceed pleasant and beautiful valleys, intersected by numerous streams which irrigate and fertilize the country. The vegetable productions are wheat, maize, pulse, cotton, sugar, indigo, &c. There are extensive forests and good pastures, where horses and cattle are reared. In one of the intervals between the low collateral branches of the Andes is situated Salta, the capital of the province of that name, in Lat. 24. 15. S, and Long. 64. W., on the great road leading from Buenos Ayres to Lima by the way of Potosi. It was founded in 1582, and has long been a place of some consideration in this thinly-peopled region. The climate, however, is very unhealthy. The population amounts to about 9000 souls. The town of Jujuy stands on a river of the same name, in a country rich in precious metals.

Mendoza.

(For an account of the province and town of Mendoza, see MENDOZA.)

Rioja.

Rioja is situated at the foot of the Andes, and is bounded on the N. by Catamarca, E. by Cordova, S. by San Luis and San Juan, and W. by Chile. Like the other provinces in this region, it is mountainous, including the Sierra Famatina and Sierra Velasco, which form the three parallel valleys of Guandacol, Famatina, and Arauca. Rich silver mines are worked in the Sierra Famatina. Vines are grown in the north of the province; agriculture is carried on in the W., and cattle are fed on the rich pastures in the S. Rioja, the capital, is a small and unimportant city, situated at the foot of the Sierra Velasco, in Lat. 28. 30. S, and Long. 68. 35. W. It contains about 8800 inhabitants.

La Plata.

Santiago del Estero.

Santiago del Estero is situated between Tucuman and Cordova, being south of the former and north of the latter. It is of great extent in all directions, and is one of the most fertile of these provinces. Agriculture is the chief occupation of the inhabitants of Santiago. Honey, wax, many valuable woods, cochineal, &c., are obtained here, and some manufactures are carried on. All kinds of grain may here be brought to perfection; yet the inhabitants are slow to avail themselves of the advantages presented by nature. The city of Santiago, situated on the road to Bolivia through Cordova, in 27. 55. S. Lat, and 63. 20. W. Long., is of little importance. Pop. 4000.

San Juan.

San Juan is bounded on the N. by Rioja, E. by San Luis, S. by Mendoza, and W. by Chile. In the north of the province there are some gold mines, which are worked to a small extent. The country is remarkably fertile, producing wheat, maize, olives, and vines in abundance. The produce of the olive plantations is much esteemed in Buenos Ayres; but the natives direct their attention chiefly to the cultivation of the vine, which grows luxuriantly, and to the making of wines and brandies, which they export in large quantities as far as Potosi, Buenos Ayres, Santa Fé, and a great portion of the eastern side of the Rio de la Plata. The city of San Juan, situated in Lat. 31. 15. S, and Long. 68 35. W., was founded as early as 1560, and is consequently one of the most ancient places in the republic. Pop. 8000.

Santa Fé.

Santa Fé is bounded on the N by the Gran Chaco, E. by Entre Rios, S. by Buenos Ayres, and W. by Cordova. This fertile country is irrigated by numerous rivers, some of which are of considerable size. The chief employment of the inhabitants consists in the breeding of cattle and horses, the skins of which animals are conveyed to Buenos Ayres. Santa Fé, the capital, is situated on the western bank of the Parana, and has risen to importance by becoming a depôt for goods on the river. The inhabitants of the town amount to about 4000. The largest town in the province is Rosario, which occupies the farthest south, and therefore most important position of any town on the Parana, being nearest to the markets of the west. It is 150 miles above the confluence of the Uruguay and Parana, and the river is here navigable for ships drawing 14 feet. In the latter half of 1854 the vessels that entered and cleared were 290; tonnage, 11,000; value of cargoes, L.760,000. Pop. 12,000.

San Luis.

San Luis is bounded on the E by Cordova, S. by the territory of the Pampas Indians, W. by Mendoza and San Juan, and N. by Rioja. The soil is poor; and though the climate is salubrious, the inhabitants are very indolent. Agriculture is not pursued to any extent, but large numbers of cattle are reared. San Luis, the capital, is a very ancient town, and the only place of any importance in the journey between Buenos Ayres and Mendoza. It is situated in a fertile valley at the foot of the Sierra de Cordova. Pop. 1500.

Tucuman.

Tucuman, one of the most important and fertile provinces in the republic, is bounded by Salta on the N., and by Santiago and Catamarca on the S. and S.W. It contains mines of gold, silver, copper, and lead; but these are only worked to a small extent. The other productions are wheat, maize, rice, sugar, and tobacco, of which thousands of bales are exported to Cordova, San Luis, San Juan, Mendoza, and other cities. Fruits of various sorts are abundant, and potatoes here attain an enormous size. Tucuman, the capital of the province, is a straggling city, situated in 26. 50. of S. Lat., and 64. 35. of W. Long. To the west of the city is a mountain of great height, from which numerous rivers descend to fertilize and beautify the surrounding territory. Along all the lower parts of this mountain are immense clusters of trees, and amongst them many of bitter oranges. The city is surrounded by these woody tracts, in which the trees sometimes attain an extraordinary size, and the timber is of the best quality used in America. The houses in general are of an inferior description; but the place is memorable from its having taken a distinguished part in the revolutionary struggle. Pop. 8000.

History.

To the Spaniards belongs the honour of first discovering this part of the South American continent. In the year 1516, Juan Dias de Solis, having been furnished by the court of Spain with two ships for the purpose of exploring Brazil, arrived, in the course of his voyage, at the mouth of the Rio de la Plata. Touching on the N. coast between Maldonado and Monte Video, he took possession of the land in name of his sovereign; but, thrown off his guard by the deceitful friendship of the natives, he was slain, along with a few attendants who had followed him on shore. The coast was immediately abandoned by the survivors on board of the vessels; but in the year 1526 a fresh expedition, under the celebrated Sebastian Cabot, then in the service of Spain, entered the river, and cast anchor opposite the site of the present Buenos Ayres.

This took place at the time when a Spanish captain called Garcia was making discoveries in other parts of the same river. Advancing about 300 miles upwards, Cabot discovered a fine river, the Tercero, flowing into the main stream Up this he sailed with his fleet, and disembarking his men, built a fort, in which he left a garrison; whilst he himself, with his remaining followers, pursued his discoveries still farther up the river. The Indians with whom he came in contact exhibited abundance of gold and silver plates, particularly the latter, brought by them from the eastern parts of Peru. This circumstance led Cabot to believe that mines of the precious metals existed in the country in which he then was; and accordingly he gave the name of *Rio de la Plata*, or River of Silver, to the noble stream by which it was watered. The Spaniards soon determined on colonizing this valuable acquisition, and, to prevent any interference on the part of the other nations of Europe, Don Pedro de Mendoza, with two or three thousand followers, was sent from Spain to secure the possession, and establish a relationship between it and the mother country. He landed upon the western shore of the La Plata in the year 1535, and founded the city of Buenos Ayres, which he so named from the salubrity of the climate. Pursuing his way into the interior, he explored all the country as far as Potosi, at which mines of silver were discovered nine years afterwards. The first settlers at Buenos Ayres were most unfortunate; their town was burned by the Indians, and after suffering every privation, they were shortly afterwards compelled to abandon the place. Previously to this event, Assumption, the capital of Paraguay, had been founded; and thither the wretched remains of the expedition retreated. A second armament was fitted out, and an attempt made to rebuild the town, in 1542; but it was overwhelmed by a calamity similar to that which had overtaken the former. The chief attention of the Spaniards was for some time directed to forming settlements in Paraguay, in order to facilitate their communication with the mines of Peru, where Pizarro and his successors were gathering in a rich harvest. Contentions with the Indians were frequent and bloody, for the Guarani Indians of the vast plains upon either bank of the La Plata proved much more difficult to subdue than the timid and tractable Peruvians.

It was not until the year 1580 that the Europeans succeeded in their attempts to found a town upon the site chosen by Mendoza. Before this period, however, they had established themselves at Santa Fé, Mendoza, and some other places in the interior; so that, as Dr Southey observes, the history of this part of South America differs from that of any other colony in one remarkable circumstance,—the first permanent settlement was formed in the heart of the country, and the Spaniards colonized from the interior towards the sea. But they were not permitted quietly to enjoy the success of their third attempt to found Buenos Ayres. Stimulated by the recollection of their previous triumphs in demolishing the works of the invaders on the same ground, the Indians once more attacked it; but the town was so well fortified and garrisoned as to bid defiance to their efforts. From this period the city began to prosper; and the ship which carried to Castille the intelligence of its refoundation took home a cargo of sugar, and the first hides with which Europe was supplied from the wild cattle which now began to overspread the country, and soon produced a total change in the manners of all the adjoining tribes. The immense pampas of La Plata appear to have been originally stocked with cattle from a few which had been brought by the earliest settlers; and so rapidly had they multiplied that, about the year 1610, no less than a million is said to have been driven from the country in the neighbourhood of Santa Fé into Peru.

From the first period of the colonization of this country till the year 1778, the government was dependent on that of Peru, although the chief of Buenos Ayres had the title of Captain-General. A false idea of what constitutes wealth led Spain to estimate the value of her possessions by the number and richness of their mines of gold and silver; and Buenos Ayres being deficient in these, its more solid advantages of a fertile soil and a salubrious climate were consequently overlooked. The pernicious system of policy practised by Spain towards her colonies was the main cause why this city remained for such a length of time almost entirely unknown to Europeans. Apprehensive lest commodities might be introduced into Peru by way of Buenos Ayres, and thus prejudice the sale of the cargoes imported by the fleets which they sent to Panama, the early traders solicited and obtained from the government the prohibition of every kind of commerce by the Rio de la Plata. Those whom this measure most nearly affected put in a strong remonstrance against it, and were so far successful that, in 1602, permission was granted them to export for six years, in two vessels belonging to themselves, and on their own account, a certain quantity of flour, tallow, and jerked beef, but only to two ports. Upon the expiration of the term, an indefinite prolongation was solicited, with an extension to all kinds of merchandise, and liberty to trade also with other ports. This application was vehemently opposed; but notwithstanding, in the year 1618, the inhabitants of the shores of the Rio de la Plata were authorized to fit out two vessels, not exceeding 100 tons burden each. Several other vexatious restrictions were imposed on them; and to prevent any traffic with the interior of Peru, a custom-house was established at Cordova del Tucuman, where a duty of 50 per cent. was levied upon all imports. This custom-house was also designed to prevent the [illegible] of the precious metals from Peru to Buenos Ayres, even in payment for mules furnished by the latter city. By an order of 1622 the permission previously given was prolonged for an indefinite period; and with a view to promote the prosperity of the country, a royal *audiencia* was established at Buenos Ayres in 1665.

Under such a miserable system of policy, it is not surprising that the provinces of the Rio de la Plata languished in indigence and obscurity. But the resources of so extensive and fertile a territory could not remain for ever concealed. As the population and wealth of the country increased, the continual remonstrances of the people at last opened the eyes of the Spanish government to the importance of the colony, and a relaxation took place in the system of commercial monopoly which had hitherto been rigorously adhered to. Indeed the absurd restrictions had been followed by their natural consequence, smuggling; and to such a height was the contraband trade carried that, in order to put a stop to it, the government of Castille gave permission to register ships to sail under a license from the council of the Indies at any time of the year. The *flota* which hitherto had embarked from Spain once a year, and was the only legitimate means of communication with America, dwindled away from 15,000 to 2000 tons of shipping; and in 1748 it sailed for the last time to Cadiz, after having carried on the trade of Spanish America for two centuries. The register-ships now supplied the market with European commodities at a cheaper rate and at all seasons of the year, and from that time Buenos Ayres gradually rose into importance Other relaxations in the mercantile system followed soon afterwards. In the year 1774 free trade was permitted between several of the American ports; and this was subsequently followed by additional liberties.

The improvements which took place in Buenos Ayres by this enlargement of its commercial relations were frequently interrupted by circumstances which carry us back to an early period of its history. The Spaniards and Portuguese have, by a singular coincidence, been destined to be rivals, not only in the Old, but in the New World. The neighbouring territory of Brazil belonged to Portugal, and bitter hostilities frequently took place between the two countries. It is computed that, in the hostile incursions which the Brazilians made into the Spanish possessions in this quarter of America, they destroyed upwards of 400 towns and villages. These marauders, the offspring of Portuguese, Dutch, French, or Italians, by Brazilian women, were called Mamelucos. Their principal object was to carry into slavery the Indians whom the Jesuits had partially civilized; and in exercising their inhuman trade they committed the most horrid enormities. It does not appear that their acts were authorized by the government which they professed to obey; for repeated decrees were passed in favour of the oppressed Indians. These, however, were seldom or never observed; and governors and others, who profited by the captivity and sale of the native tribes, winked at the traffic. But the rivalry and animosity of the Portuguese were productive of other results besides those consequent on hostile incursions. We have alluded to an extensive contraband trade, originating, in the first instance, in the blind policy of Spain. This was chiefly carried on by the Portuguese, who were enabled, by extending their settlements to the banks of the Rio de la Plata, to organize a system of smuggling which ultimately almost annihilated legitimate commerce. But this illicit trade, though detrimental to the mother country, by whom it was finally put down, contributed not a little to the prosperity of the colony.

In the year 1778 the provinces of the Rio de la Plata, Paraguay, Uruguay, and Bolivia were erected into a viceroyalty, of which Buenos Ayres was constituted the capital. At the same time, it was thrown open to free trade of every description, even with the interior of Peru; and such was the effect of this wholesome measure that the number of vessels trading with South America was at once augmented, and kept gradually increasing from year to year.

In the year 1806 a British squadron, under the command of Sir Home Popham, appeared in the Rio de la Plata. From this armament a body of troops was landed, for the purpose of taking the capital. The British force was small, but, by the culpable negligence of the viceroy, who does not appear to have made any attempt to defend this important city, General Beresford accomplished his object on the 26th of June. This rash and unauthorized enterprise was fortunate in the first instance, but exceedingly disastrous in its issue. The viceroy having retired to Cordova, Don Santiago Liniers

a Frenchman in the service of Spain, put himself at the head of all the troops he could collect on both banks of the Plata, and on the 12th of August attacked the city at several points. So vigorous and successful was the assault, that the British general and his troops were compelled to surrender themselves prisoners of war. In the meantime, British reinforcements arrived from the Cape of Good Hope, whence the original expedition had sailed; and Sir Home Popham, after making an unsuccessful attempt on Monte Video, took Fort Maldonado, at the mouth of the River Plata But the intelligence of the first capture of Buenos Ayres was so well received by the British public that government resolved on maintaining possession of the banks of the Plata; and an armament was therefore fitted out for effectually reducing the country. The first body of troops, which were commanded by Sir Samuel Auchmuty, enabled the British to undertake the conquest of Monte Video, which was carried by storm in February 1807. In May following, General Whitelocke arrived at the head of a formidable force; and about a month afterwards these were joined by a further reinforcement under General Crawford. The army now amounted to 8000 men, and the chief command was confided to General Whitelocke, a man destitute alike of courage and ability. The reduction of Buenos Ayres was now resolved upon, the attacking army sailed up the river, and, disembarking below the capital, marched towards it, but met with a reception which was little anticipated. The inhabitants of Buenos Ayres had made every preparation for a desperate resistance. The streets were intersected by deep ditches, defended by cannon, and the windows and house-tops were thickly planted with armed men. No sooner had the British troops begun to penetrate the streets in columns than they were assailed by grape and musketry, under which they perished in great numbers, without being able to retaliate on the citizens. The cool, determined valour of the troops, and the heroic energy of their leaders, were exerted in vain. About one-third of the British army was either killed, wounded, or taken prisoners, without any material advantage having been gained. In these circumstances, it would have been madness to persist in such a mode of operation; and next day an armistice was concluded. A convention followed, the terms of which were, that the British should evacuate the possessions on the Plata in two months, and that all prisoners taken on both sides should be restored. By this capitulation Monte Video, which might have been safely maintained against any enemy, and which would have afforded a secure depôt for our manufactures, was also lost.

But the events which were now passing on the continent of Europe were destined to change completely the aspect of affairs in South America. The invasion of Spain by Napoleon in 1808 gave the colonists an opportunity of throwing off their allegiance to the mother country. The princess-regent of Portugal, claiming the crown of Spain, despatched emissaries to La Plata to concert measures for her residence at Buenos Ayres. Her proposals were received with enthusiasm; but when on the point of being crowned with success, they were rendered abortive by the viceroy Cisneros, who was a staunch supporter of the rights of Ferdinand VII.

From this period the principal supporters of the Princess Carlota changed their views, and formed plans of ultimately setting up the standard of independence. After some political struggles, they succeeded in deposing the viceroy, and, on the 25th of May 1810, named a *junta gubernativa*, the leading member of which was Don Mariano Moreno, the secretary. As the eyes of the people in the provinces were opened to the daring nature of the step which had been taken, the authority of the junta became more and more circumscribed, and was soon reduced to the limits of Buenos Ayres. Monte Video did not recognise it at all. But Moreno was nothing dismayed by this want of support, and his measures became more decisive as the emergency increased. He succeeded in expelling the viceroy from the country; and had not the junta itself become divided, such a man at the head of affairs would have soon brought matters to an issue. It became impossible for the junta to exist in its then disjointed state. Moreno and his party withdrew; and he having accepted a mission to England, unfortunately died on his passage.

The people of Buenos Ayres having so far succeeded in establishing their independence, considered themselves powerful enough to proselytize in the provinces. A division of patriots under Ocampo was sent against Cordova, where a formidable faction opposed to the new order of things had been organized by Liniers; and this leader was taken prisoner, and shot, along with several influential persons The opposition to the republicans was by these violent measures put an end to; but though nearly the whole of the country was now in favour of independence, there were continual disputes as to the form of government that should be established,—Buenos Ayres endeavouring to obtain the supreme power, while the other provinces contended for equal rights. In January 1813 a sovereign constituent assembly was convened at Buenos Ayres. It was not until now that the Spanish flag and cockade were replaced by the bicolour. Now also the coinage bore the republican arms.

Monte Video still stoutly maintained the sinking cause of Spain: the effort was unavailing. Twice the soldiers of the fortress, in attacking the soldiers of Buenos Ayres, were driven back. In 1812 the town was taken, when between 5000 and 6000 royalist troops laid down their arms, and an immense quantity of military stores was likewise given up. The changes which the government of Buenos Ayres underwent we need not follow; and the civil dissensions by which the country was afflicted are equally endless and uninteresting. In 1816 a congress of deputies from all the provinces met at Tucuman, which named General Pueyrredon director of the republic, and declared the countries on the Plata independent. An army was raised and disciplined to defend the country, and to assist the people of Chile against their common enemy. The combined forces gained over the Spaniards the two decisive victories of Chacabuco (1817) and Maypu (1818). Various attempts were made by the Spaniards to regain possession of La Plata, but they were all without success; and finally their troops were totally defeated by the republicans in July 1821. In 1824 the independence of La Plata was recognised by the British government. The internal dissensions in the country previous to the appointment of Rosas dictator in 1835, and the events which led to his downfall and flight in 1852, are briefly narrated in the article BUENOS AYRES. This event, which seemed to put an end to a protracted war, was in reality but the signal for fresh contests. The people of Buenos Ayres, exulting in their newly-obtained liberty, were still animated with all their old jealousy of the other provinces, and of General Urquiza, who supported their rights. Accordingly, when the governors of all the provinces, assembled by Urquiza at San Nicolas, appointed him provisory director until a general Congress, which was to meet at Santa Fé, should prepare a constitution, the representative assembly of Buenos Ayres accused Urquiza of attempting to set up a new tyranny, and forbade the execution of the treaty of San Nicolas. Urquiza, in the exercise of his provisory power, dissolved the assembly, and occupied the city with his troops. While thus possessed of supreme power, the director followed a more liberal policy than Rosas, by acknowledging the independence of Paraguay, opening the La Plata to ships of all nations, and permitting free commerce in the interior of the country. But no sooner had Urquiza quitted Buenos Ayres to attend the Congress at Santa Fé, than a revolution took place in the town; his troops were obliged to retire; the representative assembly again met, and appointed General Pinto provisory governor of the province. But the province of Buenos Ayres itself soon became divided, the country rising against the town; civil war raged afresh; and General Urquiza besieged Buenos Ayres by land and sea. Meanwhile all the other provinces sent deputies to the Congress of Santa Fé, which prepared a federal constitution, and published it May 1, 1853. The representatives of Brazil and Bolivia attempted in vain to mediate between the contending parties; and afterwards the ministers of Great Britain and France interfered with as little success. On the 26th of June 1853 Commodore Coe, the commander of Urquiza's squadron at Buenos Ayres, influenced, it is said, by a bribe, went over to the other side. Mutiny and desertion broke out in the besieging army; and Urquiza was obliged to retire to the province of Entre Rios, of which he was governor. Then ensued a separation between the contending parties. Buenos Ayres declared itself a sovereign state; while the other provinces fixed their capital at Parana, and appointed Urquiza president of the republic for six years. In this divided condition La Plata has since remained; and although several attempts have been made to negotiate a reunion, none has proved successful. Two treaties were concluded in December 1854 and January 1855, by which the two states were to allow free commerce between their territories, to use one national flag, and to defend each other against foreign aggression. Fresh misunderstandings and aggressions however arose; and these treaties were declared null March 18, 1856. But the country has purchased, at the expense of this division, a respite from the long series of revolutions and tyranny, civil and foreign wars, which have agitated it from the period of its independence to that of its dismemberment. The thirteen provinces endeavoured to lessen the preponderance of Buenos Ayres by opening up the Parana and Paraguay to commerce, and by imposing extra duties on merchandise coming by Buenos Ayres. At the same time, they are turning their attention to the internal improvement of the country, by colonizing its vast and rich though almost unpeopled territories, by constructing railways to connect its various parts, and launching steamers on its magnificent rivers. The experience of the last half century seems at last to have taught the people and their leaders how ruinous it is to fight about constitutions and governments, and to neglect or wantonly to destroy the undisputed gifts which nature has so lavishly bestowed. A few years of peace would probably do much to develop the resources of the country, and create a common interest among the provinces, which would unite them more firmly together than laws or treaties ever could.

PLATA, Rio de la, a large estuary of South America, formed by the confluence of the Rivers Parana and Uruguay. It is about 185 miles in length; and its breadth gradually increases from its head towards the sea. At Buenos Ayres, about 30 miles below the confluence of the two great rivers, it is 29 miles across; at Monte Video, 70 miles farther down, it has expanded to 53 miles; and at its mouth, between Cape San Antonio and Punta de la Ballena, its breadth is about 130 miles. This vast sheet of water is by no means deep: the average depth at the mouth is 10 fathoms; farther up it becomes gradually shallower; and between Monte Video and Buenos Ayres the average depth is only 3 fathoms. The estuary is also much impeded with sand-banks; and the currents are very strong and variable, on account of the immense body of water brought down by the rivers, which drain an area estimated at 1,200,000 square miles; being thus inferior in this respect to the Amazon and Mississippi only. The tides in the La Plata are hardly perceptible; but this is owing not to any real deficiency in their force, but to their being confused, and, as it were, concealed by the other currents. Violent storms frequently agitate the La Plata, chiefly raised by the gales called *pamperos*, which drive the water in a great volume in one direction. From these causes, the navigation is here so difficult that the estuary has been called *El Inferno de los Marineros* (Sailors' Hell). The water of the rivers is very long in mingling with that of the ocean; it floats muddy and dark on the surface in an easterly direction; and at the distance of 600 miles from the land it has a velocity of 1 mile an hour, and spreads over a breadth of 800 miles. Of the two great rivers that form the Rio de la Plata, the largest is the Parana, which rises in Brazil not more than 100 miles N.W. of Rio de Janeiro. The upper streams of this river have various names; but at the confluence of the Rio Grande, the longest of them, with the Parnahiba, the combined river takes the name of Parana, which it retains till it merges itself in the Rio de la Plata. The Parana flows southwards, receiving several large affluents, and separates Paraguay from Brazil and La Plata. It then turns to the west, and flows in that direction for 50 miles, still forming the boundary between Paraguay and La Plata. On receiving the Paraguay from the north at Corrientes, it again turns south, and flows through La Plata till it falls into the Rio de la Plata by several branches, forming the island of Martin Garcia and others. The Martin Garcia channel, by which the Parana is entered, is difficult of navigation, and does not admit vessels drawing more than 14 feet of water. The total length of the Parana is 2040 miles,—namely, 500 from the source of the Rio Grande to its confluence with the Parnahiba, 1000 from that point to the union of the Paraguay and Parana, and 540 thence to the Rio de la Plata. It is navigable to Corrientes for ships drawing 7½ feet, and for smaller vessels to Candelaria, 150 miles farther, where rapids occur. The principal affluent of the Parana is the Paraguay, which exceeds, in the volume of its water and in the length and directness of its course, the river that retains the name. It issues from several lakes in the Sierra Diamante in Brazil, and flows southwards, separating La Plata from Brazil and Paraguay. Its principal tributaries are the Pilcomayo and Vermejo, both from the west. Its whole length from its source to Corrientes is about 1890 miles; and it is navigable to Assumption, 200 miles above Corrientes, for vessels drawing 7½ feet. Above this point it is believed to be navigable for smaller vessels for 800 miles, and the Vermejo for 500. The Parana also receives from the west the Salado, which is entirely within the provinces of La Plata, rising in the N.W., flowing S.E., and joining the main stream at Santa Fé. Like all rivers from within the tropics, the Parana has a low and a high season, depending on the periodical rains. The former lasts during the winter and spring of the Southern Hemisphere, from June to December, and the latter during the summer and autumn. The difference in the height of the river in these seasons varies at different parts, being about 3 feet where it is wide, 8 feet where narrow, and on an average over the whole about 4 feet. The Uruguay rises in Brazil in the Sierra de Santa Catharina, and flows first west and then south, separating Brazil and Uruguay from La Plata, and falling into the Rio de la Plata, where its blue waters preserve their clearness for miles before they are lost in the muddy current of the Parana. Its whole length is more than 800 miles, and it is navigable for ships drawing 5 or 6 feet for 250 miles. The estuary of La Plata is fitted by nature to be the outlet of a most extensive river trade, though as yet its advantages have been turned to very little account. Goods from foreign countries destined for the interior are generally unshipped at Buenos Ayres, and put on board smaller river craft. But as, until lately, all the river trade was performed by sailing vessels, the means of communication were very imperfect; for no ships could ascend the rivers unless they had not only a wind up the stream, itself not a very frequent occurrence, but one sufficient to impel them against the current running from 2 to 4 miles an hour. At the same time, large steamers could not ascend on account of the shallows. But since the opening of the rivers in 1852 steamers have been introduced, after the model of the Mississippi boats, which will much accelerate and facilitate the conveyance of goods.

PLATÆA, or Plataeæ, an ancient city of Bœotia, stood on the southern bank of the Asopus, under the northern declivity of Mount Cithæron. Its early history is characterized by a determined resistance to the domineering power of Thebes, and a steady alliance with Athens. Its later annals are rendered remarkable by two very important events. The one is the famous battle of Platæa, which took place in 479 B.C., between the Persians and confederate Greeks. In that year the Grecian troops under Pausanias took up their position near the walls of the city, on a level meadow between two branches of the river Œroë. Up from the banks of the Asopus, in pursuit of them, came the invaders, led on by Mardonius. A scattered fight ensued. The Greeks drove their enemies back, stormed their camp, and routed them over the country, till only a few were left to carry the news of the disaster to the East. In the full flush of success, the confederates returned to honour the scene of the battle. Assembled round a sacrifice in the market-place, they took an oath to defend and maintain for ever the independence of the town. Out of their spoils they contributed eighty talents for the erection of a temple to Minerva in the place. The privilege was also conferred by them upon the citizens of paying religious honours every year at the graves of the illustrious slain, and of celebrating, at the end of every five years, the feast of the Eleutheria, in commemoration of the deliverance of Greece. Equally notable with this victory was another event,—the siege of Platæa by the Peloponnesians under Archidamus in 429 B.C. In anticipation of the approach of the enemy, the children, the old men, and the mass of the women, had been sent away and consigned to the protection of Athens. There were only left 400 citizens and 80 Athenian allies to hold the town, and 110 women to take charge of the household affairs. To wrest the city from this devoted band, the invaders set themselves with sanguine determination. At first they tried to storm the place. A mound was thrown up, the battering-ram was plied, and a pile of brushwood was set on fire close to the wall. After all these attempts had been foiled by the ceaseless activity of those within, they turned the assault into a blockade, and, casting up two lines of circumvallation, sat down in the shelter of the intermediate space. The besieged were now doomed to wait, and to continue to wait

in vain, for relief. It is true that in the second year of the siege 212 of their number, taking advantage of a tempestuous winter night, climbed lightly over the enemy's fortifications, amid the darkness and turmoil of the storm, and escaped in safety to Athens. But the rest remained shut in from all hope, until, in the summer of 427 B.C., they were compelled, haggard and weak with famine, to give themselves up to the mercy of their relentless foes. The men, after a mock trial, were butchered one by one in cold blood; the women were sold as slaves; the houses were razed to the ground; and two temples to Juno, the one surrounded with an inn, and the other newly erected, were all that was left to mark the site of the city, until its restoration by the Lacedæmonians in 387 B.C. After this date there is nothing very important in the annals of Platæa, except its second destruction by its inveterate enemy Thebes in 372 B.C., and its second restoration by Philip in 338 B.C. Its ruins are still seen near the small village of Kokhla. (For a detailed account of the celebrated siege of Platæa, see Thucydides.)

PLATFORM, a plane surface, lying level, of any materials, for the reception of the foundations of a building, or for the piers of a bridge. The term is likewise applied to a level scaffold raised above the ground for a temporary purpose.

PLATINA, or PLATINUM (Spanish *plata*, silver), is a metal of a white colour, exceedingly ductile, malleable, and difficult of fusion. It is the heaviest substance with which we are acquainted, its specific gravity being about 21·5. It is subject to no change from air or moisture, is not attacked by any pure acid, is dissolved by the influence of chlorine and nitro-muriatic acid, and is subject to oxidation by pure potassa and lithia. It is found only in the Ural Mountains and in South America, where it is usually procured in small lustrous grains combined with palladium, rhodium, &c., and is for the most part commingled with sand. The portions of it which are found seldom exceed a small pea in size, but occasionally it has been found in lumps varying in size from a hazel nut to a pigeon's egg. (See CHEMISTRY; also MINES AND MINING.)

PLATING is the art of covering the baser metals with silver or gold, either for use or ornament. Of late, manufacturers have availed themselves of electro-chemical decomposition for the purpose.

PLATO.

THE birth of Plato is nearly coincident with that great epoch of Grecian history, the commencement of the Peloponnesian war. In the first year of that war, the Athenians, having ejected the unhappy people of Ægina, apportioned the island amongst colonists from themselves.[1] Amongst these Athenian occupants were Aristo, and Perictione, or Potona, as she is also called, the father and mother of Plato. Their residence, however, in the island was not permanent nor even long, as the intrusive colony was in its turn ejected by the Lacedæmonians, on which occasion his parents returned to Athens.[2] It was during this interval, and in the year 429 B. C., that the philosopher was born.[3]

From these circumstances, it has been commonly supposed that Plato was born in Ægina. They are not, however, sufficient to establish such a conclusion. For a colonization of the kind here described did not necessarily imply residence on the part of those persons to whom the lands were allotted.[4] Nor is the fact of the recovery of the island by the Lacedæmonians from the hands of the Athenians, mentioned by the contemporary historian. Ægina was still in the occupation of the Athenians in the fifth year of the Peloponnesian war;[5] and in the eighth year of the war we find that the poor exiles, who had meanwhile obtained a refuge at Thyrea, were there cruelly exterminated by the Athenians.[6] On the whole, it seems more probable, from the constant designation of Plato as "the Athenian," without any other addition, though this alone, it must be allowed, is not decisive of the fact, that Athens itself may claim the honour of having been his birthplace.

It is remarkable that his proper name was not that which his fame has immortalized, but Aristocles, after his paternal grandfather.[7] The name of Plato is said to have been given to him by the person who was his master in the exercises of the gymnasium, as characteristic of his athletic frame in his youth.[8] In this way, being familiarly applied to him, it gradually prevailed, to the entire disuse of his family name.

The philosopher was connected by descent with the ancient worthies of Athens; on his mother's side with Solon, and on his father's with the patriot king Codrus.[9] And thus, according to the notions of nobility prevalent amongst the Greeks,[10] he could trace up the honours of his parentage to a divine founder, in the person of the god Neptune.

A circumstance is related of his infancy, which, though obviously fabulous, cannot properly be omitted in his biography, as a pleasing and appropriate tribute of the imaginative genius of the Greeks to their poet-philosopher. Whilst he was sleeping when a babe, on Mount Hymettus, in a bower of myrtles, during the performance of a sacrifice by his parents to the muses and nymphs, bees, it is said, lighted on him and dropped honey on his lips, thus giving an evident augury of that peculiar sweetness of style by which his eloquence would be distinguished.[11]

For the same reason, a similar fancy, which has thrown a poetical ornament over the account of his first devotion to philosophy, must not be passed over in silence. Socrates, it is related, was apprized beforehand, in a dream, of the first visit of the gifted pupil, who was destined to carry philosophy forth on the wings of his genius to its boldest flights. Socrates was telling his dream to some persons around him, how he seemed to see a young swan coming from an altar in the grove of Academus, and first nestling in his bosom, then soaring up on high, and singing sweetly as it rose in the air, when Aristo presented himself, leading his son Plato, whom he committed to the instruction of the

sage. Socrates, it is added, struck by the coincidence, immediately recognized the fulfilment of his dream, and welcomed Plato as the young swan from the altar, represented to him in the vision.

The accounts of his early education, to which we should naturally have looked with great interest, are extremely meagre. We only know by general notices that he passed through the usual course of education adopted amongst the higher classes of the Greeks. That education was directed to the cultivation at once of the powers of the mind and of the body, under the two great divisions of literature and gymnastics. The youth was delivered to the charge of the grammarian, the teacher of music, and the trainer. From the grammarian he learned the art of reading and writing his own language, and a knowledge of its authors, especially its poets; from the teacher of music, skill in performing on the lyre and the flute, together with the principles of the science of music; from the trainer he acquired strength and expertness in the several exercises of wrestling, and boxing, and running, by which it was intended not only to mature the powers of the body, but to qualify the youth for attaining eminence at the public games. These were the schoolmasters of the accomplished Athenian, and with these he was occupied until he had reached about his twentieth year. Accordingly, the names have been transmitted to us of those who discharged these offices for Plato; of Dionysius, as the grammarian under whom he learned the elements of that command over his own language, and its literary resources, which his matured eloquence so richly displayed; of Draco of Athens, and Metellus of Agrigentum, as his masters in music; and of Aristo the Argive, as his master in gymnastics. It is added that he also studied painting; but the name has not been given of any individual who acted as his preceptor in the art.

In evidence of his great proficiency in these early studies, it has been stated, that he gave specimens of his genius in every department of poetical composition; that in epic poetry he laboured after the highest excellence, and only abandoned the attempt on comparing his efforts with the poems of Homer, and despairing of reaching so high a standard; that in dramatic poetry, he had prepared a tetralogy, the four plays usually required of an author in order to competing for the prize at the festival of Bacchus, but changed his purpose only the day before the exhibition, in consequence of impressions received from Socrates. And even in gymnastics excellence has been claimed for him; since it has been asserted that he actually entered the lists at the Isthmian games.

Whatever credit we may give to these particulars, there can be no doubt, that so inquisitive a mind as that of Plato, and so resolute a spirit in the prosecution of its undertakings, received the full benefit of this preliminary culture; and that he was thus amply prepared for entering on the severer discipline of those pursuits which engaged him when he became a hearer of Socrates.

This preliminary education, in fact, was very imperfect as a discipline of the mind. It gave the youth a forwardness and fluency of knowledge, so that he was fain to fancy himself, when he had scarcely attained manhood, equal to undertake affairs of state, and to serve the highest offices of the government. But it did not form his mind or character. He had yet to learn the nature of man; to study the principles of ethics and politics. This task of instruction devolved on the sophist or the philosopher (as the same person was at first indifferently called), into whose hands the Greek youth was now delivered.

Plato, accordingly, at the age of twenty years, began to be a regular attendant on the lessons of Socrates. The reputation of Socrates as a teacher in this higher walk of education, now eclipsed that of all other professors of philosophy. He had at once exposed the incompetence of the sophists who preceded him, and superseded them in their office. Plato would be conducted to him by his father, as the account states he was, very much in the way which is depicted under caricature by the comic poet,[1] as to the most distinguished master of the day, to be qualified for taking on him those public duties to which every citizen of Athens might be called; to enable him to distinguish himself in counsel and argument, and obtain influence and importance in society. From the numbers that resorted to Socrates, as well as to the sophists before him, it is plain that, to obtain instruction in philosophy for its own sake, or to become philosophers themselves, was not the object with which he was sought by the generality. Here and there the spark fell on a kindred genius, and lighted up a flame of philosophy in the breast of a disciple. Thus from the school of Socrates came the founders of several other schools; and, on the whole, a greater impulse was given by his teaching to the study of philosophy than had ever been felt before in Greece. Still, as Socrates himself did not profess to teach his hearers wisdom, so neither did they in general come to him as learners of wisdom, or as actuated by the pure love of wisdom, but to acquire practical information which their previous studies had not given them. We may imagine such a disciple as Plato first presenting himself amongst the multitude of hearers; how he would be struck by the first observation of the extraordinary manner of Socrates, especially at finding the very person to whom he came to be taught professing that "he knew nothing;" and that he was only wiser than other men on this account, that, whilst others knew not and presumed they knew, he neither knew nor presumed that he knew. The interest of such a mind as Plato's could not but be powerfully called forth by so strange an avowal on the part of a man whom he had been led to look up to as the wisest of men. To him it must naturally have prompted the questions, what philosophy might be; what the nature and condition of man; what the criteria of truth and falsehood; and thus have firmly laid hold of those tendencies to speculation which we see fully developed in the mature fruits of his genius. Again and again he is present at the searching investigations carried on in the discussions of which Socrates is the leader; soon he is himself interrogated by Socrates; and we cannot doubt that he is thenceforward irrevocably become, not the disciple of Socrates only, but the disciple and votary of philosophy.

That Plato was thus won over to philosophy from an early period of his life, is evident from the statement of Aristotle respecting him, that "from his youth he had been conversant with Cratylus, and the opinions of Heraclitus,"[2] and from the indications in two at least of his dialogues (and these supposed to be the earliest in the date of their composition, as written indeed during the lifetime of Socrates), the *Phædrus* and the *Lysis*, of his early acquaintance with Pythagorean notions.

There seems, too, but little room to doubt that he had begun at the same time to study the doctrines of the Ionic school under Hermogenes, as well as those of Parmenides and Zeno. For what he puts into the mouth of Socrates in the *Phædo*[3] respecting Anaxagoras, is probably (as Socrates himself was known to have had a strong aversion to physical science) the expression of his own disappointment and dissatisfaction at the outset of his studies, in the conclusions of the school, of which Anaxagoras was then the chief authority. Of Parmenides, again, he more than once

[1] Aristoph. *Nubes.*

[2] Aristot. *Metaph.* i. 3.

[3] *Phæd.* pp. 220–225, ed. Bip.

speaks in terms of enthusiasm, as of a name with which he had very early associations of reverence;[1] here, as in the instance of Anaxagoras, we are disposed to think, depicting, in the person of Socrates, a portion of the history of his own mind.

Judging indeed from the tenor of his writings, we should conclude that his curiosity was excited, from a very early period, to explore the whole field of philosophy; and that, so far from resting on what he learned from Socrates himself, he applied the lessons of Socrates to the extending and perfecting those researches which he was carrying on at the same time, by means of books, or oral instruction from others.[2] Socrates was to him the interpreter, and commentator, and critic, of the various philosophical studies in which he was engaged. For this is the view which he has given us of Socrates in his Dialogues. Socrates there seldom or never appears as a didactic expounder of truth. He is presented as the critic of opinions and doctrines and systems, and the judge to whom everything is to be submitted for approval, or rejection, or modification, as the case may be.

Indeed, so exuberant and energetic a mind could not have been satisfied with being simply a learner in any school. It would eagerly seek the means of comparing system with system, and of examining into points of agreement or disagreement in the theories proposed. The doubts raised by Socrates, the hints thrown out by him, the conclusions to which he pointed, but which he yet left unconcluded, would to such a mind seem as so many points of departure for its own excursions. They naturally suggest that much more must be done than merely to take up what has been said by Socrates, in order to work out, or even rightly to conceive, what had fallen from his lips. For the conversations of Socrates were not framed to convey positive instruction, so much as to set the mind of the hearer a-thinking, and to provoke further inquiry. In the living pictures of them which Plato has drawn, they leave off just at the point where we expect the teacher would proceed to speak out more distinctly, and tell us precisely what his view of the subject is. If these pictures represent (as we may reasonably believe they do) the impressions received by Plato from the conversations of Socrates, what stimulants to inquiry must he not have felt in the several particulars which he has so forcibly touched,—in the mingled lights and shadows of the scenes in which the great master occupies the foreground. Well therefore may we conceive that, at the time when he enjoyed the guidance, and control, and encouragement of Socrates, he was laying a broad foundation of erudition for that vast and richly-ornamented fabric of philosophy which the existing monuments of his genius exhibit.

From Socrates himself this demand of the inquisitive hearer could evidently not be supplied. Socrates was deficient in erudition properly so called. He had studied men rather than books. His wisdom consisted of deep and extensive observation accurately generalized, drawn from passing things, and capable accordingly of ready application to the same course of things; forcibly convincing his hearers by the point and propriety with which it met each occasion, and giving experimental proof of its soundness and truth. Erudition, accordingly, was to be sought elsewhere; and Plato therefore supplied this need from other sources, infusing it into, and blending it with his own speculations, whilst the Socratic spirit mellows the whole mass, and gives unity to the composition.

The death of Socrates—over which how his disciples mourned, appears in that affecting account of the last moments of their loved master, consecrated to his memory by the genius of Plato, the Dialogue of the *Phædo*—naturally excited alarms for their own safety amongst those who had been conspicuous among his associates. They saw, by the violent extremity to which the spirit of intolerance had proceeded, unchecked by any feeling of humanity or regard for truth, that no wisdom, or gentleness, or benevolence of character could be a security against the deadly hatred of jealousy. They found that priestcraft could stoop to employ any instruments, however mean, for the accomplishment of its vengeance; that it could instigate the actor on the scene of civil affairs to do its work of destruction, whilst the prompter of the mischief wore the mask of concern for the public good, and arrogated the merit of upholding the cause of religious truth. Persecution has ever been the same. Its essential features are vices of the human heart, not of any particular system of religion. We find it, accordingly, in several recorded instances in the heathen world, displaying itself very nearly as in the dark times of anti-Christian corruption. Athens itself had already furnished examples of its operation. In particular, the case of Anaxagoras had been a striking illustration. When not even the power and the eloquence of Pericles could save Anaxagoras from a prison, and expulsion from Athens, on account of his physical speculations,—the very philosopher whose system of physics raised an insuperable barrier against atheism, by demonstrating the supremacy of mind,—it was but too evident that there was a mysterious agency working in the heart of society, like secret fires in the depths of the earth, capable of awing and paralyzing every other power that might rise up against it.

A more recent experience of the same truth, within the memory of the youngest disciple of Socrates, was in the dark proceedings consequent on the mutilation of the Hermæ, the rude images of Mercury erected in the vestibules of private houses as well as in the sacred places of Athens, and on the discovery of the profanation of the Eleusinian mysteries by the mock representation of them in private houses.[3] The secret information on which those proceedings were carried on; the indifference shewn at the period of alarm to everything else, even on an occasion of great public interest, but the vindication of the popular superstition; the effect which the charge of being implicated in these outrages had in checking the career of Alcibiades at the moment of his triumph over his political opponents; all shewed, that it was a vain hope to resist the secret arbiters of public opinion on questions of religion. Then came the fearful consummation of this vengeance in the death of Socrates by the poisoned cup; leaving no doubt in the minds of any, that they who would follow his example in boldly and honestly inquiring into current opinions, and declaring their convictions of the truth on matters affecting the conduct of men, must either prepare themselves for exile (which alone was a great punishment in the ancient world),[4] or drink the hemlock.

[1] Μελισσον μεν και τους ἀλλους οἱ ἐν ἑστως λεγουσι το παν, αἰσχυνομενος μη φορτικῶς σκοπωμεν, ἧττον αἰσχυνομαι, ἢ ἑνα ὀντα Παρμενιδην. Παρμενιδης δε μοι φαινεται το του Ὁμηρου, αἰδοῖος τε μοι εἶναι ἁμα δεινος τε· συμπροσεμιξα γαρ δη τῷ ἀνδρι, πανυ νεος, πανυ πρεσβυτῃ· και μοι ἐφανη βαθος τι ἐχειν παντπασι γενναῖον. (*Theætet.* pp. 137, 138. *Parmenid.* p. 72.)

[2] This evident early devotion of Plato to the pursuit of his whole life, argues the mere calumny of that statement which represents him to have at first sought his fortune by the profession of arms. The calumny is a current one, which has been applied to other philosophers. He has also been absurdly represented as present at the battles of Tanagra and Delium, when he was, in truth, a mere child.

[3] The performance of religious rites in private houses is forbidden in Plato's Dialogue on Laws, x. p. 117.

[4] Cicero says of exile, endeavouring to reconcile the feelings to it, "jam vero exilium, si rerum naturam, non *ignominiam nominis* quærimus, quantum demum a perpetua peregrinatione differt." (*Tuscul. Quæst.* v. 37)

Socrates himself had the courage to take the latter part of the alternative. To him it was the natural termination of that energetic course which he had from the first adopted. He would have unsaid all his teaching; he would have practically recanted the strong language in which he had, through all his life, been discoursing of the worthlessness of the body and of the present life, and of the immortality and perfection of the soul. His philosophy, and the sense of the dignity of his character and position, kept him immured in his prison, and riveted the chains on his limbs, far more than the condemnation of his judges or the strength of the iron with which he was bound. For, as he says of himself, in the words in which Plato has expressed his sentiments, "these sinews and bones would long ago have been either about Megara or the Bœotians, had I not thought it more just and more honourable, instead of flight, to submit to the judgment of the state."[1]

But this was not the case with the hearers of Socrates. They were not, like him, placed in a commanding post, from which they could not retreat without being stigmatized as deserters of their profession, and betrayers of the truth. They might with honour and propriety consult for their safety. Whilst, therefore, as is probable, the bulk of those who had attended on the teaching of Socrates simply withdrew from public notice, and sought their homes at Athens or elsewhere, the principal disciples of the school—those who were most known as followers and admirers of Socrates—left Athens, and sought an asylum for themselves and for philosophy at Megara.

Amongst those whom Socrates drew around him were several individuals of mature age, already trained in some sect of philosophy, and eminent in their own walk of science, yet desirous of availing themselves of the far-famed wisdom of the sage of Athens. Of this class was Euclid of Megara, from whom the Megaric school derives its existence and celebrity.[2] As a disciple, he belonged to the Eleatic school, and, trained by Zeno, the great master of dialectic before him, had made that science his especial study. He had shown a singular zeal in attending on the teaching of Socrates; for he continued to resort to him even after the passing of the Athenian decree by which Megarians were excluded, under the penalty of death, from the harbours in the Athenian empire, and from the agora of Athens itself. For this purpose, he would set out from his home at nightfall, a journey of more than twenty miles,—such was the distance from Megara to Athens,—assuming the disguise of female attire that he might enter the city unnoticed.[3] His conduct on the occasion of the dispersion of the school of Socrates corresponded with this zeal. He received the members of the school with open arms, and gave them a home with him at Megara. There, for a time at least, they gathered themselves, in shelter from the storm which had driven them from Athens. But the school, in fact, was broken up. It had subsisted and been held together by the personal influence of Socrates himself, and with him its principle of vitality, as a body, was gone. He had not laboured to establish a sect or a theory; and he left, therefore, no particular symbol of union around which a party might be formed. He was himself the principle and bond of union to his disciples; bringing together around him the professors and disciples of every different sect. There was yet to arise out of his society one who, richly imbued with his teaching and method, should rekindle the extinct school with his own spirit, and bid it live again in its genuine offspring; and that individual was Plato. But the times were not yet ripe for this.

In the meantime, Plato was destined to spend several years in journeying from place to place, at a distance from the past and future scene of his philosophical labours. These were doubtless years of great importance to him, for the perfect formation of the peculiar character of his philosophy. In the course of them, we find him visiting Megara, Cyrene, the Greek settlements on the coasts of Italy, Sicily, Egypt, "exploring (as Cicero says of him in oratorical language) the remotest lands,"[4] after the manner of Solon and Pythagoras, and other wise men before him, who had enlarged their minds by contemplations pursued in foreign travel. Thus did he singularly combine in his studies the more ancient with the Socratic mode of philosophizing. The method of Socrates was exclusively domestic. He studied mankind within a small compass (the circle of Athens itself), only with a more accurate and searching eye than any one had ever done before him; and therefore drew sound general conclusions from his observations within that range of view. He evidently judged it better thus to restrict the attention, and require men to investigate closely what lay before them, than to encourage them to indulge the prevailing habit of more diffusive and vague observation. This is told us in other words by Plato himself; where he introduces Socrates as a stranger even to the beautiful scenery in the immediate neighbourhood of Athens, and as one who appeared never to have been out of the walls of the city; and as owning that, in his fondness for moral study, he was content to learn of the men in the city, who could teach him what the fields and the trees could not.[5] But this method, good as a foundation, and necessary as a corrective of desultory and superficial habits of thought and study, was not sufficient for the requirements of Plato's mind. He observes in one of his works, that there is much to be gained from contemplation rightly directed in foreign travel both by land and sea; that we are not only to look to our own country for examples, but seek in the world at large for specimens of the highest order of men, who, though rare, might from time to time be found under every form of government; and that no perfect civilization can be attained without this means of observation and improvement.[6] He describes, in fact, the course which he had himself pursued, and the benefit which he had found resulting from it.

Having sojourned for a time at Megara, together with the other disciples of Socrates, and probably there, with the assistance of Euclid, increased his acquaintance with the writings of Parmenides and Zeno, as well as studied more intimately the dialectic of their school, he appears to have proceeded to Cyrene. Cyrene was the home, not only of Aristippus, to whose school it afterwards gave its name, but of the venerable Theodorus, the most eminent geometrician of his day. Theodorus had been occasionally a resident at Athens, and an attendant on the teaching of Socrates, whilst he was himself resorted to by the Athenian youth for instruction in the science of geometry.[7] Plato no doubt had been amongst those who had thus availed themselves of the presence of Theodorus at Athens. His predilection for mathematical studies is conspicuous throughout his writings. His skill in geometry, in particular, requires no other evidence than the fact of his ready solution, in that state of the science, of the problem of the Delphic Oracle, which required the doubling of the cubic altar at Delos.[8] He has described Theodorus as present at Athens at the time when the prosecution was instituted

Plato. against Socrates.[1] He now went to Cyrene, probably with the view of following up that course of geometrical study which had been so abruptly terminated; whilst he regained also the society of a friend for whom he evidently felt respect and admiration.[2]

The course of his travels conducted him to the Greek settlements on the coast of Italy and Sicily, where the colleges of the Pythagoreans were established. It may readily be imagined with what eager curiosity Plato undertook this voyage, what delight he promised himself in seeing the place itself where Pythagoras had taught, and in personal conference with the living successors of the mystic sage, and in obtaining a greater insight into the doctrines of a school which had such charms for him. He had much to observe also in the peculiar discipline by which the Pythagoreans were formed into a distinct fraternity amongst themselves. Greece Proper had nothing to exhibit like this. For though the different sects of philosophy were distinguished there by the names of founders and places, they were not held together by any rules of discipline. But the Pythagoreans at Tarentum, Crotona, and elsewhere in Magna Græcia, had incorporated themselves into synedria, or colleges; each individual giving his property in common, and regarding the bond of connection with his brethren of the sect as closer than the ties of kindred.[3] Associations of this kind must have appeared, at the first, as anomalies even to the philosophical Athenian, accustomed as he was to regard the free intercourse of social life as indispensable to his very existence.

It has been said that Plato was admitted to the secret discipline of the Pythagoreans. Probably he was only received by them with great cordiality, and had access to writings and information respecting their doctrines, which might have been denied to one, who came less recommended to them by the sincere enthusiasm of philosophy, and approximation to their views. There are no traces certainly in his writings, or elsewhere, of his having been a professed Pythagorean; although he undoubtedly was greatly captivated by the Pythagorean doctrines, and has introduced them largely into his own speculations.

Archytas, the greatest name of the Pythagorean school after that of Pythagoras himself, was then flourishing at Tarentum. It must have been an interesting occasion when there were assembled together at Tarentum, as Cicero relates,[4] Pontius the Samnite, the father of that Pontius who defeated the Roman consul at the Fauces Caudinæ; Archytas the Pythagorean, discoursing against pleasure; and Plato the Athenian traveller. The very place where they met,—a point of contact between the old empires of the world, and the rising power destined to break them in pieces,—in itself adds to the interest. Then the characters of the two philosophers who thus met, further arrest our attention:—Archytas, the representative of the old traditionary theological systems now moulded into a scheme of philosophy and a discipline of life; and Plato, the accomplished artist, who was soon to take up the scheme of philosophy where the Pythagoreans left it, and consecrate it by the inspirations of his own genius to an eternal empire on the throne of literature:—Archytas, nurtured in the reserve and mysticism of the Pythagorean discipline; Plato, formed to busy and importunate discussion by the ever-colloquial Socrates,—two philosophers so contrasted with each other in many respects, and yet so concordant in their love of ancient wisdom and indefatigable research after truth. Plato.

From the Pythagoreans Plato proceeded to Egypt to converse with the priests of that ancient land, from which Greece had derived her original civilization and science. Since the settlement of the Greek colony in Egypt by Psammetichus,[5] there had existed a regular channel of intercourse between Greece and Egypt, and accurate means of information to the Greeks respecting Egypt. The history of Herodotus must in itself have awakened the curiosity of those who had any taste for such inquiries, to know still more of a people from whom Greece had already learned so much, and from whom evidently so much was to be learned, and must have stimulated them to avail themselves of the existing facilities of gratifying that taste. To Plato, indeed, if, according to Herodotus, the Greeks derived the notion of the immortality of the soul from the Egyptians, who were the first, he thinks, to teach it in connection with that of the transmigration of souls,[6] a visit to Egypt must have been most attractive. Herodotus has given a most instructive and interesting view of the impression which such a visit produced on his mind. What an animated picture must the still more philosophical mind of Plato have presented, of the result of his conversation with the priests of Egypt. Though the account of his having had the mysterious wisdom of the inscriptions on the Hermetic Columns unfolded to him by the priests, and of his being instructed in magic,[7] on this occasion, seems without sufficient authority, there are evident traces of information collected in Egypt, throughout his writings, and, so far, it cannot be doubted that this visit was not without its influence on the character of his philosophy.

Indeed it has been further asserted, that, whilst in Egypt, he had access to an existing Greek version of the Old Testament, and that to this circumstance we must attribute that purer and more elevated theology which his works exhibit, in comparison with those of other heathen philosophers. A strange oversight in chronology has also attributed to him a personal intercourse with the prophet Jeremiah.[8] These statements are obviously mere suppositions, by which Christians, over-zealous for Plato's philosophy, vindicated their admiration of it, whilst they asserted also the originality and supremacy of Scripture truth. At the same time, it is indisputable that Judaism diffused much religious and moral truth beyond its own pale; and that not only Plato, but the Egyptian priests, his instructors, unconsciously derived much from the inspired sources, in collecting, under the form of fable, or allegory, or maxim, portions of truth which the sacred oracles had scattered around them in their transmission.[9]

Having traversed Egypt, where he is said to have assumed the disguise of an olive-merchant, in order to journey more securely in a country not naturally tolerant of strangers, he purposed penetrating into Persia and India. But the disturbed state of those parts of Asia prevented his fulfilling his intentions. He returned accordingly to Magna Graecia, once more to enjoy the society of the Py-

thagoreans. At length, having spent several years in these travels, he turned his steps homeward. We have no means of ascertaining the exact time which these travels occupied, or at what period of his life precisely he undertook the office of teacher of philosophy at Athens. From the epistle addressed to the friends of Dion, it appears that he was scarcely forty years of age when he first went to Syracuse;[1] so that probably not more than about ten years were taken up in his wanderings.

The visit to Sicily here referred to, had for its object to explore the crater of Mount Ætna, and therefore properly belongs to that part of his history which we have just been tracing. But it had also very important bearings upon the future fortunes, both of himself and many others; so important, indeed, that Plutarch, following out a remark which occurs in the supposed epistles of Plato, attributes it to a providential arrangement, in order to the restoration of liberty to the Syracusans.[2] For it was at this time that he became acquainted with the elder Dionysius, tyrant of Syracuse, and Dion, whose sister Dionysius had married. He reclaimed Dion, who was then quite a youth, from a life of vicious indulgence, to habits of sobriety, and inspired him with an ardent love of philosophy. Thus began an intimate friendship between the philosopher and Dion, which subsisted unimpaired until the tragical death of the latter.

Through the influence of Dion, the tyrant Dionysius, who was himself a literary man and a patron of literature, was induced to receive Plato into the circle of his court. The result, however, whether it was owing to the jealousy of other philosophers who were then at the court of Syracuse, or to an excess of freedom of speech in Plato, and an ebullition of temper and disappointed literary vanity on the part of Dionysius, was unfortunate. Dionysius was affronted at some words that passed at an interview with him, and was only prevented by the interposition of Dion from slaying the philosopher in the moment of exasperation. But still he did not remit his displeasure; for on suffering him to depart, he instructed the Lacedæmonian ambassador, Pollis, in whose vessel he was to be conveyed from Sicily, either to slay him on the voyage or to sell him as a slave; observing sarcastically, "that being a just man, he would be equally happy though reduced to slavery." Pollis is said to have so far lent himself to this cruel treachery, that he actually caused the philosopher to be sold as a slave, by landing him at Ægina at a time when a decree was in force there, sentencing to death every Athenian who should set foot in the island. From this shameful indignity, however, Plato was immediately relieved by the generous kindness of Anniceris, a philosopher of Cyrene, who happened to be at Ægina at the time, and paid the twenty minæ, the price of his redemption. And such, it is added, was the noble concern which Anniceris felt for him, that he could not be prevailed on to receive back the money from the friends of Plato at Athens, but refused it, saying "that they were not the only persons interested in the welfare of Plato."[3]

The story is related with circumstantial particularity, and so far bears the aspect of truth. Still it has been questioned, as inconsistent with the character of Dionysius, who, though despotic in the power which he possessed, and often cruel in his use of it, was a man of education and courtesy, and the patron of literary men. And the treachery of Pollis, as thus exhibited, has been regarded as altogether unlikely in the high-minded Spartan. Nor again do we find any allusion in the writings of the philosopher himself to so affecting an incident in his life. The story may be thought still more improbable, if the account be true that Dionysius presented him with a considerable sum of money, with which he was enabled, during his residence in Sicily, to purchase a treasure inestimable to him, the books of Philolaus the Pythagorean. These arguments, however, may be pressed too far. Individuals possessed of absolute power have often been found capable of deeds from which their own feelings, apart from that great temptation, would have shrunk: and sudden and most unreasonable and absurd outbreaks of violence, inconsistent with their general behaviour, are characteristics of such power. And as for the Lacedæmonians, we know that at the height of their civilization they were guilty of the acts of barbarians. Their extreme cruelty to the poor debased Helots is well known;[4] and in the Peloponnesian war they slaughtered indiscriminately all whom they met with at sea, even neutrals, and persons inoffensively engaged in the business of commerce.[5] Further, there are repeated instances of Greeks selling as slaves the free inhabitants of captured cities in their wars with each other.[6] There is no reason, at any rate, to question the general truth of the story, whatever may be thought of the particulars. There can be little doubt that the visit of Plato at Syracuse ended unsatisfactorily; that offence arose between the tyrant and himself; that he was treated with great indignity, and that he returned to Athens in disgust.[7]

From this time we may contemplate him as pursuing, with little interruption, the course of philosophical labour for which his whole previous life had prepared him. The term "Academy" is now familiar to every one as synonymous with a place of learning. How strongly does this mark the celebrity of a school, which has thus immortalized in vernacular language the grove of the hero Academus or Hecademus, the ground on which Plato walked, and, as he walked, imparted to the throng around him the riches of his genius, and taste, and learning! Here, in the most beautiful suburb of Athens, the Ceramicus, Plato possessed a small patrimony, a garden, where he fixed his abode, in the immediate vicinity of the grove, his daily resort. Here, amongst the tall plane-trees which shaded the walks, were assembled, year after year, the master-spirits of the age, whether in pursuit of knowledge for its own sake, or for counsel in the direction of public or private life,—the philosopher, the statesman, and the man of the world,—to converse with the Athenian sage, and imbibe the wisdom which fell from his lips. What an interesting assemblage must that have been which comprized in it, amongst other influential persons, and young men who afterwards rose to importance in their respective states, Demosthenes, Hyperides, Aristotle, Speusippus, Xenocrates, Polemo, Dion! At once you might see in the throng the young and the gay by the side of the old and the sedate; the stranger from some distant town of Asia Minor, or Thrace, or Magna Græcia, and the citizen of Athens; the tyrant of some little state learning theories of government and laws from the philosopher of the republic; and the haughty Lacedæmonian paying deference to the superior wisdom of an individual of a country which his own had humbled in arms.[8] Nor was the audience exclusively of the male sex. The wives and daughters of Athenian citizens, indeed, were not

[6] *Ibid.*
[7] The conduct of Dionysius towards Philoxenus, the dithyrambic poet, for freely giving his opinion on the bad poetry of Dionysius, was very similar. See Diodorus Siculus, xv. 6, who also, in xv. 7, confirms the account of this treatment of Plato.
[8] In the Dialogue "on Laws," it is the Athenian stranger who instructs the Lacedæmonian and Cretan in the theory of legislation. Here we have probably a representation of what actually was seen in the Academia itself. Socrates is away; Plato speaks; Cretans and Lacedæmonians, among others, are the auditors.

in that assembly; for custom excluded these. But the accomplished courtezan, whom the unnatural exclusion of the chaste matron from social intercourse had raised to importance in Grecian society, was there, seeking the improvement of her mind by joining in the discussions and listening to the instructions of the philosopher, and thus qualifying herself for that part which she had to sustain as an intimate with the men of the highest rank and most intellectual cultivation in Greece. The celebrated Aspasia had been at once the intimate of Pericles, and a hearer of Socrates; and Plato himself pays her the compliment of saying, that both Pericles and Socrates had taken lessons in rhetoric from her, as a most accomplished mistress of the art; to whom, indeed, Pericles had been chiefly indebted for his eloquence.[1] So now in Plato's own school of the Academia were found, amongst others of the same class, the beautiful Mantinean Lasthenea, and Axiothea of Phlius.

Socrates attracted persons around him from all parts of the Grecian world, by the charm of his engaging conversation, and thus became in himself a great object of interest.[2] Plato made Athens itself also, even more than his own person, an object of interest to the civilized world of his day; converting it, from being only the centre of political intrigue and agitation to the cities of Greece, into a common university and common home for all. Compare what was said of Athens about half a century before, "that it was the nature of Athenians neither to keep quiet themselves, nor to suffer other people to do so,"[3] and its well-known character at that time of a "tyrant state,"[4] with the respect which Plato had won for it, when it became, not through the versatility of its citizens, and its inexhaustible resources, but by a truer title, through the lessons of virtue and wisdom, which it freely imparted to all, pre-eminently the School of Greece;[5]—and what an exalted opinion does the change now operated give us of the influence of Plato!

Isocrates had, at the same time, his school of rhetoric overflowing with pupils. Aristippus, also trained in the school of Socrates, was inculcating his scheme of ethics, which maintained the theory of Pleasure as the Chief Good. But esteemed as Isocrates was for the gentleness of his life, and his skill as a master of rhetoric; and acceptable as the doctrines of Aristippus must naturally have been to a corrupt society; neither of these great names sufficed to obscure the greater name of Plato, or could rival the pretensions of the Academia to be the great school of philosophy, and literature, and civilization.

A mind so intensely occupied as that of Plato, would scarcely find leisure for taking part in the political affairs of his country. The profession of philosophy was not as yet indeed become entirely distinct; but the teaching of Socrates had greatly tended to render it so. His rigorous method of interrogation which called forth the latent difficulties on other subjects, could not but produce great distrust in those who laid themselves fully open to it, as to their own ability to manage the complex matters of public concern, as well as impress them with despair of success in that walk of exertion. Socrates himself avoided as far as possible all interference in the politics of Athens. Plato strictly followed his example. Accordingly, we find, in several places of his writings, a contrast drawn between the philosopher and the man of public life; and an indirect apology for himself, as one who kept aloof from the public assemblies and the courts.[6] He betrays indeed strong disgust, not unmixed with contemptuous feeling, at the state of misrule into which the democracy of Athens had degenerated in his day, and he was evidently glad to avail himself of the plea of philosophy to absent himself from scenes so uncongenial to his taste. Doubtless, independently of any political bias, he was glad to escape from the sycophancy and tumult of the popular assemblies at Athens, and to enjoy the calm shades of his beloved retreat. This was the sphere of action for which nature and his whole previous life had peculiarly fitted him. Here he could effectually diffuse the salutary influence of his philosophy, in counteracting, in some measure at least, the selfishness of the world. Here he could maintain an undisputed supremacy over minds, which (such was the impatience of all authority in those times) no mere external power could have controuled or so entirely subjected to the direction of an individual.

Through the influence, however, of his Pythagorean friends, with whom he appears to have held constant intercourse, Plato was prevailed upon, at the age of sixty-five years, to quit the retirement of his garden for a time, and pay a second visit to Sicily.[7] It was the policy indeed of the Pythagoreans, like that of the Jesuits in modern times, to keep up an active intercourse with society, whilst in their internal system they cultivated philosophy with the ardour of exclusive devotees. Socrates wished to govern the conduct of men by an appeal to their reason; convincing them of their errors and follies, and leading them to seek the means of informing themselves aright. The Pythagoreans, like the Jesuits, aspired to carry out their views by a moral hold over men in society; by taking part accordingly in the management of states, and by a secret influence over those in power. The accession of the younger Dionysius to the throne of Syracuse, and the opening presented for producing an effect on him through Plato's influence with Dion, the next in power to the tyrant, were opportunities which would not be lost by their watchful zeal. Such seems, if we may proceed on the authority of the Epistles, to have been the occasion of this invitation of Plato to Syracuse. We see, at the same time, that there was a struggle of factions at Syracuse at this period. The party opposed to Dion, in order to counteract his influence, obtained the recall of Philistus, a man distinguished alike as a statesman, a commander, and an historian,[8] and a strenuous supporter of the existing government, but then in banishment through the ingratitude and caprice of the elder Dionysius. The result was, that though the reception of Plato at Syracuse was most flattering, for he was welcomed with the royal pomp of a decorated chariot, and the celebration of a public sacrifice, his mission was ultimately fruitless.

At first everything seemed prosperous. The change wrought in the manners of the court is described as marvellous. Philosophy became the fashion; and the very palace was filled with the dust stirred up by the number of geometricians. Even the expulsion of Dion, which soon followed, through the successful intrigues of his enemies, did not at once estrange Dionysius from the philoso-

[7] Diogenes Laertius says, he went to Sicily on this occasion, in order to found a city according to the principles of his Republic, but that Dionysius failed in his promise of land and men for the purpose. But others, he adds, stated that the object of his visit was the liberation of the island from tyranny. In *Vit. Plat.*

[8] Cicero speaks of Philistus as a writer in the following manner: Philistum doctum hominem et diligentem. (*De Divin.* i. 20.) Catonem cum Philisto et Thucydide comparares? quos enim ne e Græcis quisquam imitari potest. (*De Clar. Orat.*)

Plato.

pher. He would not indeed allow Plato to leave Sicily with Dion; but, using a gentle constraint over him, detained him within the precincts of the citadel; shewing him at the same time all respect, and hoping at last, as it seems, to bring him over to his interest. At length the attention of Dionysius was called to preparations for war; and Plato, released from his embarrassing situation, was enabled to return to Athens.

He was not, however, deterred from once more making the trial, how far an impression could be made on the mind of Dionysius, and the restoration of Dion to his country effected; and, as on the former occasion, so now, he was chiefly induced to undertake the enterprise, by the earnest intercession of his Pythagorean friends. Dion himself was living at Athens, waiting the opportunity of returning to his country; and his relatives at Syracuse sent letters to Plato, urging him to use his exertions in behalf of Dion. Even Dionysius himself wrote a letter to him, entreating him to come, and promising satisfaction at the same time in regard to Dion. He also sent a trireme for him, with Archidemus, a disciple of Archytas, and others with whom the philosopher was acquainted, to render the voyage more agreeable to him.[1] For a while Plato persisted in declining the invitation, pleading his advanced age, for he was now sixty-eight years old;[2] but at length he gave way to these united solicitations. Dionysius, indeed, like his father, was fond of drawing around him men of eminence for literature and philosophy. At this time, amongst others of the same class at his court, were the philosophers Diogenes, Æschines, Aristippus, and some Pythagoreans. Plato might have not unreasonably hoped, therefore, that a mind delighting in such society, or at least ambitious of the reputation of being a patron of literature, might yet be influenced to sound philosophy. He was, besides, desirous of making an attempt to produce a reconciliation between Dionysius and Dion. Thus did he pass the Straits of Sicily a third time, to be a third time disappointed in the object of his voyage. Though he was welcomed, as before, with great splendour and demonstrations of respect, not only were his endeavours for the restoration of Dion unsuccessful, but he incensed the tyrant by venturing to intercede in behalf of Heraclides, a member of the liberal party at Syracuse, who was under suspicion of having tampered with the mercenaries. Still Dionysius was desirous of retaining the friendship of the philosopher. Plato was removed, indeed, from the garden in which he lived, under the pretence of a sacrifice about to be performed there by women, and placed in the quarter of the mercenaries. Such a situation was most unpleasant to him; as he could not but feel himself in danger amongst that lawless class, who naturally disliked him, as an enemy of the power which gave them employment and pay.[3] But this indignity was probably more the effect of the hostility of the opposite party against Dion, than an act of the weak tyrant himself. Plato, in his perplexity, applied to Archytas and the Pythagoreans at Tarentum, to extricate him from these difficult circumstances. At their instance, accordingly, Dionysius consented to the departure of Plato, and dismissed him with kindness, furnishing him with supplies for his voyage.

Thus did Plato once more return to Athens, heartily disgusted with the untoward result of his visits to Sicily.[4] Though the friend of Dion, the head of one great party at Syracuse, he had acted in Sicily consistently with his conduct at Athens, in not taking any active part in political affairs. Even Dionysius himself seems, throughout his conduct towards him, to have been jealous rather of his personal regard for Dion, than suspicious of any exertion on his part in the cause of Dion against him, and to have sought to detain him at Syracuse, not out of fear or ill will, but for the honour of the presence of the philosopher at his court. This is further evinced by the subsequent conduct of Plato. For, in the expedition which Dion planned and executed against Dionysius, he took no part; making answer to the invitation to join in it, "that if invited to assist in doing any good, he would readily concur; but as for doing evil to any one, they must invite others, not him."[5]

Plato.

The remaining years of his life were gently worn away amidst the labours of the Academia. These labours were unintermitted to the very close of a long life; for he died, according to Cicero's account, in the act of writing; his death happening on the day in which he completed his eighty-first year. "Such," adds Cicero, "was the placid and gentle old age of a life spent in quietness, and purity, and elegance."[6] Another account, however, of his death states that he died during his presence at a marriage-feast.[7] And another account besides (evidently the invention of some enemy to his fame), attributes his death to a loathsome disease.[8] On his first residence in the garden of the Academia, his health had been impaired by a lingering fever, in consequence of the marshiness of the ground. He was urged to remove his residence to the Lyceum, the grove afterwards frequented by the school of Aristotle; but such was his attachment to the place, that he preferred it, he said, even to the proverbial salubrity of Mount Athos; and he continued struggling against the disorder for eighteen months, until at length his constitution successfully resisted it.[9] Adopting habits of strict temperance, he thus preserved his health during the remainder of his life, amidst the harassings of foreign travel, and the undermining assiduities of days and nights of study.

Plato was never married. He had two brothers, Glauco and Adimantus, and a sister, Potona, whose son, Speusippus, he appears to have regarded with peculiar affection and interest, as the destined successor to his school of philosophy. He inherited a very small patrimony, and he died poor, leaving but three minæ of silver, two pieces of land, and four slaves, and a few articles of gold and silver to the young Adimantus, the son, as it would seem, of his brother of that name.[10]

In person he is described as graceful in his youth, and, if the etymology of his name be correct, as remarkable for the manly frame of his body.[11] One circumstance, however, is mentioned, which detracts in some measure from his bodily accomplishments; the imperfection of his voice, which has been characterized as wanting in strength of tone.[12]

In regard to moral qualities, he was distinguished by the gravity, and modesty, and gentleness of his demeanour. He had never been observed from his youth to indulge in excessive laughter.[13] Several anecdotes are told of his self-command under provocation; as, for example, his declining to inflict the due punishment on a slave when he found himself under the excitement of anger.[14] A pleasing instance is given of his amiableness and modesty, at a time

Plato.

when his fame was at its height. Some strangers, into whose company he had been thrown at Olympia, coming afterwards to Athens, were received by him there with the greatest courtesy. All the while, however, they were ignorant who their host was. They merely knew that his name was Plato. On their requesting him to conduct them to the Academia, and show them his namesake, the associate of Socrates, they were astonished to find, by his smile and avowal of himself, that they had experienced so much unpretending kindness from the great philosopher himself.[1] Again, being asked by some one if there would be any saying recorded of him, he answered with the like modesty, "One must first obtain a name, and then there will be several."[2]

The gravity of his manner was by some interpreted as severity and gloom. The comic poet Amphis complained of him, that "he knew nothing but to look sad, and solemnly raise the brow." Aristippus charged him with arrogance. It is no wonder, indeed, that, in contrast with the coarse freedom of Diogenes, and the excessive affability of Aristippus, he should appear haughty and reserved. But that this character did not really belong to him, we may judge from the social humour which mingles even with the sarcastic touches of his Dialogues, and from the anxiety which he shewed to correct such a disposition as a fault in Dion. His favourite pupil Speusippus was distinguished by the opposite quality of a lively temper; and to his especial direction we find Plato sending Dion, that he might learn, by the conversation and example of Speusippus, a more conciliatory and agreeable mode of address.

The instance given of his vanity in putting himself forward at the death of Socrates, as competent to retrieve the great loss in his own person alone, bears evident marks of a calumny. It may be so far true, as it represents a desire upon his part to console his brother disciples under their common affliction. But as an evidence of an assumption of superiority over them at such a moment, it accords little with that feeling of dismay for themselves, under which he, in common with the rest, fled to Megara as an asylum; or with his indisputable affection for the person of Socrates, and veneration for his wisdom and talents.

Again, the strictness of Plato's philosophical profession, amidst the general dissoluteness of manners at Athens, was construed by some who had an envious eye on his reputation, as only an affected austerity. It was complained of him, that his life did not answer to the high requisitions of his moral teaching.[3] Two of his brother disciples in the school of Socrates, Antisthenes and Aristippus, imputed to him the grossest licentiousness. The former taking offence at Plato for objecting to a treatise, which he proposed to read, on the Impossibility of Contradiction, vented his spleen in a most abusive dialogue, which he entitled Satho, intending at once by that term a satirical play on the name, and a stigma on the character, of the philosopher. These calumnies are in some measure supported by the tenor of certain epigrams attributed to Plato, and by passages of his Dialogues, which display a license of impure allusion, shocking to the feelings of the reader, in these days at least. His calumniators then found occasion for their scandal, in observing amongst those by whom he was surrounded, the young and the handsome. But though we may see much to reprobate in such passages, and painful as the impression is which they leave on the mind, as evidences of the deep corruption of human nature, we are not warranted in regarding them as conclusive of corresponding immorality of conduct in a writer of his age and country. They would show, indeed, that the writer has not escaped the contagion of the vicious atmosphere which he breathed; and they are of course a great drawback in our estimate of the purity of his sentiments and character. But we ought to set off against them the high tone of religious and moral feeling which is the general characteristic of his philosophy; the beacon which it holds up to warn men of the debasing allurements of pleasure, and of the misery consequent on the indulgence of passion; and its glowing exhortation to seek for true happiness, not in externals, or by aiming at a mere human standard of virtue, but by internal purification, and by imitation of the perfections of the Deity.

Much has been said on the absence of any reference to Xenophon in the Dialogues of Plato. Xenophon, in his *Memorabilia*, has spoken of Plato, and alluded to the affection with which Plato was regarded by Socrates.[4] But Plato has not availed himself of any opportunity of paying the like compliment to Xenophon. This silence cannot, perhaps, be entirely accounted for, without supposing that there was a feeling of literary jealousy on the part of Plato. But there are some considerations which may partly account for Xenophon's not appearing as an interlocutor in the Dialogues. Xenophon, though a man of philosophical mind, evidently attended the teaching of Socrates, not to learn the art of disputation, or for the indulgence of a speculative curiosity. When he philosophized, it was as a man of the world, acquainting himself with human nature, with the manners and opinions of men, in order to his own conduct in life. He was not one of those eager and flippant sciolists, whom Plato takes delight in submitting as apt experiments to the interrogatories of Socrates. Nor was he, again, a devotee of science, like the wise Theætetus, the interesting person who gives occasion to the dialogue of that name, and whom in some points he resembled. He would not therefore naturally be selected by Plato, in order to the carrying on of discussions intended for the development of his philosophy. It is remarkable, that Plato has only in two places even alluded to himself; in the *Phædo*, to explain his absence from the death-scene in the prison;[5] and in the *Apologia*, as amongst those present at the trial of Socrates, and capable of giving evidence as to the nature of those instructions which Socrates addressed to the young.[6]

Such was the character of this eminent man. His distinguished career exposed him to the shafts of envy and detraction; and the high aspirings of his mind were clogged and weighed down by that corrupt heathenism with which he was surrounded. Still his reputation for wisdom and virtue stands above all these attacks and circumstances of disparagement. The more we converse with him in his writings, the more we are charmed by the deep feeling of natural piety which pervades his philosophy as its master-thought, and by the sound practical wisdom which shines forth from them as the real character of the man, reclaiming and subduing the wild aberrations of his speculative fancy.

His remains were buried in the place which he had ennobled whilst living. Nor were they unattended by the

Plato's Writings and Philosophy.

customary tributes of honour and affection. Aristotle, who had been his constant disciple during the last twenty years preceding his death, displayed his veneration for his preceptor by consecrating an altar to him. A festival, called after him Platonea, was instituted in honour of him, and celebrated annually by his disciples. A statue, dedicated to the Muses, was afterwards erected in the Academia by Mithridates the Persian. He had not, indeed, been dead but a very few years, when the great celebrity of his name called forth from his nephew and successor, Speusippus, an express work in his praise. Seneca further tells us of a singular mark of honour which was paid to him on the very day of his decease. There were some Magi, he relates, at Athens at the time, who, struck by the singular circumstance of his having exactly completed the perfect number of nine times nine years, performed a sacrifice to him, esteeming him on that account to have been more than man.[1] The story is evidently the invention of his later admirers. It is referred to here, as a testimony of the enthusiastic admiration with which his name has been ever attended. To the same feeling must be ascribed the fiction of the discovery of his body in the time of Constantine the Great, with a golden tablet on the breast, recording his prediction of the birth of Christ, and his own belief in the Saviour.[2]

PLATO'S WRITINGS AND PHILOSOPHY.

The writings of Plato obtained an early popularity. Already, during his lifetime, copies of them appear to have been circulated. An iambic line, *λογοισιν Ἑρμοδωρος ἐμπορευεται*, proverbially applied, long after the time of Plato, to those who made a traffic of the writings of others,[3] shews that there was an immediate demand for them in Greece. The Hermodorus here referred to, was one of his hearers, who is said to have sold the writings of the philosopher in Sicily for his own profit. The fact of their early circulation is further evidenced, if it be true, as has been stated, that complaints were made by some of the persons whose names appear in the Dialogues, and even by Socrates himself, of the manner in which they had been represented in them by Plato.[4] It is very probable, also, that during the long time in which he was publicly teaching at Athens, and, doubtless, recurring frequently to the same topics of discussion, considerable portions of what he delivered orally, were treasured up in the memory of some who heard them, and afterwards written down, and thus published to the world without having received the finishing touches of the author's hand. The practice, indeed, of thus carrying off the oral lessons of the philosopher is alluded to by Plato himself in passages of his writings, as in the *Phædo*, and *Theætetus*, and *Parmenides;* where the dialogue is related by some one remembering what has passed in conversation on a former occasion. This circumstance may, at once, account for the comparative inferiority of some of the Dialogues in point of execution, and for the fact that some have been passed under his name which are not really his; whilst we have, at the same time, a very considerable collection of writings authenticated by testimonies descending from his own times.

It is by no means necessary for our purpose here (which is to obtain a just general view of the character of the philosopher and his writings), to enter into the criticisms by which doubts have been thrown on particular Dialogues, and on different Dialogues by different critics, out of the number commonly included amongst the genuine works of Plato. We may only remark, that these doubts do not rest on external testimony, but are drawn from considerations of the internal character of particular writings, which have been judged inferior to the rest in matter and execution. Nor is it necessary that we should discuss the various theories proposed for connecting the several Dialogues, and tracing in them the gradual formation and development of the philosophical system of the author. This inquiry certainly has its interest; and could we arrive at any clear results in the prosecution of it, it would be valuable, for the light which it would throw on the interpretation of the philosophy of Plato. But though we can discover a connection between several of the Dialogues, like that of a series of discussions on the same subject, it is not possible to decide on the order in which the points discussed presented themselves to the philosopher's mind, or which we are to regard as the more mature expression of his doctrines. This inquiry further demands a decision of the agitated question concerning the double teaching practised in the ancient schools, known by the technical division into esoteric and exoteric, or mystic and popular; the former addressed to the mature disciple, the latter to the novice or general hearer. There are undoubtedly marks of a recognition of this distinction throughout the writings of Plato;[5] and it is also probably referred to by Aristotle, when he speaks of the "unwritten doctrines" of Plato.[6] But we cannot practically employ it in determining the relative value of particular discussions or statements in his writings, without involving ourselves in a maze of theoretic disquisition, and ending at last, perhaps, in absolute scepticism respecting his doctrines.

But there is a particular class of writings attributed to him, which would possess a peculiar interest for us, if we could establish their genuineness; respecting which, however, the severe verdict of modern criticism compels us to hesitate in pronouncing on their genuineness. We mean what are commonly published in the editions of his works as the Epistles of Plato. By some the question has been regarded as settled beyond controversy, against their reception.[7] The style of their composition has been judged to be quite below the character of Plato's mind. The apologetic tone of the chief part of them has also been considered as evidence of their having proceeded from friends or disciples of Plato, vindicating his character from misrepresentations in regard to his intercourse with the court of Syracuse. But though we may allow weight to these considerations, they are not sufficient peremptorily to decide the question against the Epistles; particularly as we have in their favour the authority, not only of Plutarch, who founds much of the narrative in his Life of Dion upon them, but of Cicero, referring to them and quoting them expressly as writings of Plato.[8]

Perhaps no philosophical writer has ever received so early and ample a recompense of his labours, not only in the reception and circulation of his writings, but in the still more glorious tribute of the spread of his philosophy, as Plato has received. We have mentioned the ordinary marks of admiration which accompanied him during his life and after his death. A more enduring monument was reserved for him in the foundation of the school of Alexandria, not many years after his voice had ceased to be

Plato's Writings and Philosophy.

heard in the groves of the Academia. There, as in a fitting temple, on the confines of the Eastern and Western Worlds, was enshrined the philosophy which had moulded into one the philosophical systems of the East and the West. And though, in the course of things, the infusion of Eastern Philosophy predominated at Alexandria, it was still under the venerated name of Plato that the new system was taught. The disciples of the Alexandrine school were proud to call themselves Platonists, and to regard themselves as interpreters of the teaching of Plato, whilst they altered and disfigured that teaching. Here, then, was erected the proper monument to his fame. Meanwhile, in the Academia, teachers in regular succession transmitted their inheritance of his name, and by the charm of that, prolonged a feeble existence. For the spirit which had formed and animated the school had fled with him; and the Middle and New Academics only attested, by their lingering decay, the strength of the foundation on which they had been built. How great the influence of Plato was on the philosophy of the Romans, needs not to be told to those who are even slightly acquainted with the philosophical writings of Cicero. And even when Christianity threw into the shade all systems of man's wisdom, the only philosophy which maintained its credit at the first, was that of Plato. Christian teachers were found, not unwilling to own that there was great accordance between his doctrines and the revealed truth. Whilst, on the one hand, there were disciples of the philosopher who claimed for him all that was excellent in the Christian scheme, there were Christians who asserted, that he had learned his superior wisdom from the elder Scriptures. All this shews the hold which his name still retained over the minds of men at this period. The great father of the Western Church, St Augustin, avows himself a warm admirer of Plato. He concedes the approximation of the Platonists to the Christian doctrines; affirming that all other philosophers must yield to those who had speculated so justly as they had respecting the Chief Good.[1] Afterwards, indeed, we find Aristotle supplanting Plato in favour with the Christian controversialist. The struggle had been for some time between their respective advocates, which of them should obtain the lead in the Christian schools. But Plato, on the whole, had the mastery, though the result of the struggle was an eclectic system, in which the principal differences of the two philosophers were studiously reconciled. In fact, we may consider Platonism as in the ascendency in the Christian schools, until the period of Scholasticism, that is, until the twelfth and the following centuries, when the discipline of argumentation was at its height in the Church, and with it the study of Aristotle's philosophy. Even then the theories of Plato maintained their ground. The speculations pursued by members of the Church continued to be for the most part Platonic in their principles, though they were conducted and modified by the dialectical method of Aristotle.

What, then, was the character of this philosophy, it will naturally be asked, which both rendered it so attractive to those amongst whom it arose, and also secured for it such an immortality?

It is a very remarkable circumstance that, as far as we know, Plato should have escaped all censure at Athens on account of his philosophy, when other philosophers, who, like him, became centres of popular attraction, were the objects of extreme persecution. It is the more remarkable, as not only his master experienced such persecution, but his immediate disciple, Aristotle, was forced to fly from Athens to escape the storm with which he was threatened. Coming between these two, and enjoying, at the height of his popularity, an influence perhaps surpassing that of either, he yet was suffered to wear out his life unmolested, amidst the tranquil labours of his school.

Plato's Writings and Philosophy.

The only evidence to the contrary of this is an unauthenticated anecdote, told by Laertius, of Plato's having accompanied Chabrias to the citadel of Athens, and shewn his zeal in support of that general, under the capital charge brought against him. Upon this occasion, it is said, Crobylus, the sycophant, meeting him, observed, "Are you coming to plead for another, as ignorant that the hemlock of Socrates awaits you too?" to which he replied, "When I served my country in the field I underwent dangers, and now in the cause of duty I undergo them for a friend."[2]

But though we may refuse to believe this story, it is quite evident, that the condition of philosophy at Athens was not without its obloquy and danger even in its most flourishing times under Plato. We may gather from many passages of the writings of Plato, that the cause of philosophy still needed defence, and that great caution was required on the part of those who publicly professed the study of it. A re-action indeed had taken place in favour of philosophers, in consequence of the severity with which Socrates had been treated; and the assailants of Socrates suffered retribution from the popular feeling. Still there was in the mass of the Athenian people a strong antipathy to philosophy, from their ignorance of its real nature. They had been taught to regard philosophers as idle and mischievous drivellers, ever prosing about nature and the phenomena of the heavens, and as contemners of the gods.[3] They had seen also how some of those to whom Athens owed her greatest calamities, had been amongst the students of philosophy. Alcibiades, for example, had been a hearer of Socrates; one of singular natural endowments, in the formation of whose mind Socrates had taken especial pains, and who might therefore be regarded as the test of what philosophy could effect. The people had loved him as their spoiled child, in spite of all his follies; but they had felt also the mischief and misery of his wild career of ambition; and they threw the blame on his instructors, and the system in which he had been trained. Again, a great prejudice had been excited in the public mind against philosophy in general, from the many low and mercenary professors of it with which Greece abounded; minute philosophers, patronized by the public for their temporary services in teaching the arts of public life, but who produced ignominy and disgust to the true profession by their unworthy monopoly of its name. Add to this, that popular opinion had been corrupted by the false teaching, which had been so long and extensively at work throughout Greece. Erroneous principles of judgment and conduct had taken root in the public mind; or, to describe the case more correctly, all principles were unsettled, and the state of the public mind was a state of inward anarchy and insubordination. A philosopher, therefore, seriously devoted to his profession, and pursuing it with a single eye to the advancement of truth, was necessarily regarded with suspicion and dislike. For it is a natural propensity of the mind to adhere to what is established, whether it be good or evil, simply because the transition is easy, and no effort of thought is required, no trouble of self-examination imposed, no censure of self exacted; and what is inveterate in their own minds passes with men for the oldness of truth and nature. A reformer, therefore, is always an object of aversion; and no reform is successfully accomplished, until it has worked its way by subduing the prejudices which it has to encounter at the outset. Not

Plato's Writings and Philosophy.

only was the opposition to sound philosophy produced in the minds of the vulgar by this distemper of public opinion; but even the better part of society, the more educated and reflecting members of the community, were infected by it. The majority of these would be deterred from taking up a profession exposing them to so much dislike and risk. Some of them, too, with a view of standing well with the mass of those amongst whom they lived, and promoting their own interest, would avail themselves of the popular clamour against philosophy, cry down the pursuit of it as innovation and danger, and make it their business to exaggerate, instead of counteracting, vulgar prejudices on the subject.

These obstructions to the teaching of philosophy are pointedly referred to by Plato, as existing in his time, and demanding his attention, in order to the success of that mission of reform which he had undertaken. He treats the vulgar prejudice against philosophy as not altogether unreasonable,[1] in consequence of the perverse opinions which had been popularly inculcated; and endeavours to disarm the public hostility, by alleging the causes of the disrepute into which philosophy had unjustly fallen. Alluding, as it seems, particularly to the instance of Alcibiades, he points out, that it is not philosophy which corrupts the young, but the passions of the young and high-spirited which pervert the means of good to the greatest mischief. None but those of the highest order of talent and natural gifts are fully susceptible of its influence; but then these are the very cases, he observes, which are also capable of the most mischief, through their greater susceptibility of the seductions of the world. There cannot but be objections against philosophy, he further observes, as long as the mass of mankind is, as it is found, incapable of appreciating real essential good for its own sake; and as long as those of superior nature, who should be its devoted friends, and examples of its influence, are drawn away from it in pursuit of popular opinion. He endeavours, accordingly, to evince that there is no just ground for alarm, at least in those days, at the power of philosophy. It was now deserted and helpless, fallen amongst those who were not its own people. If disgrace now attached to philosophy, it must be imputed to the unworthy alliance into which it had been forced. The mean artisan, who has made his fortune, now quits his prison, and decks himself out, and aspires to the hand of the daughter of his master in her poverty and destitution.[2] It was no wonder, therefore, that such spurious fruits, of so unsuitable alliance, were then seen in the world, and that the few who clung to the true profession were like strangers in the world, living away from public affairs, as unwilling to join in the general iniquity, and unable to resist it effectually by their single strength.[3]

If Plato thought it necessary thus to apologize for the pursuit of philosophy, it is clear that there was yet reason to apprehend an outbreak of violence against its professors. In fact, however, he appears not only to have escaped all such outrage, but, whilst he propagated, by his oral teaching and his writings, a system of doctrines directly contrary to the impure morality and superstition established around him, to have enjoyed an esteem beyond that which any other teacher on the same ground ever obtained.

The explanation of this is in a great measure to be sought in the circumstances under which his philosophy was formed and matured, and to which it was peculiarly adapted.

What Themistocles admitted truly of himself when he answered, that he should not have achieved his glorious deeds if Athens had not been his country, was as truly applied by Plato to himself, when he enumerated amongst his causes of gratitude to the Gods, that he was born an Athenian.[4] For his philosophy was eminently Athenian. Viewed at least as we have it in his writings, it was the expression, by a master-mind, itself imbued with the spirit of the age, but rising above that spirit by its intrinsic superiority and nobleness, of those tendencies of thought and action, which had been working in Greece, and especially at Athens, the centre of Grecian civilization.

The Peloponnesian war terminated with leaving Athens humbled before the confederacy, which the hatred and jealousy of her power had leagued against her. But the loss of her ascendency in Greece was not the worst evil brought on Athens by the result of that war. The machinery of faction, by which the war had been principally carried on, produced the most mischievous effects on the character and happiness of the Greeks at large; aggravating the symptoms of evil already existing in the constitutions of the several states, and, not least, in that of Athens. Not only did the insolence of the Athenian democracy gain strength in the result, and rise beyond all bounds, but the excesses in which party spirit had indulged, drew into prominence the selfishness and ferociousness of a demoralized people. Then might be clearly seen the levity and licentiousness of men, who, living amidst constant hazards, had learnt to regard nothing beyond the enjoyment of the passing hour; the cunning and cruelty engendered by mutual distrust; and the wanton contempt of all law and religion, prompted by the sight of the calamities which the tempests of social life scatter indiscriminately on the good and the evil. On this stock of corruption, speculative irreligion, and speculative immorality, had also grown up as its natural offshoots. Men were found hardening themselves against the reproaches of conscience and the fear of retribution, by arguing against the fundamental truths of religion and morals. In religion, it was contended that there were no Gods; or that if the existence of a divine power were conceded, there was no Providence over human affairs; or, lastly, that if there were a Providence, the wrath of the offended Deity was placable by the prayers and sacrifices of the offender. In morals, the question was debated, whether all was not mere matter of institution and convention, and the device of the weak against the stronger power; and whether right might not change with the opinions of men.

This state of things had produced and fostered a spurious race of philosophers, familiarly known by the name of the Sophists; a name, not at first implying that disrespect, by which it afterwards characterized the pretensions of those to whom it was given. For the Sophists evidently were not the primary corruptors of the public mind in Greece, but themselves the offspring of that moral chaos, which resulted from the internal disorders of the country; and which they sustained, as its own children paying the recompense of their nurture to their genuine parent. They were an evidence of the corruption having reached the higher classes of society: for their instructions were sought by those who could pay for them, and who desired to qualify themselves for office and power in the state. Going about from place to place, and domesticating themselves wherever they could obtain a reception, they undertook to render all that flocked to them adepts in the arts of government, and even in virtue. The pretension would have been absurd and extravagant, but for the prevailing looseness of opinion on moral subjects.[5] But when right was

Plato's Writings and Philosophy.

understood as nothing more than what happened to be instituted and in fashion, there was an opening to every unprincipled teacher to adapt his moral lessons to the varied requirements of each distinct society.[1]

At no place were these universal teachers more cordially received than at Athens. The anxiety with which an expected visit from any one of greater note among them was expected at Athens, and the zeal with which the young hastened to see and hear the wise man on his arrival, are depicted in lively colours by Plato. At Athens, evidently, if anywhere, the Sophist felt himself at his proper home. There was his readiest market. Herodotus may justly have been surprised at the success of so vulgar a deception at Athens, the seat of literature, as that practised by Pisistratus, when he exhibited to the people a woman of great stature, arrayed in full armour, and pompously borne in a chariot into the city, as the goddess Minerva, reinstating him in her own citadel.[2] It would have been still stranger if these impersonations of Athenian wisdom had not succeeded in imposing on the understanding of Athenians. For their minds were in that fluctuating state which disposed them to receive every various form of impression from any plausible teacher. Their general cultivation of mind, and taste for literature, prepared them for listening with pleasure to exhibitions of rhetorical and dialectical skill, such as the Sophists gave. And from admiration of the skill thus displayed, the transition was natural to consider that as the only wisdom, which was capable of maintaining both sides of a question with equal plausibility, and that the only virtue, which could shift and accommodate itself to every expedient with equal satisfaction.

Yet the Athenian was not entirely the creature of those circumstances, which had so considerably modified his character. He yet retained some traces of that high feeling so beautifully touched by his own tragic poet, when that poet speaks of "the pious Athens," and appeals to the ancient associations of religion which consecrated the land. Religion indeed had acquired the name of superstition, or the fear of supernatural powers, δεισιδαιμονια; but even this marks that there were some who cherished, though in that degenerate form, a veneration for the truths of the Divine Being, and the Divine agency in the world. Nor was the Athenian ever insensible to his pride of birth, and rank among those of the Grecian name.[3] He dwelt on the recollections of a remote antiquity of origin, as distinguishing him among the members of the Greek family. He claimed to be the offspring of the Attic soil, αὐτοχθων, whilst others were descended from successive immigrations of strangers. Amidst his fickleness, and susceptibility of every passing impulse, he yet felt himself strongly influenced by his veneration for the past, and loved to connect himself with the ancient glories of his country. In the Athenian character, accordingly, may be observed the union of extremes; devoutness of deep inward feeling, accompanied with superficial irreligion and profane dissoluteness of morals; a mercurial temperament, ever eager for change, floating like a light cloud over a deep-rooted reverence of antiquity, and the traditions of ancestral wisdom and virtue.

Now, on accurately studying the writings of Plato, we find them, both, a reflexion of this state of the public mind at Athens, and a corrective of it. Full of imagination and of severe subtile thought, they are formed to attract and fix the attention of the literary Athenian. Bringing the Sophist on the scene, and giving sketches of the social life of Athens, and making conversation the vehicle of his instructions, Plato in a manner transferred to his own teaching, what was every day witnessed at Athens in the professorial exhibitions of the Sophists themselves. His philosophy, a counterpart, in its way, to the drama of the comic poet, instructed the people, at once, through their wisdom and their folly. As Aristophanes spoke to them under the mask of folly, and gave utterance to lessons of severe wisdom under that mask; so Plato, on the other hand, put on the mask of the sage, and in grave irony ridiculed and exposed the light-hearted folly of his countrymen. Both were wiser than they seemed to the outward observation; as was indeed the volatile Athenian, to whom they addressed their counsel. Both presupposed that delicacy of perception and quick tact in their fellow-citizens, which would be flattered by such indirect modes of address, and would, at the same time, appreciate the jest of the one, and the irony of the other. Both speak with the freedom of the democratic spirit. But the counsel of Aristophanes is that of the privileged jester of the sovereign-people amidst festal scenes and the enthusiasm of mirth; whilst Plato appeals to the Athenian at the moment of quiet, serious reflection on the surrounding folly, and treats him as a contemplative spectator, rather than himself an actor in it.

Before the time of Plato, there were no philosophical writings which answered the requisitions of the Athenian mind. There were poems of the early philosophers. There were didactic writings of the later Pythagoreans, and even dialogues discussing speculative questions. Anaxagoras, too, whose name was well known at Athens, had published a treatise of philosophy.[4] But none of these, if they were even accessible to the Athenian, were calculated to attract his attention. The philosophical poems differed nothing from prose but in the metre, and were exceedingly dry and uninviting to the general reader. The books of Pythagoreans were very few, at least at this time, and hardly known to any but the devoted student of philosophy.[5] Nor would the dialogues of Zeno or Euclid, concerned about mere logical subtilties, or the physical discussions of Anaxagoras, possess any charm for the lively Athenian. Even afterwards, the instructive writings of Aristotle did not obtain that reception which could save them from a temporary oblivion. But the dialogues of Plato supplied exactly what was yet wanting in this department of Athenian literature. They were the proper development of the philosophical element in the genius of the people. The shrewd practical talent of the Athenians had been strikingly exhibited in the successful achievements of their great generals and statesmen, and in the lead of Athens itself amongst the states of Greece at the close of the Persian war. Their taste in arts, and poetry, and general literature, had put forth splendid fruits in the works of Athenian artists, Athenian masters of the drama, and of history. But their genius for abstract speculation as yet had nothing which it could claim as strictly its own. Socrates indeed laid the basis for such a work. During the half century preceding the appearance of Plato as the leader of a school of philosophy, Socrates had been engaged as a missionary of philosophy, awakening the curiosity of men; turning their thoughts to reflection on themselves, as creatures endued with moral and intellectual faculties; and inspiring them with longings after some information on questions relating to their own nature, and a taste for discussions addressed to the resolution of such questions. Plato succeeded him, and carried the philosophical spirit, now fully called into action, to its result. His works accordingly display this spirit at its maturity; exemplifying at the

[2] Herodot. *Clio*, 60.

[3] *Ibid.* vi. 59; Ἀθηναιος ὢν Λαμψακηνῳ, shews in a few words the Athenian estimation of themselves.

[4] Laertius says that Anaxagoras was the first to publish such a treatise. In *Vit. Anax.* viii.

[5] It must be of the more modern Pythagoreans that Dionysius of Halicarnassus speaks, when he recommends the reading of them, not only for their matter, but for their style. *De Vett. Scr. Cens.* iv.

same time that peculiar combination of qualities which formed the Athenian character. Thus are they at once serious and lively, abstract and imaginative; full of deep thought and feeling intermingled with gaiety and humour; instinctive with the awe of religion and ancient wisdom, whilst they present also an image of Athenian versatility, and frivolity, and love of change. They convey indeed a strong rebuke of the vices of the times. They draw, in no softened colouring, outlines of the evil and misery resulting from the profligacy of existing governments, and the excesses of individual cupidity; the two great causes assigned by Plato for the prevailing evil of his times. But these lessons were calculated rather to interest the hearer or reader by their faithful representation of manners, than to alienate him, as we might at first think, by the justness of the censure. Athenians would give their attention to such descriptions, as they did to the invectives of their orators,[1] acknowledging the general truth of the representation; and each, at the same time, taking no offence at what he applied to others, and to every one rather than to himself. Philosophy too, taught, as by Plato, colloquially, was such as peculiarly to suit the taste of the Athenian, whose life was in the agora, or the ecclesia, or the courts of law; and who regarded the interchange of words as no unimportant ingredient in everything that he had to do.[2] Such conversation, too, as that of Plato's Dialogues, elegant conversation, steeped in the well-spring of Grecian literature, and expressed in language such as Jove, it was said, might use, and adorned with the charms of an exquisite musical rhythm, could not but be highly attractive to Athenian ears. We may see, accordingly, in these circumstances, at once, an occasion for the existence of such writings as those of Plato, and a reason of the peculiar mould in which they were cast, as well as of the success which attended them.

Not only, however, was the general character of his philosophy, as viewed in connection with the writings which convey it, derived from such influences; but the internal structure of it was the natural result of the peculiar education of such a mind as his, under the circumstances to which we have referred. His philosophy was essentially dialectical or colloquial; an examination and discussion of systems, and doctrines, and opinions. According to his notion, the true philosopher is the dialectician; the investigator, who has fought his way, step by step, through every argument capable of being adduced in support of, or against, a particular opinion, refuting those that are unsound, until at length he has found rest in some position that cannot be shaken.[3] Hence he is the disciple of no particular system of philosophy, whilst he brings all systems under his survey, and compels all to pay a tribute to his stock of truth, by discussing them, and rejecting in them what will not abide the test of examination. We have seen that he was engaged in studying the doctrines of Heraclitus, and of the Pythagoreans, and of the other schools, whilst he was also a hearer of Socrates. He had thus begun in early life to analyse different systems by the searching method of Socrates; and his mature philosophy was only the same proceeding more deeply imbibed in his own mind, more extensively carried on, and more vigorously applied. So far, indeed, does the colloquial spirit predominate over his philosophy, so entirely dialectical is it in its whole internal character, that it leaves on the mind of the reader more an impression of a series of discussions, in order to the determination of the questions considered, than the conviction of any thing positively determined. Hence it is that Cicero, speaking of Plato's writings, says, that "in them nothing is affirmed; and much is discoursed on both sides; everything is inquired into; nothing certain is said."[4] So also Sextus Empiricus raises the question, in what respect the philosophy of Plato differs from that of the Sceptics.[5] And again his doctrines have been characterized as brilliant clouds, which we seem at the point of grasping, when they vanish from our hands. This effect is doubtless partly to be ascribed to the disguise of his irony; to the artist-design which presides over his whole instruction. But it is also the proper effect of that dialectical philosophy which is worked out in the Dialogues. Whilst he is a consummate artist throughout, he is also illustrating the lessons which he had learnt from Socrates, by bringing false opinions to the test of discussion, and leaving truth, for the most part, to be collected from refutation of error, rather than positively enunciating it, or exactly defining it.

For when we come to examine his philosophy more closely, we find, that it begins and ends, like the lessons of Socrates, with a confession of the ignorance of man. Socrates had led him to perceive how much was taken for granted in the popular opinions and systems of philosophy; how even those who had a reputation for wisdom and talents took up principles which they had never examined, and which they could not satisfactorily account for, or defend, when pressed in argument. Imbibing, accordingly, the spirit of the Socratic method, he did not endeavour to *teach*, in the proper sense of the term, so much as to explore and test the minds of men; to ascertain, how far they really understood the doctrines and opinions which they professed. The fundamental error of the Sophists was, that they assumed all current opinions to be true. They did not think it necessary to examine this preliminary; whether the opinions on which they built their fabric of knowledge were true or false. It was enough for them, that certain opinions were *actually* held; and to these, as given principles, they directed their whole system of teaching. Their teaching, accordingly, was entirely πρὸς δοξαν, relative to opinion; and it must, consequently, stand, or fall, as existing opinions could be maintained or impugned. Now, with Plato, as with Socrates, the investigation of this preliminary point (that is, whether existing opinions are true or no), is everything. The presumption that they are true, is what he will by no means admit. He demands a positive evidence of them. And as the presumption of their truth is a bar to all inquiry concerning them, he commences with the opposite presumption of their falsehood, or at least a confession on the part of the inquirer, that as yet,—until he has investigated,—he does not *know* the *truth* of his opinions.

For the same reason, he avoids all dogmatism in his conclusions. Those might aspire to communicate the knowledge of new truth to the mind, who, as the Sophists did, assumed that knowledge was entirely subjective; or who held that any opinion which could be produced in the mind, was simply true, was really known, because it was there. But as Plato denied the truth of Opinion, if it had no other evidence, but that of its mere presence in the mind; so, neither would he concede that any process of the mind in itself, or any argumentative and persuasive instructions, could produce, *by their own force*, a conviction of truth in the mind. In other words, he required the student of philosophy, not only to begin, but to end, with a confession of the ignorance of man.

We have an apt illustration of this in the dialogue entitled the *First Alcibiades*. There Socrates is introduced,

---

[1] Thucyd. iii 38; Demosth. *passim*.

[2] Ου τους λογους τοις ἐργοις βλαβην ἡγουμενοι, ἀλλα μη προδιδαχθῆναι μαλλον λογῳ προτερον, ἢ ἐπι ἃ δεῖ ἐργῳ ἐλθεῖν, κ. τ. λ. (Thucyd. ii. 40; also iii. 42.)

[3] Ὥσπερ ἐν μαχῃ δια παντων ἐλεγχων διεξιων, κ. τ. λ. (*Rep.* vii. p. 167.)

questioning Alcibiades concerning his plans of life, and shewing how entirely he had presumed on his knowledge of matters with which he was unacquainted; and that until he could be brought to feel and confess his ignorance, there was no possibility of his being able to direct himself or others aright.

In the *Meno*, the same is illustrated by the comparison of the effect of the searching questions of Socrates, on the mind of the person submitted to them, to that of the torpedo. Meno says, he had thousands of times, and to many a person, and with much credit to himself, as he thought, spoken on the subject of virtue; but on conversing with Socrates, he was quite at a loss now to say even what virtue was.

To the same purport is the general application by Socrates in the *Apologia*, of the oracle which pronounced him the wisest of men. The oracle, he observes, had only used his name by way of example, as if it had said, "He, O men! is the wisest of you, whoever, like Socrates, is convinced, that he is in truth worthless in respect of wisdom."[1]

The method of Plato, accordingly, is the reverse of didactic. The Sophists could employ a didactic method; because they assumed principles as true, from which they might proceed to argue and persuade. But this was precluded to Plato, assuming, as he did, that all opinions demanded a previous examination. It was necessary for him to extort a confession of ignorance, to make men sensible of the difficulties belonging to a subject. It only remained, therefore, for him to proceed by Interrogation. In a colloquial philosophy, Interrogation is what experiment is in physical inquiry. It is the mode of discovering what the real state of a person's mind is, in regard to the opinions which he professes. The whole art of Socrates consisted in putting questions to the person with whom he conversed, so that an answer bearing on the point in debate might be elicited; that the grounds on which a given opinion was held might fully appear; and the person's own answers might open his mind to see it in its proper light. This method Plato has followed out in the interrogatory of his Dialogues. Under such a method of philosophy, the answerer is brought to teach himself. The lesson thus given by the philosopher, consists wholly in the questions which he puts. He preserves, from first to last, the simple character of the inquirer; and he *pronounces* only so far as he approves or rejects the answer given.

The popular opponents of this method called it a method of producing doubt; and regarded it as dangerous to the principles of the young. Plato carefully obviates such a misrepresentation of his proceeding, and guards his method from being confounded with that of the Sophists. The Sophists taught the art of exciting doubts on every subject; a mere effort of gladiatorial skill. They professed to make men apt to cavil and dispute on any given subject.[2] All principles, according to them, were equally stable; all were equally open to be impugned. They, therefore, did not care how they unsettled the minds of men, if their skill could only find materials on which to exercise itself. In Plato's hands, however, the awakening of doubt has for its object, to remove the unstable ground on which opinions may happen to be rested, and to lead to more settled convictions. With him it is exalted into a regular discipline of the mind. With the Sophists, it was perverted to strengthen that universal scepticism in which their whole teaching was based. So strictly does Plato confine the application of his method to the single purpose of investigating the truth, that he strongly objects to the use of it as a mere exercise of ingenuity; lest the young, led on by the pleasure of refuting and perplexing others, should think, at last, that there were no real distinctions of right and wrong.

Plato seems the more anxious to distinguish his method of inquiry from that of the Sophists, as his method did in some measure resemble theirs. It was inquisitive on every subject, as theirs was. It did superficially appear to be nothing but questioning, and doubting, and cavilling. It did appeal to the reason of every man, and oblige him to see how he could defend his opinions. And on this very ground Socrates had been attacked: for he was accused of corrupting the young, by making them "doubt," ἀπορειν ποιουντα.[3] Plato fully admits that this practice, as pursued by the Sophists, was dangerous to the principles of the young. In fact, he observes it would be even better to suffer them to remain under the guidance of some principles, which, though not true, served as restraints on their passions, than to remove everything from their minds, and leave no check whatever to licentious indulgence. By a beautiful illustration, he compares the effect produced by the sophistical method, to the case of a child brought up amidst wealth, and luxury, and high connections, and the society of flatterers, but in ignorance as to his real parentage. Suppose, he observes, such a person to come to know that those, whom he has hitherto believed to be his parents, are not so, and at the same time not to know who his real parents are. It is clear, that whilst in his state of ignorance concerning his supposed parents, he would respect and attend to them more than to his flatterers; but on finding out his mistake, unless he were of a superior character, such as is rarely met with, he would attend to his flatterers more than to those whom he once supposed to be his parents. So would it be, then, he shews, with one who should find out that the popular principles of morals in which he had been trained, were not the truth, without arriving, at the same time, at the real truth. He would no longer be controlled by those moral principles of which he had discovered the falsehood; but having nothing to substitute in their place, he would give way afterwards, without reserve, to the seductions of pleasures, the flatterers, whose blandishments he had before in some measure resisted.[4] In opposition to such a system of cavilling, Plato holds an even course between the scepticism which merely doubts about everything, and the dogmatism which pronounces on everything without examination.

The method by which he accomplishes his object, carried out to the fulness of a regular system and discipline of the mind, is, what he calls by a term conveying to a Greek ear its colloquial origin and application, DIALECTIC. As contrasted with the spurious method of the Sophists, or the method of contradicting on every subject, and involving the mind in endless perplexity, it was the true art of Discussion. As contrasted with the mere wisdom of opinion, δοξοσοφια, which the Sophists inculcated, it was philosophy, real science, or knowledge of the truth. The method of his philosophy, and his philosophy itself, thus run up into one, and coincide under the common name of Dialectic.[5]

To trace the manner in which this coincidence was effected, will lead us to a perception of the true character of Plato's philosophy, as a system mediating between the dogmatism of the sciolist on the one hand, and the scepticism of the disputant on the other.

The hypothesis, we observe, on which he founded the whole of his proceeding, was the fallaciousness of Opinion; the Sophists, on the contrary, assuming the truth of Opinion

[1] Ὥσπερ ἂν λεγοι ὅτι· Οὗτος ὑμῶν, ὦ ἄνθρωποι, σοφωτατος ἐστιν, ὅστις, ὥσπερ Σωκρατης, ἐγνωκεν, ὅτι οὐδενος ἄξιος ἐστι, τῃ ἀληθειᾳ, προς σοφιαν. (*Apolog. Soc.* p 53.)

[5] Ἀλλα μην το γε διαλεκτικον οὐκ ἀλλῳ δωσεις, ὡς ἐγῳμαι, πλην τῳ καθαρῶς τε και δικαιως φιλοσοφουντι. (*Soph.* p. 275.) Ὁ μεν γαρ συνοπτικος διαλεκτικος· ὁ δε μη, οὐ. (*Rep.* vii. p. 173.)

universally. Whilst to the Sophists every opinion served as a ground of argument, and for them there was no need to look beyond the *apparent;* it was necessary for Plato, to seek for some Criterion of Truth out of the region of mere Opinion. Commencing with denying the sufficiency of what metaphysicians call Subjective truth, or the assumption that whatever is perceived by the mind is true, because it is so perceived; he had to search after Objective truth, truth independent of the mind of man, and exempt from the contingencies and variations of human judgment, as a foundation of his system of knowledge.

The hypothesis, accordingly, of the fallaciousness of Opinion from which his Method set out, involved a corresponding hypothesis in philosophy of the fallaciousness of the senses. It is the joint application of these two fundamental principles that combines his Method and his Philosophy in one master-science of DIALECTIC. Opinion, according to him, is the kind of knowledge derived from the information of the senses, and is therefore no proper knowledge at all, but mere belief or persuasion, πιστις; whereas true knowledge is founded on that which is purely apprehended by the intellect, without any intervention whatever of the senses. Dialectic, as it is Philosophy, is conversant about that which IS, or which has BEING, as contrasted with presentations to the senses, which have only the semblance of Being; as it is a Method, it investigates the reason, or account of the Being of everything;—the account of everything as it IS, and not as it APPEARS; not being satisfied, like its sophistical counterpart, with opinions of which no account can be given, but bringing all to the test of exact argument and definition.

In order, therefore, to give his Method a firm basis, and his Philosophy a distinct object, it was required, that he should establish a sound theory of Being, or, in other words, a sure Criterion of Truth. Such, then, was his celebrated Theory of IDEAS.

There are four distinct views embraced in this theory as it is developed by Plato; four phases, as it were, under which it is presented.

I. The first, and most strictly Platonic view of it, according to what we have already stated, is in its connection with logical science. None of the great philosophers before Plato; none, that is, of those who had speculated on the universe at large, as Thales, Pythagoras, Heraclitus, Parmenides, Anaxagoras, were conversant with logical science. Zeno the Eleatic, and Euclid of Megara, were known indeed as dialecticians. But the kind of logical science which they professed, was a rude and imperfect art, consisting chiefly in the knowledge and use of particular fallacies, and not founded in any deep study of the nature of thought and reasoning. They were, besides, mere dialecticians, rather than philosophers in the most extended sense of the term. Plato's mind, however, while it was engaged in logical studies, was also no less intent on the investigation of the first principles of all things. And, as has been often observed in other cases, the favourite study of his mind gave its complexion to his theory of first principles, or doctrine of Ideas.

The term "Idea" does not indeed convey to the understanding of a modern any notion of a connection of the theory with logical science. In our acceptation, it belongs exclusively to metaphysics. But in Plato's view there was no separation of the two branches of logic and metaphysics. Both were closely united in the one science to which he gave the name of Dialectic, and which was accordingly at once a science of the internal reason,—that is, of the processes of the mind in its silent speculation on things; and of the external reason,—that is, of the processes of the mind in communicating its speculations to others in words. The terms, therefore, belonging to the one process, are indiscriminately applied to the other. Thus, to "give a reason" of the being of a thing, διδοναι λογον τῆς οὐσιας, was equivalent to a scientific view of it; and the word λογος denoted at once the terms of language by which that reason was expressed, and the reason itself as it existed in the mind. Thus, too, the word ἰδεαι, or ideas, was only a little varied from the logical term εἰδη, or species, which indeed is sometimes substituted for it in the phraseology of Plato. The simplicity, accordingly, and invariableness, and universality, which belong to terms denoting the agreement of a variety of objects in certain characteristics, were transferred to supposed counterparts in the mind itself, or to the notions represented by the terms which are the name of the species. Hence the idea, or *eidos*, was conceived to be, not simply a result of a process of the mind, but something *in* the mind, and as having a being independent of the mind itself. As the species expressed in words was universal, so its counterpart in the mind was the universal nature in which the individuals to which it referred, participated. In that, the mind, perplexed by the variety and anomaly of individual objects, found an invariable sameness. In the contemplation of it, the mind no longer wavered and doubted, but obtained a fixedness of view. The idea, or species, therefore, was to be explored and reached in order to a just theory of everything, and was in itself that theory.

Further, as there is a relative classification of objects by means of words; some standing for characteristics common to a greater number of objects, whilst others stand for characteristics of only some out of that number; this property of words was in like manner conceived to have its counterpart in the mind. A graduated series of species was supposed to exist, first in the mind, and then independent of the mind, by means of which, as by steps, the mind might rise to the highest species, the ultimate idea itself, in which all others were comprehended. And hence there was no real perfect science but that which penetrated to this ultimate nature or being; and all other ideas, or theories, were truly scientific only as they participated in this.

This notion of "participation" of the ideas, was a still further application of logical language to the business of philosophy in general. For, as the several particulars belonging to a species all possess those characteristics which constitute their species, as well as those which connect them with a higher species or genus of which they are the species, their logical description is made up of an enumeration of those characteristics, together with the name of the higher class or genus under which the whole species is included. The higher class is an ingredient in the specification of a lower; or, conversely, a lower class participates in a higher. So Plato considered everything in the universe, as being what it is, by a "participation" of the Ideas; and consequently, that to explore its nature we must ascertain the idea which thus constitutes it. The Pythagoreans before him spoke of things as existing by "assimilation" to the essential being. Plato's logical views occasioned this change of phraseology; for he varied only the term, as Aristotle observes, whilst he followed the Pythagoreans as masters in the fundamental conception of his theory.[1] Aristotle, indeed, whilst he assigns the logical studies of Plato as the occasion of the form of the ideal theory, more particularly accounts for the theory, from Plato's observation of the importance of Definitions in the ethical discussions of Socrates. Plato found how effectual an instrument Definition had been in the hands of Socrates in silencing the impertinencies of false opinion on moral subjects. As it had brought moral questions to an issue, so it might be applied, he thought, generally, as a stay to the extravagancies of opinion on all subjects whatever. Accordingly he had only to generalize the principle of definitions, and the result was the theory of

Ideas, or the universal science of reasons, and the ultimate criterion of all truth.

To understand, however, rightly how Plato was led by logical considerations to his theory of Ideas, we should observe more particularly what his view was of the nature of logic. We should greatly misapprehend him if we supposed that he had that notion of the science which has prevailed since the systematic exposition of it by Aristotle. As it was conceived by Plato, it answered strictly to its original name of Dialectic, rather than to that of Logic; being the art of discussion, or the art of drawing forth the truth from the mind by questioning, rather than the art of deducing consequences from given principles. It was a higher, more comprehensive science, than the art of Deduction. For it was conversant about the discovery and establishment of principles; whereas the logical science which is employed about Deduction, assumes the principles in order to speculate about their consequences. It left the latter inquiry to be pursued by subsequent research, whilst the more ambitious flight of those who first speculated on the nature of Discourse was directed to the discovery of truth. In Plato's hands it was an energetic reform of the quibbling shallow logic, which was as yet known and practised in the schools. This logic had no concern for truth, but only for victory and display. It consisted in a skill of wielding certain sophisms, known by familiar names in the schools, and founded on the equivocations of words. An appearance of truth being all that it aimed at, it did not exact of the student any consideration of the nature of things. It was enough that he could give the word reason, the mere logos, the symbol or counter. He was not taught to go beyond this legerdemain of language, or to search out the reason of the being of things, and correct the paralogisms involved in the use of words, by reference to the realities represented by them. This sophistical method affected indeed to be a didactic art; to instruct and furnish the mind with principles applicable to every subject of discussion. It considered, forsooth, language as an universal science of nature already constructed; and, proceeding on this supposition, professed to enable the student to apply the wisdom already embodied in language, to the purpose of appearing wise himself, and imparting to others the same apparent wisdom. But going no further than this, it ended in mere δοξα, mere opinion. It produced, that is, in the result, only a wavering state of mind, subject to be changed by every new impression of opposite arguments, and, after all, imparted no steady knowledge.

It was a great reform, then, which Plato undertook, in following up the example proposed in the conversations of Socrates, and instituting a proper science of Dialectic, a science of the reason of the being of things. It was a change from an empirical system, a vain art of words, to a scientific method or investigation of the reasons themselves, on which an instructive use of words must be founded.

For, we must observe, it was still a science of words which he teaches as the true Logic or Dialectic. It had throughout a reference to discussion. Still it was a real science as compared with the verbal and technical logic of his predecessors. Though it was a science of words, it had for its object the determination of such words as should fully correspond to their intention as symbols, in characterizing and denoting the proper being of the thing signified. These reasons of the being of things, the λογοι της ουσιας, were the Ideas.

His logical method, accordingly, was an analytical, inductive method. Setting out on the assumption of the erroneousness of opinion as such, it examines hypothesis after hypothesis on each subject proposed for discussion, rejecting and excluding, as it proceeds, everything irrelevant. The scrutiny instituted consists in searching for the grounds of contradiction with regard to each opinion, and shewing that opposite views on point after point in the matter discussed, are at least as tenable as the assumptions contained in the given opinion or hypothesis. Hence it consists almost entirely of refutation, or what both he and Aristotle denominate *elenchus*, a process of reasoning by which the contradictory of a given conclusion is inferred.

A method of this kind was calculated fully to put to the test every unsound opinion. It collected everything that could be said either for or against a given opinion. It made the maintainer of it state on what grounds he maintained it, what consequences followed from it; and either forced him to self-contradiction in his defence of it, or obliged him to modify it according to the requisitions of the argument. And the result was, that whatever stood its ground after this complete sifting of the question, might be regarded as stable truth. When refutation had done its utmost, and all the points of difficulty and objection had been fully brought out, the dialectical process had accomplished its purpose; and the affirmative which remained after this discussion might be regarded as setting forth the truth of the question under consideration. For everything connected with it, and yet not founded in the truth of things, was then removed. And the result therefore might be accepted as a simple truth of being, an object which the eye of the intellect might steadily contemplate, and therefore matter of Science.

The process throughout corresponds with the process of investigation in modern philosophy. Only we must conceive the dialectical investigation of Plato as nothing more than an admirable scheme for clearing a question of everything foreign to it; whilst the latter draws out the true law of nature from the promiscuous assemblage of phenomena under which it is presented to observation, and lies concealed until analysis has done its work on the mass. The nomenclature of the two methods varies accordingly. Argument is the instrument of the former; experiment that of the latter. Refutation is the primary business of the former; rejection and exclusion of irrelevant phenomena that of the latter. Definitions of words, as they are signs of the being of things, are the result of the former; whilst the latter develops laws of nature.

Both processes are carried on by Interrogation. But whereas the analysis which investigates a law of nature proceeds by interrogation of nature, the analysis of Plato's dialectic proceeds by interrogation of the mind, in order to discover the true being or "idea" of the thing discussed. Therefore it was that Socrates called his art, in his own playful manner, μαιευμα, a kind of midwifery;[1] a delivering of the mind of the notions with which it was pregnant. Thus the dialectic of Plato, being entirely directed to observation on the mind, and not to external nature, takes the state of knowledge as it exists in the mind for the ground of its proceeding. It deals with things; that is, as they exist in the forms of thought; going, as Plato says, "from species to species, until it arrives at the principle of all things,"[2] and following throughout the steps by which the mind advances in obtaining an exact view of any object of its contemplation. It is, in fact, the true thought spoken out. The process of thinking by which it is attained, is the dialectical process of interrogation. The decision of the mind when its conviction is settled, is the dialectical conclusion.[3]

The chief logical instrument employed in this method is Division. The being able to divide according to genera, and not to consider the same species as different, nor a different one as the same, is stated to belong especially to dialectical science.[4] In searching out the true definition of the being of a thing, this portion of the internal process of

Plato's Writings and Philosophy.

the mind would naturally strike the attention. General ideas being founded on general resemblances of objects, the first step towards a more distinct idea of an object is to see that the generalization is complete; that it neither excludes nor includes any objects which it ought not to exclude or include. The true idea of any object would be that which characterized every object belonging to the idea, and none other. The analysis accordingly pursued by Plato is conversant about Division, using the induction of particulars in subordination to this.[1] We find, indeed, a constant use of Induction by Plato, after the manner of Socrates. But it is always in reference to the main purpose of determining, not a general fact, but the dominant Idea in every object of thought.

At the same time, we may observe, the Dialectic of Plato is truly a method of investigation, though it does not penetrate to the depth of the modern analysis. It employed deductive reasonings; but these were not essential parts of its method; since the whole was a process of ascent to the theory of the Ideas.

Afterwards, indeed, Dialectic approximated to what is now commonly understood by Logic. The transition was first to the consideration of it as a method of drawing out the probable conclusions deducible from given premises. This was natural. For in Plato's method every opinion was admitted as an hypothesis to be examined, in order to rejecting the falsehood and eliciting the truth that might be contained in it; and so far his Dialectic might be regarded as a speculation on probabilities. This transition prepared the way for a further one, when Dialectic became strictly the science of Deduction. Attention would be drawn more and more to the use of words as instruments of reasoning, when Dialectic was once exalted into the rank of a science.

The progress seems to be this. The science being cultivated primarily with a view to discussion, the importance of language in order to reasoning could not fail, from the first direction of the mind in this channel, to strike the philosophical observer. The phenomena of sophistical argument would suggest the necessity of inquiry into words as they are employed in reasoning. Philosophers, accordingly, would be led to examine into the nature of words considered as signs and representatives of thought. Thus they would proceed to arrange words into classes, according to their import in this respect. Thus would be obtained that great division of words into those that denote an individual alone, and those that stand both for many and for one, or into singular and common;—the fundamental principle of logic properly so called, or of logic as the science is now considered. The use of Division and Definition would soon appear. These processes, indeed, would be naturally discovered in the very prosecution of discussions addressed to the refutation of false opinions and popular fallacies. The early dialectics, accordingly, abounded in the use of them.[2] Afterwards, as the analytical power of language came to be more particularly observed, the connections of words in propositions and arguments would attract speculation. The possibility of exhibiting any given proposition or argument under abstract formulæ, in which unmeaning symbols were substituted for the terms themselves of the proposition or argument, would at length be discovered. Thus in the result would be erected a formal science of logic, in which language would be considered as an artificial system of signs, and the validity of arguments would be explored in their abstract forms, independently of the subject-matter about which they happen to be conversant.

When Plato, however, drew his Theory of Ideas from the logical speculations in which his mind was engaged, there was no such system as that now found in treatises of logic. There are the materials in the writings of Plato for constructing a method of dialectic, such as the science presented itself to his view; but that method remains, even to this day, to be fully explored and stated. It is clear that he had such a system, and that his writings proceed on regular method; though he has nowhere accurately sketched it, and perhaps never even proposed it to himself in the form of a system. His thoughts were engaged in this, as in other subjects, in giving the great outlines of his philosophy. It was enough for him to have seized the bearings of logical truth on all truth; and to this general view of the science he has made everything secondary and subservient.

II. The next aspect under which the Theory of Ideas should be considered, is that in which it sums up and measures the infinites of the sensible world. In this point of view, it more immediately represented its Pythagorean prototype, than under its logical aspect. It is in reference to this intention of the theory that Aristotle objects, that whilst it professes to give the account of things, it introduces an additional number of objects in the Ideas themselves; an absurdity, he observes, like that of attempting to facilitate a calculation by adding to the numbers to be calculated.[3] It was, accordingly, an endeavour to reckon up the individuals of the universe, and exhibit their sum in one statement. As Plato's logical speculations gave their colour to his whole philosophy, so the devotion of the Pythagoreans to mathematics led them to form a mathematical theory of the universe. The universal nature of Number gave them the ground for this application of their peculiar studies. For all things are in number; and there is nothing from which the notion of number may not be abstracted. That number, then, which alone measures all other numbers,—Unity,—would be regarded as the common measure of all things. And thus the philosophy of the universe would be reduced to a system of calculation; and the infinity of existing things summed up in definite proportions of numbers. The Greek word *logos*, whilst it combined in it the notions of "word" and "reason," also further combined that of "ratio," and reasoning and calculating were expressed by the one term λογιζεσθαι. This marks the connected trains of thought by which the arithmetical theory of the Pythagoreans was formed. The effects of this combination of thought are seen, not only in the fundamental conception of the theory, but in our ordinary phraseology on the subject of reasoning even at this day; as, for example, in our use of the word "Term,"—that is, "limit," or "boundary,"—for words, not only in their logical signification, but even in their familiar use.[4]

It appears to have struck the mind of Plato that the theory of the Pythagoreans was not sufficiently comprehensive, or even ultimate, as an account of the Being of things. The simplicity of Number did not adequately explain the great variety of natures found in the universe; and though the science of Arithmetic held almost the highest place in his scale of knowledge, on account of its ab-

(*Phædr.* pp. 362, 363.) Plato appears to have been the author of a work "On Divisions," not now extant.

[3] Ὡσπερ εἴ τις ἀριθμῆσαι βουλομενος, ἐλαττονων μεν ὀντων, οἰοιτο μη δυνησεσθαι, πλειω δε ποιησας ἀριθμοιη. (Aristot. *Metaph.* i. 7.)

[4] Hobbes uses the mathematical phraseology throughout. Reasoning, with him, is "reckoning," and words are "counters." (*Leviathan*, i. 4, *et alib.*

Plato's Writings and Philosophy.

stract nature, and its leading to the consideration of Being, apart from the changeable objects of sense; he still viewed it as practically implicated with the physical sciences, and, as such, therefore, not strictly and exclusively conversant about Being. In like manner, the science of Geometry, though purer than the physical sciences, as being conversant only about abstract magnitudes, is excluded from the highest place. Geometry, no less than Arithmetic, might seem to be simply an intellectual contemplation; since, though it employs visible figures in its demonstrations, the demonstrations do not properly refer to these, but to the abstract notions which the diagrams represent. Yet Geometry, as it assumes its principles, and its truths consequently depend on assumptions which in themselves demand evidence, cannot, he observes, rank as a science of perfect intelligence.

Perfect intelligence, *νοησις*, implies an absolute stay to the thought; something beyond which no further inquiry can be made, which may be seen as it were by the mind's eye immediately in itself. And such an object only is furnished by the Idea. Though, accordingly, Plato thus carried his theory beyond that of the Pythagoreans, we find him still cherishing the Pythagorean doctrine of Number, by assigning to it the second place in his scale of knowledge, and only barely distinguishing it, in regard to scientific value, from his own Theory of Ideas.[1]

When we come indeed to look more closely into his theory, the mathematical approximation will distinctly appear. The ideas are the finite, applied to the infinite of the sensible world, and thus producing measure and proportion in the universe.[2] The physical sciences, as, for example, astronomy and music, are not truly scientific, because, addressing themselves to what is passing before the senses in the world, they do not consider the immoveable beings themselves, which are only imperfectly represented in the observed physical movements. The astronomer computes the actual velocities of the heavenly bodies; the musician counts the intervals of sounds. But neither of these is intent on the real beings, the Ideas themselves of velocity and of harmony. We can discern in such language as this, a mathematical basis of thought. Perpetual variations, as contemplated in their inconstancy, admit of no calculation. To estimate them, we must find the limit to which they continually approximate, and we thus, as it were, reduce to fixed order the apparent disorder and irregularity, and see the variable in its ultimate form of invariableness. This notion is not fully developed by Plato. But it is conveyed in his doctrine of a twofold class of sciences, under the same names; a popular astronomy, for example, and an higher astronomy; a popular music, and an higher music; the latter of which are sciences of the invariable and the finite, and run up into his Theory of Ideas.[3]

III. The third phasis of the Theory is that in which it is a philosophy of Being, in opposition to the mere knowledge of sensible phenomena. According to the school of Heraclitus, the sensible world was ever flowing, ever in a state of "becoming" or incipiency; being a mere development of successive phenomena, displacing each other without cessation. As duration is no positive existence as a whole, but is made up of an infinite number of moments, each of which is gone as the succeeding moment appears; so was it asserted generally in the doctrine of that school, that every object in the universe was a mere collection of successive phenomena. Of nothing could it be affirmed that it IS. The very sensations, no less than the objects of them, were in constant production; being the momentary, ever-varying results of the concourse of agent and patient. Colour, for example, as the object, and sight of the colour in the eye as the sensation, are momentary relations simultaneously produced by something that acts in the coloured object, at the moment, on something that receives the impression in the eye.[4] This doctrine resolved all knowledge into sensation, and (which was equivalent to this) made "man the measure of all things," according to the celebrated enunciation of Protagoras.

Plato saw that, if these views were admitted as an account of the universe, his whole dialectic must fall to the ground. It would be nothing but miserable trifling to try to call forth those reasons of things which he conceived to be in the mind, if knowledge were of this fluctuating character.[5] There could not, in fact, be then any such reasons. There was nothing stable, nothing that remained in the mind, to serve as the standing criterion of true and false opinions. There would be no distinguishing whether all that passed in life were not a dream, or whether the occurrences in dreams were not rather the realities.[6] Some sure criterion was therefore wanted, to which the phenomena of sensation might be referred. The theory of Ideas, as a theory of Being, furnished this.

Plato admitted, accordingly, the perpetual flux of sensations and their objects, as taught by Heraclitus, whilst he refuted the sophistical extravagancies into which the doctrine had been carried. Granting, therefore, that there was no test of truth or falsehood in the sensations themselves, he points out, that the ground of fallaciousness is in the judgments formed by the mind concerning the impressions of the senses. The soul is endued with a common power of perception, to which the reports of the different senses are referred, and by means of which the mind is enabled to compare past and present sensations of the same kind, as also different sensations with one another. It is in the conclusions then formed on these comparisons that we are to seek for knowledge; or in the purely mental processes, abandoning altogether the mere informations of sense.[7]

He was led, accordingly, to examine these processes of the mind, in order to discover the grounds of truth and knowledge. He observed, that when the mind compares two sensations, and decides on their similarity or difference, there is always some ground on which that judgment is made. When, for instance, it decides on the equality of two things, there is a standard to which they are referred, the general notion of equality itself, which serves as a middle term for testing the equality of the two things compared. In like manner, there is always, whenever a comparison is made by the mind, some general principle, which is the medium of the comparison. And this is a principle not in any way produced by the sensations; for it is evidently prior to them, and independent of them; being appealed to by the mind as a criterion of them. This general principle, then, is in every instance the Idea; and not being formed by the sensations, it is not subject to their variableness. It remains unmoved, and the same, amidst the flow of the sensations, or of the objects of the sensations;—the standing criterion of all the judgments of the mind to which it applies.[8]

Hence we may see the peculiar meaning of the term "Idea" in Plato's philosophy. It consists in its contrast with the objects of sensation. The latter never attain to any definite perfect form—to any clear outline, as it were, to

[1] *Rep.* vi. *ad fin.* The importance assigned to arithmetic in the early philosophy, is shewn in that line of Æschylus: Και μην ἀριθμον ἐξοχον σοφισματων, ἐξευρον αὐτοις. (Prom. 459.)

Plato's Writings and Philosophy.

the eye. They flow and have vanished before they could attain to such form; since, in the very succeeding one another, they not only pass away, but undergo alteration. But the standard to which they are referred in the mind, is a positive defined shape, or form, or species, simple and uniform, analogous to an object of sight of which we can clearly trace the whole outline by the eye.[1] For the like reason, the term *exemplar*, παράδειγμα, is also applied to denote the Idea. As the one perfect standard to which all the reports of the senses are referred, it appears in the light of a pattern, to which they would be conformed, but for that incessant mutability which necessarily belongs to them. This, however, was rather the Pythagorean view of general principles than the Platonic, though Plato himself not unfrequently recurs to it.

Plato, at the same time, in thus constituting Ideas the sole absolute criteria of real existence, did not intend to deny all reality whatever to conclusions drawn from our sensible experience, such as those of the physical sciences. But he means, in the first place, to shew the delusive character of all informations of sense which are not corrected by the internal reason of the mind. In the next place, his design is to point out the inferior knowledge which every other kind of evidence conveys, but that which is drawn from the intuitive perceptions of the mind. The informations of sense, he teaches, are only a knowledge of semblances or idols, εἰκασία, conjecture founded on mere images of the truth. He describes this kind of knowledge by an admirable illustration from a supposed case of men placed in a long cavern, with their bodies so chained from infancy, that they can only look before them, whilst the light of a fire from behind casts on the side opposite to them, the shadows of vessels, and statues of stone and wood, carried along a track leading upwards from the cavern by persons who are themselves concealed by a wall, like the exhibitors of puppets. As men so circumstanced would see nothing of themselves, and of each other, or of the things thus carried along, but the shadows, they would mistake the shadows for the realities; they would speak of the shadows as if these were the things; and if any voice was heard from the persons carrying along the figures, they would think the sounds proceeded from the passing shadow.[2] Just like this, he declares, is the influence of education in the lower world of sense on the minds of men. They must be carried up from this cavern, in which they see everything only by an artificial light, to the light of the sun itself, to the region of Ideas, where alone objects are seen as they are in themselves.

As to the knowledge conveyed by the physical sciences, neither is this properly Science. It amounts only, as he states it, to belief or opinion. These are less intellectual than the mathematical sciences, because they are conversant about human opinions and desires, or about the production and composition of things, or about the means of sustaining things produced and compounded.[3] They are therefore as unstable as the things about which they are. But they are still not devoid of evidence, so far as they collect the real informations of the senses, and do not learn from mere shadows. This is implied in his calling such knowledge belief, and distinguishing it from conjecture; though he is rigid in preserving the exclusive prerogative of Truth to the knowledge of the Ideas.

The evidence of Experience was necessarily slighted in such a philosophy, and condemned as insufficient for the discovery of truth. For what is Experience but the memory of several similar previous informations of sense, combined into one general conclusion? And though Aristotle allows that such a general conclusion, in which the mind acquiesces, might be regarded as scientific,[4] this could not be admitted by a philosopher who placed the objects of sensation out of the pale of Being. It was not enough for Plato's system to answer in favour of the scientific value of Experience, that though this and that particular instance of an information of sense had no immoveable truth in it, yet, from the observation of a number of similar instances, a general uniformity might be inferred, and an immoveable general principle established. He would grant that generalization was a corrective of experience. For this he did when he granted some importance to the arts in education, and for the purposes of life. But truth with him must be *universal*, not simply general: it must be that which is always the same, not simply that which is only for the most part. And the highest degree of the evidence of experience, even that which amounts to what is called moral certainty, falls short of this absolute universality. It might be urged, for example, that though what was sweet to one person and at one time, might be bitter to another person and at another time; and though what seemed the same sensation of sweet, was not in fact the same at two successive moments, but a reproduction; still it was possible, by combining recollections of many similar instances, to form a general notion which should adequately characterize that sensation. Still Plato would say, this was only belief or opinion, and not science. The object of science must be such as cannot be otherwise: it must be absolutely one and the same permanent being: you must altogether quit the stream of the world of sense, and land on the rock of unchangeable eternal Being.

Thus Rhetoric is strongly reprobated by Plato, on the very ground on which it is systematically taught by Aristotle, of its being nothing more than an instrument of persuasion, or an art speculating on the means of persuasion. Much of his invective indeed derives its point from its application to the servile rhetoricians of his day. Still we find him condemning Rhetoric on the abstract ground of its having no higher view than persuasion. In the modern view of the subject, as in Aristotle's, Rhetoric is a real science, so far as it is framed on just conclusions respecting those modes of speaking, or writing, which excite interest and produce conviction. With Plato it is mere quackery; and for this reason, that it is founded on experience of what persuades, being only an ἐμπειρία or τριβή, a knack acquired by experience and converse with the world; an accomplishment, learned by practice, without any real knowledge, in flattering the passions of men. He in fact regarded Experience as corresponding with what we call empiricism; contrasting it with the conclusions of abstract reason, as we contrast an illiterate and unscientific use of experience with that of the philosopher.[5]

Looking to that sort of Experience on which the popular teaching of the Sophists was founded, Plato, we should say, was fully justified in his condemnation of the experimental method of his day. It was in truth mere quackery. It was content with shadows and images of the truth, and entirely directed to *producing* a desired effect, without caring for the absolute truth;—a shallow philosophy of sensation, not founded in the nature of things. He had thus to contend against a system, which distorted that criterion of truth, which man has in himself, by the right use of his reason conjointly with his experience, to the undermining of all truth and reality. This empirical system was the crying evil of those times.

[1] Hanc illi ideam appellabant, jam a Platone ita nominatam; nos recte speciem possumus dicere. (Cicer. *Acad. Qu.* i. 8.) Formæ sunt, quas Græci ἰδέας vocant, &c. (Cicer. *Topic.* 7.)

Plato's Writings and Philosophy.

It had infected politics, and education, and private intercourse, as well as philosophy. In opposition to it, he had to take up an antithetical position; to call in question the existing acceptation and use of the human criterion of truth; to limit it within its proper bounds, and guard against its perversion. Accordingly the whole stress of his philosophy is on this point. It is a perpetual polemic against the sophistical principle, that "man is the measure of all things."[1] This amply accounts for his disparaging so much as he does, the scientific value of Experience, and insisting on the necessity of the existence of higher principles than those of Experience, in order that the mind may duly receive and appreciate the information of sense. He taught men, at any rate, to perceive that the popular notion of that evidence of truth which man has in his own nature was false and deceptive, and that in all judgments and reasonings there is also something more than is merely of man.

IV. The fourth leading point of view under which the Theory of Ideas remains to be considered, is its aspect as it is a theory of the Cause of the universe. Under this aspect it is identified with the speculation into the Chief Good. Here it is an account at once of the first principle of motion, and of the end to which all things tend as their perfection and ultimate good. According to Plato, there was no other cause worthy of the name, or which really accounted for the phenomena of the universe, but "The Good," or, as it is technically called, the Final Cause. The early speculations of philosophers had been chiefly directed to the material phenomena of the universe, and had attempted to account for them in a rude manner, by referring them to some one or more of the material elements. Some indeed had introduced also moral influences into their theory. The Pythagoreans combined with their speculation of the mysterious Unity, the notion of Love as the one-making principle. The Ionic school, however, appears to have led the opinion of philosophers in regard to the cause of the universe at the time of Plato. And though Anaxagoras asserted the ascendancy of Mind, he had lost sight of his great theory in the explanations from material causes, to which he descended in the completion of his system. Socrates began a strenuous opposition to the physical philosophers. Plato carried on that opposition, and, blending the familiar ethics of Socrates with the moral and theological mysticism of the Pythagoreans, established the Final Cause or theory of "the Good," as supreme over the domain of science.

Anaxagoras had certainly prepared the way for the theory. Plato took up his doctrine of a Divine Intelligence, and gave it that development which, as it had been taught by Anaxagoras himself, it yet waited to receive. It was but a vain theory of a Supreme Mind (sublime and important as the simple enunciation of the great truth was), which did not also exhibit the Supreme Mind as operating in the universe by design, and as diffusing the energy of its intelligence and goodness, as well as of its power, throughout its operations.

The Supreme Mind, therefore, according to Plato, must be conceived, as exemplifying the attributes of its own nature in the works which have proceeded from it. If it be granted that there is a Supreme Mind, that must be the true measure of all things in the universe. All things must have been framed according to the scheme which such a mind would contemplate in their production. As intelligence, it cannot be regarded but as working for some object, ἕνεκα του; for by this is intelligence distinguished from unintelligent force; and the only object to the Supreme Intelligence is the most perfect nature, which is itself. The pattern of its own perfections, therefore, must have been present to it, and in its design, in the construction of the universe. In other words, the Deity himself is not only the author of all things, but he has designed to exemplify in them his own attributes. The principle, accordingly, by which all true philosophy must hold, and which it must carry out into its speculations, is, that "God is the measure of all things."[2] And hence, whenever the proper being of any thing is to be explored, it must be studied in that light in which it is seen as a work of the Supreme Mind, designed after the pattern of the Divine perfections. In such a contemplation, the theory of the Best is the view by which philosophy must be guided; for, in Ancient Philosophy, an object of intelligent aim, and good, are equivalent terms. The object at which the most perfect Intelligence aims, must be, therefore, that which is best; and in tracing out, accordingly, the workings of the Divine Mind in the world, we must look for "the best" in everything. That notion of everything by which it is "best," is both its real nature, and the cause of its being produced.

But why is not everything, as it is actually seen, a work of "the best?" why is not good visibly impressed on everything as it stands forth to the view? why must we, in short, resort to the Idea of good, in order to ascertain its nature, instead of taking it simply as it appears?

The antagonist force of unreason in the nature of that which has body, and is apprehended by the senses, occasions all the imperfection and evil in the world, as the world actually exists. It subsisted already in the mass of disorder and confusion which the Divine Intelligence, by its operation, had brought into order and regularity of motion; and it still subsists, though reduced into subordination to intelligence. It is overruled so as to minister to the designs of mind, but still impedes by its contrariety of nature the development of good in the world. And thus Plato says that it is impossible for evils to perish out of the world, for that there must ever exist a contrariety to good.[3] Evil pre-existed, and evil accordingly must be displaced by the presence of good; as contraries are displaced by contraries; and as all generation, or production, is carried on by a process from contrary to contrary. Thus, though evil retires before good in the world of generated things, evil still manifests itself in the very act of its retiring before good; and a perpetual opposition of good and evil remains. What we see, accordingly, in the world, is not the perfect accomplishment of good, but effort and tendency after good in all things. The effects of a struggle between reason and unreason are manifested, on the one hand, in the evanescent imperfect nature of all sensible things; and, on the other hand, in their constant renewing, or in that undying vigour with which they flow on, and are reproduced, and aim at a perfection beyond themselves.[4]

Though, therefore, the Divine Artificer has designed everything in the world for the best, they are not actually the best as they are presented to our senses. They are the best that such things can be, but they do not attain to the Idea of good, according to which they have been made. Time, for example, only imperfectly represents the divine eternity, which is its true Idea. In eternity there is no distinction of past, present, and future. But the bodily nature of things will not admit of this co-instantaneous development of the divine Idea. Existence is here broken up into successive moments; and these successive moments, marked by the periodic motions of the heavenly bodies, introduce the distinctions of number into the simple idea of duration.[5] Again, the velocities of the heavenly bodies, which are observed by the astronomer, must be conceived as very in-

Plato's Writings and Philosophy.

adequate representatives of the "real velocities performed in the true number and true figures,"[1] which are the "Ideas' after which they have been established. Or, again, it is clear that the ideas of the good, and the just, and the honourable, and the beautiful, as they are seen in the world around us, are only imperfectly developed. Our thoughts are distracted by the contemplation of them in the world, by the multiplicity of forms under which they are apprehended by men, and it seems to the superficial glance as if there were no one perfect standard of each. At the same time, we are able to trace evident signs of such a standard, when we look thoughtfully at the course of things. We cannot doubt, on such examination, that these principles exist, and are working their way, and that the universe has been constructed after the pattern of them. But all that the most attentive study will disclose to us as actually observed, is *tendency* towards these principles—a "becoming" or incipiency of being.[2] We do not see their full effect, or what would be their effect, if the world were such as to give them free scope and exercise, and if the impressions of sense did not diversify and obscure the presentations of them to our minds. Must we not say, then, that if we formed our notions of these principles from the visible world, and the impressions of sense, that we must estimate them improperly? And must we not rather elevate our minds to the Ideas themselves, after which the universe has been constituted in its present order, and take our measures of them from the Divine Being, whose goodness, and truth, and beauty, they represent?

Thus did the Theory of Ideas serve as a moral explanation of the course of nature, and meet the demand of philosophy, by removing the perplexity of the mind on the contemplation of the apparent disorder of the world, and giving a firm stay to the thought in this direction. This apparent disorder has been the constant appeal of the atheist and the sceptic in all ages. And in Plato's time there was need, we find from several passages of his writings, of an answer on the part of philosophy to speculative objections on this ground. The Theory of Ideas supplied this answer. By the theory of a perfect model of good, imperfectly wrought out in the visible universe, the existence of evil was accounted for in some degree, and the eye of thought was enabled to see a chain of goodness, and beauty, and order, binding together the most untoward appearances of the moral world. As the Pythagoreans enchained these disjointed portions of the moral fabric, by supposing a fundamental Unity pervading the whole, and reducing the multiple and the unlimited to definite proportion—a sort of key-note, modulating the apparent discords of nature[3]—so Plato made the one moral good the all-pervading moderator of the system of the universe. The abstract notions, the genera, and the species, and the definitions, which dialectical science brought out by the aid of language, presented the materials for extending the moral view to other notions besides those strictly moral; and thus a theological and moral complexion was spread over the whole region of philosophy.

Ideas of evil were evidently excluded. "The good" could not be the cause of all things, but only of those that were well constituted; of evils it was causeless.[4] Evil, as we have seen, had no exemplar or pattern in the nature of the Author of the universe. It was a condition of that bodily nature on which the good was actively displayed. Evil arose from the nature of the "diverse"[5] inherent in body; that nature in body by which it was contradistinguished from the "sameness" belonging to the Ideas.

In considering the Theory of Ideas under the different aspects which it presents, we have in fact taken a summary view of the whole of Plato's philosophy. This theory is the cardinal principle of the whole. The speculations on particular branches of philosophy are all included in this one theory, which binds them together and explains them. For when the mind had once risen to the contemplation of the Ideas, it needed no further helps from observation or study of nature to understand all knowledge. The mind was then in possession of the only true principles of knowledge; and to enter into the consideration of material and sensible phenomena, was only to return to the darkness and the dreams from which the eye of the intellect had been purified,—to quit the light of the sun for the cavern of shadows.

Accordingly, all his writings are devoted to the establishment of this theory. Proceeding on that notion of the importance of the theory which he inculcates, he bends every thought to this one point. No one science is set forth by him in detail; no one subject obtains with him a full and explicit consideration. All is resolved into its most abstract and general view, that the mind may be led to see the common principles of all truth; so intent is he throughout on his theory of Ideas, whatever may be his immediate subject of discussion. He assumes hypotheses, and examines them, and refutes them, in the way of argument, without pronouncing on either side of a particular question, as if indifferent about the establishment of any mere opinion, and desirous only of clearing his way for the perception of his theory.

But to place that theory in its full light, we should advert to the theories of Knowledge and of the Soul, which are intimately connected with it. These theories contain his account of the origin of the Ideas.

Knowledge, according to Plato, is Reminiscence, Ἀνάμνησις, a recovery of forgotten truth, which had been possessed by the soul in a former state of existence. His dialectic professed to do nothing more than to lead the mind, by apt interrogation, to perceive the Truth for itself. It abandoned the attempt to communicate the Truth by didactic propositions. It only removed falsehood, and left the truth to its own course, to suggest itself to the mind, now disabused of its error and prejudice. It appealed to principles as certain criteria of truth, and yet confessed its inability to state those principles, and place them distinctly before the mind of the learner. They were simply referred to, as existing in every mind, whatever might be the peculiar opinions of the individual to whom the questions of the dialectician were addressed. How, then, could those principles have been acquired? No time in the present life could be pointed out when they first appeared in the mind. They are prior to the sensations, for the sensations are referred to them; and the sensations we have had from our birth. These standard principles, then, must have been acquired in a previous state of existence, and what is commonly called learning, is, in fact, Reminiscence; and to know, is, properly speaking, to remember.[6]

In proof of this account of the origin of the Ideas, Plato

[1] *Repub.* vii. p. 158; also *Philebus*, p. 303.

[2] Παντα τα ἐν ταῖς αἰσθησεσιν ἐκεινου τε ὀρεγεται τοῦθ' ὁ ἐστιν ἰσον και αὐτου ἐνδεεστερα ἐστιν (*Phæd.* 170); προθυμεῖται μεν παντα τα τοιαῦτα εἶναι οἷον ἐκεινο ἐστι δε αὐτοῦ φαυλοτερα (*Ibid.* 171). He goes on to say this applies to all subjects as well.

[3] Δεσμῶν δ' ὁ καλλιστος, ὃς ἂν αὐτον και τα ξυνδουμενα ὁτιμαλιστα ἑν ποιῆ, τοῦτο δε πεφυκεν ἀναλογια καλλιστα ἀποτελεῖν· ὁποταν γαρ ἀριθμῶν τριῶν, κ. τ. λ. (*Timæus*, p. 307.) The Pythagoreans were fond of describing moral ideas by terms drawn from mathematics and music. The good man, for example, was τετραγωνος ἀνευ ψογου; and the words πλημμελῶς, ἐμμελῶς, and the like, borrowed from their philosophy, are familiarly used in a moral sense.

[4] Ὀυκ ἄρα παντων γε αἰτιον το ἀγαθον, ἀλλα τῶν μεν ευ ἐχοντων αἰτιον, τῶν δε κακῶν ἀναιτιον. (*Rep.* ii.)

[5] Θατερου φυσις. (*Tim.* p. 315.)

[6] *Phædo*, pp. 166–174.

Plato's Writings and Philosophy.

introduces Socrates making an experiment on the mind of an uneducated person. Socrates is represented putting a series of questions to a slave of Meno, one of his disciples, and at length eliciting from the youth, after repeated correction of his errors, a right enunciation of a geometrical truth. Socrates then points triumphantly to the instance, and bids Meno observe how he had *taught* the youth nothing, but simply *interrogated* him as to his opinions, whilst the youth had himself recalled for himself the knowledge thus evidently existing in his mind.[1]

Again, in illustration of the same, Plato refers to instances of association. Often, on the sensation of a particular object, we are reminded of something else not present to us. On seeing a lyre, or a dress, which one whom we love has used, a thought occurs of the person to whom it belonged. So also, on seeing pictures of objects, persons and objects will be suggested to the mind, unlike as well as like to the objects in the picture. Or one of two friends, being presented to our view, we are reminded of the other who is absent.[2]

Now the instances here referred to, both those of association, and those of the self-teaching of the mind by the excitement of its reflection, are highly interesting and important in the history of the origin of ideas. But they do not prove the point for which Plato adduces them. The case of the slave interrogated by Socrates certainly shews, that there are principles in the understanding, which are not derived from external information, but which only wait to be developed by occasions apt to call them forth. And as to the instances of association, we can only say, it is an ultimate fact of our mental constitution, that particular objects serve to bring others before our thoughts. All such instances are illustrations of the fact, that the mind is not passive in its admission of truth, receiving knowledge simply as something infused in it from without; but that its knowledge is, in great measure, owing to its exertion of its faculties, and its bringing to bear on the instruction given its own intuitive convictions;—that consequently the excellence of all teaching consists, not so much in the positive mass of instruction conveyed, as in stirring up the mind to exercise the powers with which it is gifted, and to learn from itself.

The stress of Plato's argument in favour of the theory of Reminiscence, and of the previous existence of the Soul as a consequence of it is laid, we find, on the ground of the priority of the ideas compared with the several particular sensations which are referred to them as criteria. But the priority which he here claims for the Ideas, is not, in fact, a precedence in the order of time, but of logic. In the process of reasoning, general principles are prior to, and more known than, the particulars which fall under them; because in possessing them we possess the particulars, and the particulars, as yet unknown, are known by deduction from them as already known. Thus we familiarly speak of a conclusion as *following* from the premises. Now, Plato appears to have transferred a priority of this kind to the Ideas, and then to have concluded their priority ABSOLUTELY, as principles existing in the mind independently of the occasions on which they are called forth. But to establish a theory of Reminiscence, it was further required to be shewn, that the ideas are prior in the order of *time*,—that we possess them antecedently to, and independently of, all experience. The instance which he has given of the way in which a mathematical conclusion is reached by the simple leading of the mind in the right track, is an instance of what has in modern philosophy been more properly called "Suggestion,"—not of Reminiscence. So far from being an instance of Reminiscence, it shews, on the contrary, that the general principles of the mind are developed *subsequently* to the particular occasions which suggest them. It shews, further, that these principles are in some way dependent on such occasions for their development, though not dependent on them for their truth and reality; for the mind accepts them as true, and as the criteria of all other truth, at the moment when they are presented to it. This, then, is what is really illustrated in Plato's instance in the *Meno*. Geometrical science is the best illustration of it, though it is seen also in all our judgments and reasonings; because the remote conclusions to which we are brought by the chain of exact demonstration in that science from a few very simple definitions, present the fact most strikingly. Those conclusions are clearly far beyond the apparent compass of the definitions themselves. They are strictly deduced from them, however, and with an irresistible cogency of argument. The wonder is accounted for by the fact to which Plato has called our attention. The demonstration of the problem appeals in every successive step to the intuitive convictions of the mind. Ideas are suggested by which the statements at each point of the proof are tested; and we sanction the conclusion ultimately, because the process by which we arrive at it has been approved throughout by clear principles of our own minds.

But though the theory of Reminiscence has not been satisfactorily made out by Plato, he has the merit of having distinctly noticed and marked, in speculating on the origin of the Ideas, a class of notions of which no previous account, as it seems, had been given. The philosophy of sensation had before his time chiefly engaged the attention of thinking men, whether of those of the Eleatic school, who made everything "stationary," or of the Ionic, who made everything "flow."[3] It had been carried into the extreme of refinement by the Sophists, its devotees, when Plato commenced his antagonist system. He found that this philosophy was too narrow a basis for the structure of science, and that it could not stand alone. He saw that it left altogether unexplored the perceptions of the mind itself, such, for example, as the notions of equality, identity, time, causation, right, &c.; and that these notions were, in truth, more important for the establishment of science, than those which had previously chiefly attracted the attention of philosophers. He applied himself accordingly to examine and characterize these principles. The main thing to be accomplished in such an inquiry, was to distinguish them accurately from the informations of sense; to shew that they were not included in, or in any way derived out of, the informations of sense, but developed by the workings of mind. This fact he has recorded in his theory of Reminiscence,—a term expressing the point of contrast in his method, to that of the empirical philosophers before him exclusively founded on Sensation.

The truth and importance, accordingly, of Plato's Theory of Ideas, appear in this; that by that theory he laid a stable foundation of science, in the principles themselves of the human mind. His error is, that he carried that theory too far; that he included in it notions which are not part of the fundamental principles of the mind, and thus involved his theory in vagueness and paradox. The war of Nominalism and Realism is well known to every one who has looked into the History of Philosophy, or of theological opinion. This found its occasion in the wide generalization of the Ideal Theory. Had Plato restricted his theory to such notions as really exist in the mind; and had he not extended it, without discrimination, to those which belong to general terms, and which are purely notional; there would not have been that ground for controversy on the subject. As the case has been,—one class of disputants, looking to the generalizations of language, the genera and species of logic, took the nominalist view of the subject,—

[1] *Meno*, pp. 352–361. [2] *Phædo*. [3] Plato characterizes them; the one, as the τοῦ ὄντος στασιῶται; the others, as οἱ ῥέοντες. *Theæt.*

imputing to the whole of the ideas the attribute of one portion of them;—the other class of disputants, justly observing the reality of certain general principles, became the advocates of realism throughout. What has been already said on the dialectical origin of the theory, will sufficiently account for the confusion of two such dissimilar classes of principles in Plato's system.

How shall we wonder, therefore, that the great logical philosopher who followed him should find it necessary to combat the theory of Ideas in the undefined form in which it had been left by its author. As thus left, it stood in the way of those exact arrangements of the objects of thought which the rigorous method of Aristotle required, and introduced a class of existences for which he could find no place in his system.

Nor, further, will it be matter of wonder that controversies should have arisen in the schools respecting the nature of the Ideas; such as, whether they subsisted by themselves, or were bodies, or were actually separable from sensible things, or only separable from them in thought; or whether they were locally situated anywhere, or only in the Divine Mind. The establishing of the theory in its general form was the great business of Plato: it was enough for him to have projected it above the horizon of philosophy. Others would elaborate it after him with more or less skill. Various speculations would be raised concerning it; and controversy would at length reduce it to more definite form, and a precision beyond the contemplation of its author.

But, however just and important the Ideal Theory is in its connection with metaphysical science, it is but too clear that it retarded the advancement of sound physical philosophy, by its substitution of final causes for physical, and consequently withdrawing attention entirely from the latter. It would follow, indeed, from the suspicion thrown over the informations of sense, and the undervaluing of experience, that physical science would be slighted under such a system of philosophy. But the dominion of the theory of Ideas would necessarily exclude any other consideration in order to the truth, but that of tendencies or final causes. No other view of nature, but that supplied by this theory, would be conceived to possess the stability which science demanded. Accordingly, hypotheses would occupy the place of investigation here. The philosopher would be speculating on what ought to be, instead of observing accurately what IS; and assuming *a priori* notions of "the best," in order to determine the law of physical facts. The principle, "that all things are constituted for the best," no doubt holds good in physics as well as in other studies of the Divine workmanship; but it is here the termination of inquiry, not the commencement. It may even be employed instrumentally in the process of inquiry, to lead the mind to a point to which investigation should be directed. And this it may effect in two ways: either, from considering the good intended in the structure of some object, we may be led to see the parts of that structure in a way which discloses their real organization, and which we should otherwise not have observed; or, from taking our view of an object, not as it is actually exhibited in inferior specimens, or in those states of it in which it is seen only in progress, or under distortion, but from the most perfect specimens,—those most answerable to a divine intention or tendency to the best,—we may judge what it *is*, by considering what it *would* or *should be*. But to lay down final causes as principles from which the truths of physics may be deduced, is, as Bacon says, to corrupt natural philosophy with theology, and to render it barren of all fruits.

Such, then, is the state of Plato's Natural Philosophy. In fact, though he asserts the importance of physics in his own sense of the term, the science has no place in his philosophy. He goes so far indeed as to say that no art can flourish apart from a knowledge of physical truth; and he attributes the imperfect Rhetoric of his day to its want of such a foundation.[1] But even whilst he imputes the superiority of Pericles as an orator to his studies under Anaxagoras,[2] he strongly objects to the system of that philosopher, as we have already seen, on account of his leaving out all consideration of final causes.

Accordingly, in the dialogue which fills up this department of his system, he speaks in the person of the Pythagorean, Timæus, and strictly follows the Pythagorean notions. The detail of this dialogue consists of a history of the order of the formation of the universe in all its parts; commencing with an account of the universe at large, and the hierarchy of the heavens, and ending with a minute explanation of the structure of man, in regard to his moral and intellectual, as well as his physical powers. And here mathematical figures and proportions are the principles into which the composition and motions of all bodies are resolved. But the theory on which the whole speculation turns, and which gives the explanation of the phenomena, is the theory of "the BEST." It is an account of Good operating throughout the universe, conforming everything to itself, and constraining the untoward nature of body to yield to its sovereign power. An intelligent and good author of all things is assumed; and his order of proceeding is inferred from that which presents itself to our view as "the best." Thus the Father of the universe constructs it after the eternal unchanging pattern; "for that is the noblest of generated things, and the best of causes." He formed by his immediate operation whatever is of eternal unchanging nature. Nothing, indeed, but Himself, is immortal and indissoluble by its own nature; but, good as he is, he can never be disposed to destroy what is good. And therefore the fabric of the universe and the celestial beings, the generated and visible divinities included in it (with the highest order of whom Plato's description identifies the luminaries of the heavens), subsist eternally, not of themselves, but by virtue of their participation of Good."[3] Whatever is subject to death,—as the bodily nature of man and brutes,—being imperfect, is the work of the generated divinities, imitating the power of the Supreme. It is with these secondary Gods that he connects the popular mythology; deriving from them the parentage of Saturn, and Jove, and the other objects of heathen worship; and leaving the further account of their origin to be given by the current tradition. Thus the supreme God is described as the author of all good throughout the universe; and where anything of evil or imperfection is, the agency of the subordinate powers, and the irrational nature of body, are interposed to guard him from imputation of evil.

Derived as his history of the universe evidently is from the early theogonies, it is very remarkable that it keeps clear altogether of the oriental dualism. There is but one active principle in his system of the universe, the principle of Good; and nothing forms or moves but that only. "Let us not," indeed, he expressly says in another place, "conceive that there are any two gods, of contrary sentiments, causing the revolution of the universe."[4] He seems indeed to personify the irrational force of body, where he describes it under the name of Αναγκη, necessity.[5] But he is evidently only speaking in metaphorical language here (that language probably derived from personifications found in the early cosmogonies), intending to represent that inert power by which Nature, as we speak, acts according to its laws.

It must have been observed all along how important a place the nature of Body, σωματοειδες, occupies in Plato's philosophy. He has nowhere, however, attempted to give any positive description of the nature of Body. It is, in

Plato's Writings and Philosophy.

truth, rather a condition in order to the development of the ideal theory in connection with the phenomena of sensation, than any positive nature, according to his conception of it. He has left it in the most mysterious form: nor does he seem indeed to distinguish it from Space, when he shadows it out by negatives of the attributes of all actual existence. In giving an analysis of production or "becoming," γενεσις, he enumerates three principles as concerned in the process: 1. The thing produced; 2. That in which it is produced; 3. That from which the thing produced takes the pattern of its production; depicting them under the analogy of the father, the mother, and the offspring.[1] The notion of body is here represented by the intermediate term of the three, namely, that in which the production takes place. "The nurse," "the general receptacle," and "the laboratory," ἐκμαγεῖον, are also expressions by which he endeavours to characterize it, as being in its own nature incapable of being presented to the senses or the intellect. "As a person," he says, "observing a perpetual succession of figures moulded of gold, if asked during the process what was moulded, could only safely answer, that it was gold;"[2] so we must be content to speak of this nature, calling it only a receptacle of forms or species, and not attributing to it any particular species whatever. The tendency of this theory of Body is obviously to remove all material phenomena from the class of real existences. And it seems to point to the origin of Plato's ideal theory in some older philosophy avowedly idealistic. At any rate, the speculation concerning body, as it stands in his system, leaves a hiatus in the transition from the world of Ideas to that of material existence.

The doctrine of Soul, as delivered by Plato, is properly the connecting link between the worlds of "being" and sensation. Hence is derived the importance of the theory of the Immortality of the soul in his philosophy. For it is in the soul that the eternal and immutable is found in the presence of the incipient and evanescent; the intellectual idea in contact, so to say, with the phenomena of sense. The soul partakes of change, as it is connected with the bodily nature: it is eternal and unchangeable, as it is the seat of intelligence.

Soul, then, according to Plato, is the necessary condition for the development of intelligence in the universe, as Body is for the existence of sensation. Soul, therefore, was necessarily prior to Body, as the first condition in order to the constitution of the universe. It was the animating principle by means of which the Deity, when he brought the world out of the disorder and confusion of unreason, communicated intelligence to it, fashioning it after the pattern of the eternal ideas. And not only is the whole universe thus ensouled by the immediate agency of the Deity; but every particular system in it, in which any degree of intelligence is found united with body, has in the very gift of that intelligence a soul originally imparted to it by the Father of the universe himself.

This is the ultimate account of that immortality which Plato attributes to the soul of man. It is not as a *human* soul that it is immortal; but it derives an eternal existence from its being among the original intelligent units of the animated universe. We see indeed a constant production of living things in the world; but it is not, as they have "being," that they are thus *produced* or *generated* or "become." This is the result of that "diverse" nature which was blended in their original composition with their higher principles, with the principles, forsooth, of "sameness" and "being."

For these are the three principles into which Plato analyses Soul,—the principles of the SAME and the DIVERSE, and BEING;[3] and by these he explains the phenomena of its actual existence. No time can be assigned, then, to the origin of that which by its nature IS, and is the SAME essentially. No one soul, therefore, can now *begin* to exist. And again, whatever once exists can never cease to exist, unless there is anything capable of destroying its principles of Sameness and Being. But Death, as he shews, has no such power. It may disengage the soul from its present body by dissolving the body; but it cannot affect the essential vitality which is in the soul. This essential vitality is the direct contrary to death. It therefore recedes when death comes, according to that law of Contraries, which holds throughout the world of generation and corruption, and which is the agent in all changes. But it still lives as vigorously as ever, and returns to animate another body in the course of Generation.[4] Nor, for the same reason, can it maintain an unvaried perpetuity of existence. It remains ever undestroyed; but from that "diverse" principle which enters into its composition, it both alters in its internal character, and only imperfectly imitates the Eternal Nature by a successive re-appearance in the forms of new bodies.[5] Thus, whilst it returns to the sensible world, it migrates from the male to the female sex, or to forms of the lower animals, according to that condition of purity in which it departed from its last body, or its previous degree of intellectual cultivation. For, as we may observe, there is no original distinction, according to the theory, between the soul of one man and another, and the soul of man and brute. All are equal in intelligence and goodness, as the immediate work of the Divine Author. The varieties in the characters of souls arise from the operation of the inferior deities who framed the bodies of men and brutes, and the use which individuals may make of their circumstances in the world. Whilst the number of souls, then, remains the same, they are continually changing their habitations, and passing by death from one body to another in the different forms of animal life; undergoing degradation with the forms of inferior animals, or elevation with those of superior nature, according to their state in a former existence.[6]

The theory of the immortality of the soul thus rests entirely on the Theory of Ideas. It is the universality, and being, and truth, and perfection of the Ideas which prove the soul to be eternal.[7] Ideas are found existing in the mind, but their acquisition cannot be traced to any particular period of a man's present life. They have been there from time immemorial, for no one can say when they first appeared in his own mind. They were therefore born with us; and if so, they must have had existence before our birth: and who can limit that existence? They have existed, for ought we know to the contrary, from all eternity: and who, then, shall limit their existence by any future period? why may they not be born with us in a life subsequent to the present, as they were born with us in the present life, and so on to all eternity in endless generations? This is in substance the train of reasoning by which Plato seeks to establish the immortality of the soul. A similar argument has been reproduced in modern metaphysical treatises, variously modified and stated, but the same in substance. How little calculated it is to produce practical conviction, whilst we admire its ingenuity, is evidenced by Cicero's confession, that whilst he wept over the *Phædo*, his mind retained no deep impressions from the argument.[8]

This brings us to the consideration of Plato's ethical system, in its vital connection with his physical and metaphysical doctrines.

The two great principles on which his ethical system re-

poses, are; 1*st*, that no one is willingly evil;[1] 2*d*, that every one has in his own will a power of inducing changes in his character.[2]

These principles are only the counterpart ethical expressions of his theories of immutable Being, on the one hand, and of the world of phenomena, or mere Becoming, on the other.

For the soul of man, so far as it has any good or truth in it, is framed after the pattern of the eternal Ideas of the good and true. These Ideas, under the various moral aspects which they present, constitute its moral nature. All its desires, therefore, naturally tend to the Good and True. These qualities are what the soul would be. They are the mysterious realities to which it is striving to attain, in all those various efforts after Pleasure which it makes in the present life;—unconscious it may be, as it is in fact in the depraved, of the true nature of the objects to which its affections ultimately point. Still, if it be conceded that Ideas are the only proper Beings, and that everything else is phenomenal, or the mere product and offspring of the generating power of the eternal Ideas, it must also be admitted, that nothing else can be the real source of moral phenomena but the Good and True. In the moral, no less than in the physical world, a constant succession of passing events is found to take place. We perceive a variety of affections in the nature of man as he is in the world, directed to a variety of objects, each aiming at some particular gratification; one desire and its gratification passing away, and others succeeding it in endless flow. All this restless course, then, of moral events exhibited in the life of man is phenomenal; not in the sense of its having no reality whatever, but of its having no permanent reality—of its being no more in the result than effort towards being—restless, endless effort towards that which may give rest and full satisfaction, and stable being.

This ultimate object, then, however indistinctly sought, is the aim of every individual soul of man. Some, indeed, avowedly make mere sensual gratification the end of their desires. They endeavour to satisfy themselves with the limited and the evanescent. But the true cause of all that perverted activity which they display, is the Good itself. They know not what the Good is; but they love it in spite of themselves, and bear evidence, by their life of unceasing pursuit, that they are secretly actuated by the desire of it,—and that they can find no rest in anything short of it. Their soul, originally formed in the likeness of the Deity, can never willingly be separated from its Divine image. In the midst of its wildest aberrations, it feels the attraction of like to like, impelling, and at the same time reclaiming it to right.

This accordingly is Plato's meaning in the principle, which he so emphatically lays down, that "no one is willingly evil." It is very different, we may observe, from saying that no one commits evil willingly. And Plato himself takes care to guard his theory from this misconstruction. He readily grants, that acts of wrong are distinguished by being voluntary and involuntary, without which there could be neither merit nor demerit; but he strenuously maintains that this distinction does not apply to evil itself. It is in all cases involuntary. No one can choose it in itself. It is necessarily the object of aversion, as the good is invariably the object of choice and pursuit.

How is it, then, it will be inquired, that men do become evil;—that whilst they are really seeking to be conformed to a divine pattern, they practically do what is evil, and, losing more and more of their likeness to the Eternal Being, conform themselves rather to the fleeting character of the world of sensation?

Plato's Writings and Philosophy.

The explanation is found in the other great principle of Plato's philosophy, the theory of Becoming, to which we have referred. Change is the characteristic of all that belongs to this subject; as immutability is the characteristic of Being. The course itself of successive phenomena may be varied by impressions from circumstances. In the soul there is a principle of change in the power of regulating the desires,—in indulging them to excess, or moderating them, according to the will. And the circumstances in which the soul is placed, as connected with the sensible world by means of the body, present the occasion for such change. The humours and distempers of the body produce discomposure in the soul. It becomes diseased analogously to the body. This state of disease is what is commonly called folly, ἄνοια; and it takes the form either of madness, μανία, or of mere ignorance, ἀμαθία. Where even ignorance only is the result, the internal harmony of the soul is disturbed. Pleasures and pains are unduly magnified; the democracy of the passions prevails; and the ascendancy of reason is cast down. In addition to these disturbances or ailments through the body, come the influences of evil governments, evil public lessons, evil education. Hence the soul is changed from what it was when it first came from the hands of its Divine author. The eternal Ideas after which it was framed are not effaced from it. This cannot be; for then it would cease to have being; but it loses distinct apprehension of them,—mistakes appearances of good for good itself,—and under that delusion willingly does evil, and presumes on obtaining happiness by a course of evil conduct.

But the same principle of change in the soul gives an opening also for its moral restoration. As the soul is deteriorated by the contagion of the body, so it may also be restored to a sound state by remedial treatment. The yielding to every passing desire, and suffering the desires to grow out of proportion, and destroy the harmony of the soul, is the cause of men's falling into that blindness which hides the good from their mental eye. By restraining them, and moderating the desires, the internal disorder is gradually corrected; reason resumes its ascendancy; the soul once more "sees and hears aright," and thus returns to that good to which its desires naturally tend. It is a long process, indeed, by which the restoration is effected; a process of gradual purification, καθαρσις, of the soul, by chastisement and suffering. Nor is it accordingly completed in a single life; many courses of existence must be passed through. Not only is the present life of the soul a consequence of its conduct in a former one; but it is destined to many successive stages of existence, each adapted to the character acquired at the stage next preceding, until its defilements are purged away.

These ethical doctrines of the philosopher, when divested of the extravagance of his theory, so far accord with the truth both of inspiration and experience, as they indicate, that the utmost man can do in the present life is insufficient to restore in him the lost image of God. Whilst they lay down this truth under the disguise of the remedial process of the transmigration of the soul, they further agree with the inspired authority, and with experience, in imposing on man the duty of *commencing* the process of restoration, and in holding him strictly responsible for the state of his mind and affections, through that power of self-direction and capacity of improvement by discipline, with which he has been endued. Thus does he also bear evidence both to the fact of the perfection of man at his creation, and that of his existing corruption. But he differs from the Scripture account of that corruption, in making it originally a physical rather than a moral debasement,

Plato's Writings and Philosophy.

and representing it as taking place by a gradual process, and not by a sudden and entire fall, the effect of a first transgression of a positive divine command.

The Sophists, indeed, boasted of their power of transforming the characters of men, and accordingly made great profession of "teaching virtue."[1] But they coupled with this pretension, the admission, that all opinions on moral, no less than on other subjects, are equally true. All opinions in morals, they said, are true; "but all are not good. What we would effect, therefore, is to lead men to such opinions as we know also to be both good and wise."[2] But this was a mere evasion; for if all opinions are equally true, then must also each man's view of good be true, as well as that which his instructor would inculcate on him; and there is no fixed standard to which he may be conformed. Plato's theory of good, as the sole object of desire,—or the invariable tendency of the will to good, and its invariable aversion from evil,—was a strong ground of opposition to the sophistical doctrine. It pointed out that there was a principle in man superior to instruction, and independent of the accidents of worldly circumstances, the Θεος μετρον, the "God-measure," the fixed Divine standard, to which all moral teaching should be directed, and from a reference to which all moral discipline obtained its value.

From this mode of enunciating the fundamental principles of morals, it followed, that the practical morality which Plato teaches, should be directed to the means of removing the false appearances of good by which the mind is deluded to evil. He shews, accordingly, that there are false pleasures as well as false opinions—that men's ignorance extends, not only to mistakes in regard to their wealth or bodily accomplishments, but as to their moral characters; for that most men think themselves better than they really are.[3] Thus does he apply to morals more particularly, the general confession which his philosophy exacts of its disciple on all subjects, that he knows not what he presumed he knew, and sends every one to learn himself, in order that he may be truly a moral man.[4]

This, therefore, according to Plato, is the great purpose for which philosophy must be cultivated. Philosophy alone can open the eyes to see the true value of things, and alone elevate the mind from the evanescent region of the phenomenal world to the seat of true and eternal Being.

For the same reason Dialectic, as *immediately* conversant about the Ideas of the good and true, is the ultimate study of him that would seek to educate and improve the powers of his soul to the utmost.

Philosophy and morality, in fact, in his system, perfectly coincide. The love of truth is also the love of good, and the love of good is the love of truth.[5] The same process by which the good man is effected, philosophically viewed, is a power of analysing pleasure and pains, an art of mensuration, enabling the mind to discriminate between Truth and Good on the one hand, and their semblances on the other, and distinctly to apprehend them, under whatever disguise they may be presented and obscured by the senses.[6] Morally viewed, it is the one motive of the love of truth and good predominating over, and purifying, and absorbing into itself, every desire of human nature.[7] In the first view, it is wisdom or philosophy; in the latter, it is purification,—and perfect virtue,—and discipline of immortality,—the resemblance and participation of the Deity.[8]

These views of moral truth are in themselves certainly grand and ennobling. As guides, however, to duty, they are deficient in that particularity and homeliness of application which are required for the real business of morality. Their tendency, too, to contemplative mysticism is obvious, left as they are by Plato in undefined outline, and clothed in the charms of his imaginative eloquence. Nor shall we wonder that they have easily combined with the feeling of asceticism, so congenial to the human heart. The contempt which they throw over everything belonging to the bodily nature of man,—the delusiveness imputed to the senses, without any limitation of it, or guard against abuse of the theory,—and the abstractedness from the world which they propose,—admit of being construed into a theory of mortification of the body, and of the purifying efficacy of self-inflicted punishments. These tendencies, indeed, of Plato's ethical doctrines, were, not long after his time, exemplified in the apathy and austerity of the Stoic morality. And it is well known to what extent they have been developed in the teaching and practice of religionists of all creeds. It cannot be denied, also, that where they take hold of a morbid and susceptible temperament of mind, they tend to substitute, in such a case, the morality of imagination and sentiment for that of common sense and household feeling, and to fritter away the convictions of duty into mere proprieties of taste; so that even whilst they elevate the character above sordid and vulgar seductions of pleasure, they emasculate and corrupt it, through the very excess of its theoretical refinement.

As bad education was regarded by Plato as the other great cause of human corruption, in addition to the influence of Body on the soul, he directs a large portion of his philosophical disquisitions to correct the evil arising from the second source. His ethical discussions go to the limiting of the desires, and curing the diseases produced by them in the soul. His political discussions have for their immediate object, the laying down right principles of education, and enforcing them by the constitution, laws, and power of the state.[9] His two great works, the most elaborate of his writings, the Dialogues of the *Republic* and the *Laws*, are rather theories of Education than of Government and Laws. The former indeed inquires more particularly into the principles on which a right government may be formed; whilst the latter gives a systematic view of the principles of legislation. Both, however, have in view the improvement of human nature by social institutions expressly framed for that purpose. It has been supposed that in the *Republic* we have his theory of a perfect state, and in the *Laws* a practical exemplification of the theory. But this is clearly a mistake. Both are doubtless intended by Plato as theoretical disquisitions on the political matters of which they treat, whilst the real matter in hand is Education.[10] This is expressly asserted by Plato himself, when he compares his legislation to the method of the philosophical physician.

---

[1] Gorgias, however, laughed at the other Sophists for pretending to teach virtue. He professed only the art of words. [2] *Protag.*

Plato's Writings and Philosophy.

When the mere empiric, he observes, should hear such a physician discoursing to his patient of the origin of the disease, and ascending to the speculation on Nature, he would be disposed to object that such proceeding was folly; "for it was not healing the sick man, but rather educating him, as if he wanted to become a physician, and not to be made well."[1] The like objection, he says, might be applied to his method of legislation; for, "whoever pursues the inquiry concerning laws," he adds, "as we are doing now, educates the citizens, but does not legislate."[2] And he goes on to say, in the person of the chief speaker, addressing the other interlocutors of the Dialogue, that in their work of legislation they were at leisure, as speculators on the subject, to consider, not what was most necessary, but what was best.[3]

We are not to suppose, then, that Plato had in view the actual foundation of a state, according to the principles of government and legislation laid down in his two famous dialogues. His object was to give an example of the most perfect life,[4] free from those impediments which all existing governments and laws threw across the path of the virtuous man. As philosophy is the guide of private life, elevating it to the knowledge of the Good and True, so he would have philosophy also seated on the throne of government, and exhibit the eternal Ideas of Good and Truth, modifying society after their pattern. Hence it is that he overlooks impossibilities in his arrangements; as is pointed out by Aristotle in his acute comments on the leading points of Plato's political theories.[5] All is sacrificed, in fact, to the one great object of Plato's mind, the sketching of the Idea of the Good as a social principle, apart from the evil influences of existing society.

The most extravagant hypotheses, accordingly, are put forward in this part of his philosophy; not indeed with a view of their being ever exemplified in any institutions of real life, but in extreme contrast with the existing selfishness of human society, and as theoretic developments of the unchangeable idea of good. Such, for example, is his theory of a community of wives and children, and the training of women to the hardiest exercises of the gymnasium and of war. We justly take exception at the immorality and unnaturalness of such hypotheses. But Plato looks down upon man from the height of his sublime theory. He sees everything in the unity and invariableness of that theory, and overlooks distinctions deeply founded in the nature of man. Thus it is that in his view man himself becomes a thing of little consideration or importance,—a sort of plaything of the Deity, θεου τι παιγνιον, scarcely worth any serious attention. "You disparage altogether the race of man," says an interlocutor in the Dialogue of the Laws. "Wonder not at it," replies the Athenian; "but make allowance for me; for it was from looking off to the Deity, and under this impression, that I said what I have now expressed. However, let it be granted that our race is not insignificant, if you like, but worth some serious consideration."[6] It is in this spirit that he himself sports with human nature, as if human beings were only so many chessmen, to be moved on the board, so as to display the admirable design of the disposing mind, and illustrate the working of the eternal Ideas. His fault is the same as in his physical speculations, that of commencing from the final cause, or the notion of the Best, and forming the world of social life after that, instead of rising from the study of its actual formation to the notion of the Best;—or at least in supposing, that he could arrive at a just view of the divine pattern of Good, by presenting a theoretic copy of it, after his own conceptions of the Best. But such extravagancies as those we have referred to, could only have proceeded from so bold a mind as that of Plato,—a mind, not checked by the repulsiveness of particular consequences from pushing a theory to the utmost.

At the same time, this fundamental notion of the Divine standard and pattern on which he proceeds, imparts a solemn dignity, in the midst of these excesses of the spirit of theory, to the substance of his speculations on government and laws.

Religion is thus secured as the basis of all right government and legislation. That government only which most resembles a theocracy is, in Plato's view, a true polity. All others, popularly termed governments, as democracy, oligarchy, aristocracy, monarchy, are merely settlements of cities, and not *Polities*,[7] being called after that power which has the ascendancy in each over the other parts of the state. So far as a state is truly such, it ought to be named, he says, after the true God, the lord over all intelligent beings. Governments, as they exist, are only the results of the struggles of contending factions: whence we find, as he observes, one party in the ascendancy excluding and depressing another, in order to its own maintenance, and no concern taken for the welfare of the whole community. To remedy this general evil of existing governments, he would have the simple and straightforward course of the divine procedure brought before the minds of men, and a conformity with that procedure inculcated on them as the only rule of life and happiness. "God," he teaches, in an animated and noble passage,[8] "as the ancient story is, holding the beginning, and end, and middle of all things that are, describes a straight line, according to nature, as he walks his circuit.[9] In his train ever follows Justice, the avenger of those that are left behind by the divine law; to which, he that would be happy, keeping close, follows in the train, humble and orderly; but whoever is puffed up with high boasting, or elated with wealth, or honours, or grace of person, together with youthfulness and folly,—his soul burning with insolence, as presuming, that he requires neither ruler nor any guide, but is competent even to be a guide to others,—is left, forsaken of God. And being left, and taking to himself others besides, such as he is, he frolics, throwing everything into promiscuous confusion. And to many he seems to be some one; but, after no long time, undergoing a retribution, of which he cannot complain, to Justice, he utterly subverts himself, and his house, and his city."[10]

Here we have emphatically recognized the great truth, that the foundations of all government and law are laid in the unchanging nature of the Divine Being. The law of right, as exemplified in the dominion of party, is the law of the strongest, fluctuating with the accidents of power, and never attaining to any permanent being. Such was the law of right, as taught by the Sophists, from city to city, and which was fully established in public opinion throughout Greece,—not only as manifested in the factious character of the particular governments, but avowedly declared and acted on as a principle of conduct. "It is nothing," say Athenian ambassadors, "out of the course of the established opinion of men concerning the Divine Being, or

Plato's Writings and Philosophy.

their sentiments concerning themselves, that we expect or do. For we hold that the Divine Nature, so far as we can judge of it, and human nature, as we see clearly, by an instinctive necessity, ever exercise power where they can obtain the mastery. Nor are we the first, either to propose the law, or to use it when laid down: it was in being when we took it up; and it will subsist for ever, for us to transmit to others after us; and we merely act upon it; convinced, that yourselves, no less than others, were you placed in the same power in which we are, would do so."[1] Here, then, is the law which belongs to the region of instability,—to that nature which is ever *becoming*, and never *is*. Contrast with this Plato's principle, which deduces the origin of law from the eternal IDEA of GOOD, and it will then be more distinctly seen what the spirit of Plato's legislation really is.

It follows, indeed, from his principle, that all instituted law is imperfect.[2] And he admits, accordingly, that if a perfectly virtuous ruler could be established on earth, it would be best that the business of government should be carried on by his will; which would in such a case be only the copy of the Divine exemplar of right. But as this is past hope in the present condition of human things, the substitute for the more perfect system is the institution of laws framed after the eternal Idea of Good; not laws adapted merely to the preservation of a particular form of polity, but embodying in them the immutable principles of right. And even such laws, as being matters of institution, are inferior in dignity to unwritten laws—the principles of right—which, themselves resting on no external sanction, are yet the conserving principles of all positive laws.

Having his eye fixed on the eternal pattern of the good and the true, Plato looked with a feeling of disappointment and disgust at the several forms of polity which the states of Greece exhibited. He is generally thought to have inclined to a preference of aristocracy, and to have regarded with aversion all popular government. But though it is probable, that, from what he saw of the tyranny of an unrestrained democracy, he sighed in secret for a better order of things, we cannot conclude from his political speculations that he regarded any single polity as the best. He, in fact, condemns all particular forms;[3] and when he asserts a preference, it is for a polity such as was nowhere seen in his times, combining in it monarchy, aristocracy, and democracy.[4] But in his view, as governments then existed, they were all one-sided; the dominion of one part of a community over the rest, and not the dominion of good over the whole. This dominion, as we have observed, was only to be found in the government of God over the world, and to it, therefore, he would have all human government conformed. His sole preference, then, is for a theocracy, if such could be realized on earth. His slighting manner of speaking of the lower orders of society, and of all indeed but those who are gifted with superior talents and other natural endowments, is to be ascribed to his general low estimate of human nature, considered apart from that cultivation, which the highest and most intellectual studies impart to it.

Respect for antiquity and prescriptive authority is strongly inculcated by Plato. In nothing was the changeableness of all generated things more evident than in the ever-varying forms of the states of Greece, and especially of Athens itself. The democracy of Athens had been an universal market, παντοπωλιον, as Plato terms an extreme democracy, of all sorts of politics.[5] And laws had so far lost their force there in the most corrupt times, that everything was transacted by the decrees of the day; the variable determinations of popular assemblies being substituted practically in the place of standing Laws, the records of former experience and wisdom. Early legislators had devised expedients for counteracting this love of change on the part of their countrymen, as Solon, for instance, and Lycurgus had done. And in some instances, we find a temporary and partial expedient adopted, by the popular assembly itself fixing the penalty of death to the proposal of rescinding a measure before a certain period.[6] Plato's expedient was supplied by the principle itself of his philosophy. If the Idea of Good was eternal and unchangeable, the constant pursuit of change must lead men astray from their happiness and the truth. They must be called back, therefore, from that which is present and passing, to the recollection of the past. They must not look on wisdom as a thing which is different to-day from what it was yesterday, or in former times, but hold it as what by its very nature is unalterable. To regard it as susceptible of improvement in the lapse of time, would be to deny its proper Being, to reduce it to the condition of mere Becoming. A distrust in the wisdom of any existing generation of men, and a sacred reverence for that of former generations, and especially for the earliest traditions of knowledge, would naturally be inculcated in such a philosophy. Thus he highly commends the Lacedemonian and Cretan politics for the provision, that no young man should inquire whether the laws were good or bad, but that "all should with one voice and with one mouth agree in declaring that everything in them is well appointed, as being by the appointment of gods;" and that no other sentiment should be allowed to be expressed. Further, not even does he permit a young person to be present when such matters are considered by the old.[7] In the same spirit, the Egyptian immutability in the arts for thousands of years, is admired, as a proof of admirable legislative and political wisdom.[8] Even in regard to the fine arts, and to sports and amusements, he reprobates the tendency to innovation, as dangerous to the serious institutions of a state, on the ground, that changes in these lighter matters "imperceptibly change the manners of the young, and bring what is primitive into disrepute, and what is modern into repute;" and that there cannot be a greater mischief to states than such a habit of "blaming antiquity."[9]

All this, which under certain limitations may be true, appears, when thus broadly laid down by Plato, a misapplication of the proper sanction of religious truth to truth in general. In religion, the only question being what is really taught by its Divine author, there can be no addition made in the course of time to the truths revealed, except by another divine revelation, though there may be advancement in the exposition and teaching of it. What is primitive and ancient, accordingly, in this subject, once fully ascertained to be so, is the truth, and the whole truth. Only we must not mistake antiquity of exposition and comment, for primitiveness of the truth itself; for these admit of improved knowledge by human study, when the original truth itself does not. The contest between the advocates of the respective claims of the past and of the present, in the matter of knowledge, is doubtless much older than the time of Plato. But his authority and eloquence have probably been mainly instrumental in starting and sustaining the controversy in modern times, through the early reception of his philosophy into the literature of the Christian church.

But we may further see a reason for the stress which Plato lays on the wisdom of prescription and authority, in that state of public opinion to which he is addressing himself. It was not, as might be supposed, a state of things

Plato's Writings and Philosophy.

corresponding exactly to a demand for religious or civil changes, in our days, under established governments and institutions. The question of change is now gravely discussed, and deliberately carried or rejected, not with the view of unsettling everything, but in order that some particular institution or law may be *established* for the future. Except in violent outbreaks of human passions long pent up within artificial restraints, exasperated by resistance, and at length forcing their way out, and levelling all barriers before them, as in the instance of the great French Revolution, it cannot be said with truth, of the struggles for particular changes in modern institutions, that they have been actuated by the mere desire of change, and the hatred of everything established. The religion and the civilization of modern times have in some measure presented a check to this. But at the centre of movement in Greece, change was the order of the day. Athens would neither rest itself, nor suffer other states to rest. When its very demagogues are forced on some occasions to endeavour to repress this incessant changeableness; as Cleon was, when he told the Athenians it was better "to have worse laws unmoved, than good laws perpetually changed;"[1]—it is evident that the spirit of change was then developed in its most fearful form. For we find the magician himself who had evoked it, starting in terror at the apparition, and finding it too strong for his direction and control. *Δοῦλοι ὀντες τῶν ἀει ἀτοπων, ὑπεροπται δε τῶν ἐιωθοτων*, "Slaves of every new extravagance, but despisers of accustomed things,"[2] are the words with which he attempts to exorcise it, and which the historian of the times puts into the mouth of one who, as the creature of the system, could most pointedly characterize it. Such was that spirit, then, against which Plato had to contend. It was an enemy not only to the existing government, but to all government, and all law, and all religion and morality. It demanded, therefore, the most forcible counteraction. It was to be met by inculcation of the opposite. According to his own universal principle, contrary was to be expelled by contrary. Everything that was ancient was to be upheld, accordingly, as worthy of veneration and acceptance, simply because it was ancient. The voice itself of antiquity, though speaking without evidence, was to be received with implicit acquiescence and submission. Thus it is that Plato is found strenuously appealing to the instinctive feeling of his Athenian countrymen, which they still retained in spite of the prevailing folly,—the feeling with which they so fondly reverted to their early glories, and delighted to view themselves in the past;—and labouring to correct their vacillations of present opinion by recalling them to the fixed lessons of their *memory*.

Political philosophy, then, according to Plato, is the history of those changes which the will of man produces in the matter of government and laws, and an endeavour to limit those changes by restoring in the social world the primitive order and rule.

Education is the means by which those changes are counteracted. It avails itself of that principle of contrariety by which all changes are carried on; and endeavours to expel the evil by inducing the good. The process by which it carries on this effect is, a discipline of the intellect, prescribed by the state, and promoted by all its institutions and customs, framed, as these are supposed to be, after the idea of the Sovereign Good. That discipline lays down a course of exercise for the body as well as for the intellect, that the body may be brought into the best condition, in order to the exercise of the intellect. The intellect itself it conducts through the steps of the several sciences, from the bodily and sensible to the unembodied and intellectual,—from the phenomenal and changeable to that which has real being, and is unchangeable. And thus in Plato's system it is classed under the two comprehensive heads of Gymnastics and Music; the latter term being understood, according to its derivation, to denote literature in general. Philosophy itself was the ultimate attainment of education,—the result of the whole intellectual training of the accomplished man. Ostensibly, under this system, there was no peculiar discipline of the heart. Indirectly there was; so far as it inculcated purification and self-denial. But the strengthening and elevating of the intellect was its direct object. Its tendency was thus to exalt the virtues of the intellect above those of the heart; and, in opposition to the evidence of facts, to assert the power of knowledge over the determinations of the will. Not that Plato denies the existence of what we call self-command, or that controlling of the passions which is the result of a previous struggle with them. But he did not admit (as Aristotle does, and urges against him[3]) that reason could ever be overpowered by the passions, or that if there were a distinct knowledge of the truth in the mind, it could give way to passion.

In the matter of Religion, Plato's theory of Ideas led him to see that there were truths above the evidence belonging to Experience, and which must be received solely on the ground of the Divine authority. For whilst he taught that the mind of man must work its way up to the Ideas by a course of argument and examination of evidence, yet, having reached the Ideas themselves, it had attained the ultimatum of truth; no further evidence of these was to be sought; they carried their own light in themselves. So, when any truth was presented to the mind, which related immediately to the Divine Being, it was not to be supposed capable of being examined in itself, and established on any higher ground of internal evidence, but must at once be admitted, if there were sufficient external authority for it. The only question respecting such truths is, are they *historically* true? Is it certain, or at least highly probable, that they have descended to us from the Father of Lights himself? Have we reason to think that they were originally real divine communications,—and are they vouched to us as such by a competent evidence?[4] Now, in regard to the primary principles of the mind, such as we have before spoken of, though they are not evidenced by any higher principles, or by any conclusions from Experience, they carry their own evidence, by their invariable presence in the mind on certain occasions, being naturally suggested by such occasions to every rational understanding. But the truths of religion are of a different nature. They cannot be authenticated by the mind itself to itself, as being out of its range of thought. They must therefore be authenticated from without. And in regard to these, accordingly, we must appeal to the Reason and Word of God, as the simple, and proper, and unanswerable vouchers of them.

This is the account of Plato's disclaimer of all evidence, either of demonstration or probability, on matters strictly divine, and his frequent appeal to mythic traditions when his discussion touches a mystery of the Divine Being or the Divine conduct. He resolves the whole authority of such matters into the evidence of "ancient story," *παλαιος λογος*,[5]—and "primitive hearing," *ἀρχαια ἀκοη*,—and "learning hoary with time," *μαθημα χρονῳ πολιον*.[6] In speaking of the generation of the subordinate divinities, in the *Timæus*, he makes

[6] *Timæus*, p. 291.

an observation applicable to the whole subject of divine things as treated by him. Instead of entering into explicit accounts of them, he observes that the subject is "too great for us, and that we must believe those who have spoken before, being the offspring of gods, in the way in which they said it, and because they must be conceived to have known their own ancestors;" adding, that we cannot refuse credit to the "sons of gods, although they speak without probabilities and necessary demonstrations, but must follow the rule of believing them on their word, as declaring what belongs to them."[1] He commends, too, the primitive generation of men for their docility in following rules of life founded on oral tradition,—their "holding as true what was said τα λεγομενα, concerning both gods and men."[2] Again, speaking of the state of the dead, and their interest in the concerns of men on earth, he appeals to the same kind of evidence. "We must believe," he says, "the voices of others in such matters, so current as they are, and so extremely ancient; and it is enough for our belief that legislators, unless they be proved absolutely unwise, have asserted them."[3] So justly does he insist on the reasonableness of being content with the voice of a declaratory authority in matters incapable, by their nature, of a direct evidence from our reason.

By the heathen philosopher, in the absence of an authentic revelation, the authority for such truths was naturally sought in ancient traditions,—traditions mounting up beyond all memory of their origin, and therefore referable to times when the world was yet fresh from the hand of God. The voice of remote and undefined antiquity, indeed, by a natural delusion, represents itself to the mind as but little different from the sanction of eternal truth. For it is but a slight and imperceptible transition from the indefinite to the infinite. Many such traditions were found in the heathen mythology, connecting themselves with another order of things, when gods conversed with men on earth. Some of them, certainly, were full of absurdity and profaneness; and all were disfigured with the colouring of fable; but still there were some, beautiful in the conception, and sublime and impressive in the doctrine. Of this latter character, for the most part, are those exquisite mythical legends, with which Plato has diversified his discussions, throwing the solemnity of religion over truths of high importance which he would specially enforce.

Thus, though he has elaborately argued the Immortality of the soul, he is not content to leave the question on those abstract grounds of conviction. He feels that the conviction which may practically influence the conduct, must be drawn from another source,—that of a simple belief in some authority declaring it,—when he closes the discussion, as in the *Phædo*, and in other places, with a scenic representation, from the legends of ancient tradition, of the doctrines which he has been enforcing. The whole of the *Timæus*, in fact, is a legend rather than a philosophical inquiry. It appeals, for the reception of its truths, to the shadows with which it veils them, and the mystic echoes of sounds heard by the listening ear from afar. In that legend, indeed, we have very considerable evidence of the pure source, from which the heathen world drew much of the sacred truth that was wrapped up and disfigured in their fables. We perceive in such a document of ancient philosophy, at once the sure and wide-spread knowledge resulting from a scriptural Revelation, and the obscurity and fallibility of the information of Tradition. To this effect are the description in the *Timæus*, of the universe as the "one" work of the "one Supreme Being,"—as the "visible likeness of one himself the object only of intellectual apprehension,"—as the "only-generated," μονογενης, of the Father of all things; and the strong assertion of the goodness, and beauty, and perfection of the universe; and particularly, in reference to this, that striking passage, "When the Father who generated it, perceived, both living and moving, the generated glory of the Everlasting Divinities, he was filled with admiration, and, being delighted, he further contemplated the working it still more to a resemblance of the pattern."[4] Add to these instances the simple and magnificent words which he has put into the mouth of the Father of the Universe, as an address to the generated gods, respecting the formation of the bodies of men and other living creatures.[5] The attributing to Him a speech at the first formation of man, is alone sufficiently remarkable; and the plural address with which it opens, makes the correspondence still closer to the sacred words, "*And God said, Let us make man in our image, after our likeness.*" The order of the generation of things, it may be further observed, agrees with the order of the Creation. First the heavens and the earth are produced, and then the living creatures; and among these Man, designated as "the most religious of animals."[6] But at the same time there is much confusion and degradation of the high subject. We look in vain for those sublime features of the inspired account, that the Creation arose out of nothing, by the word of God. This is darkly intimated in the shadowy nature which the narrative assigns to Body; but, though it be but a shadow, Body still subsists in his system, as the co-eternal contrary of the Divine Intelligence. Traces of the descent of holy truth, in the like disguise, appear in the references found in Plato to early deluges and genealogies;[7] to the notion of God as the shepherd of his people;[8] and to accounts of variations in the course of the rising and setting of the sun.[9]

Such, then, is the character of Plato's philosophy, both in its general method, and in its results, as a theory of the universe, and an information respecting the leading branches of human knowledge.

It was concerned, we find, more in investigating and establishing first principles, than in drawing out results; in exciting the love of wisdom, rather than in aiding in the research after it. With him, indeed, philosophy and its method of inquiry, as we have seen, are one; and, in like manner, philosophy and its several branches coalesce in his system into one. We have spoken of his logical, and physical, and ethical doctrines, as if they were distinct subjects; but in his mind the one theory of Ideas held these several doctrines in its embrace, and made them indissolubly one with itself. For his design throughout is, to establish universal principles common to every subject, and on these to build a structure of philosophy,—a counterpart in the human mind to the universe itself, and comprehending therefore all that relates to the Deity, to man, and to the universe. He would place the mind of the philosopher far above the scenes in which man lives, and endue him with a keenness and range of vision, extending over the whole region of speculation, and leaving no part, either from its largeness or from its minuteness, unexplored. The problem which he undertakes to solve is, how all things are both one and many; how, amidst the multiplicity of phenomena with which we are surrounded, a real unity still subsists and pervades the whole. He proceeds on the conviction, that to attain to this unity, so far at least as our faculties will enable us to attain to it

Plato's Writings and Philosophy.

(for in itself it is incomprehensible and ineffable), is to find the clue to that maze of sensible things which bewilders human observation. He was not intent, therefore, on distinguishing and arranging the several branches of knowledge, but on bringing all into subjection to his commanding theory of the perfect unity. He has not, in fact, elaborated, or even sketched, any one particular science. He has shewn how the sciences may be distributed, or rather furnished hints for such a distribution. But he has left the task of doing so to others after him, as subordinate agents, filling up the details and supplying the omissions of his system. His was characteristically a one-making mind. It analysed,—not, however, for the purpose of finding and arranging the component elements of a subject, but in search of the one vivifying principle, which gives form, and truth, and goodness, and beauty, to everything. He omits, accordingly, to examine with minuteness into secondary agencies, which are the proper study of the particular sciences, in order that he may direct attention to the master-principle, by which all subordinate principles are held together, and by which they work as concurring causes in the infinite variety of actual phenomena with such energy and constancy of operation.[1]

It was left for his pupil Aristotle to take up the business of philosophy where he had designedly left it unfinished, and, by a more rigorous method, to introduce order into the field of science, by assigning to each particular science its distinct objects and office.

It required, indeed, some philosopher worthy of such a master to take up the subject where Plato had left it, and to carry it out to the fulness of an instructive method, and a systematic exposition of truth; and such a successor was found in Aristotle. Aristotle, as controverting the Theory of Ideas, may perhaps be regarded by some as an antagonist, rather than a successor, to Plato. But every succeeding system of philosophy is partly a polemic against its predecessor, by whose labours it nevertheless has profited. So it was with the great movement of mind commenced by Plato. It languished under Speusippus and Xenocrates, and the still more remote successors in the Academia. But in the Lyceum, the rival school in name, but the rival only as the vigorous offspring of the declining parent, a crowd of hearers such as that whom the great magician of the Academia had called around him, was once more assembled, and Athens again assumed the form of an university. In Aristotle's system, accordingly, we see the productiveness of those germs of philosophy which the genius of Plato had planted and reared. Others cultivated the germs themselves; and some fostered them into a wild luxuriance. It was by being engrafted on the sturdy stock of Aristotle's mind, that they received fresh vigour, and produced fruits, though not strictly their own, yet partaking of their life and richness.[2]

If we take Plato's philosophy as a whole in its complex form, not simply as a system of philosophy, but a system in which philosophy, and eloquence, and poetry, and deep religious and moral feeling, are harmoniously combined, it stands alone in the history of literature. There is nothing which approaches to it under this point of view, nothing which may be properly regarded as a continuation of it. It is a splendid work of rare genius, like the Homeric poems or the Minerva of Phidias, which no other artist has ever equalled. Philosophical dialogues have been written in imitation of those of Plato; but how unlike to them, how altogether inferior to them in conception and execution! There is learning, and eloquence, and grace, in whatever the accomplished mind of Cicero has touched. But compare his most finished specimens in this way with the Dialogues of Plato, and what a deficiency appears! Dignity and refinement of mind, and an acquaintance with the stores of philosophy, shine forth in the Dialogues of Cicero. But we miss altogether the depth and the exquisiteness of thought, the range and the minuteness of vision, the exactness of reasoning, the lively sketches of character and manners, which interest and astonish us by their combination in the Dialogues of Plato. Xenophon had great knowledge of human nature, and has thrown an air of great naturalness over his simple descriptions, whether it is conversations and moral lessons that he relates, or stirring scenes of history. But his Socratic dialogues do not admit of comparison with the elaborate efforts of Plato. They were clearly intended only as accounts of what Socrates had taught, and did not aim at any artist-like effect, as compositions. Or, if we turn to the *Symposium* of Plutarch, there, again, much as the author admired and studied Plato, we observe an entire want of that tact in the management of the dialogue, which so engages our attention amidst the subtilties of Plato's discussions. If we compare, again, the imitations of Plato in the Dialogues of Berkeley and Shaftesbury, we find the like contrast as in those of Cicero. Superior as these are in composition to other efforts of the kind in our language, they still give no proper representation of the spirit or the form of the Platonic Dialogue. There is no life in the interlocutors of these Dialogues; and the author himself is scarcely concealed behind their masks. Nor are there any touches of natural feeling or incident to connect the argument with the personality of the speakers; such as those in the *Phædo*, where the discussion opens with the loosing of the chains from the limbs of Socrates, his bending and rubbing his leg, and expressing the pleasure arising from the contrast of his pain before; circumstances, not merely thrown in by way of dramatic interest, but leading, in immediate application, to the argument in hand. As we have said, then, the philosophy of Plato taken in connection with the admirable compositions in which it is contained, stands alone in the history of literature. It is due to the charm of the composition, that the interest of the reader is sustained amidst much of dry abstract speculation, requiring the closest attention, and considerable acquaintance with the subjects of philosophical discussion, in order to follow it. It was this charm in great measure, doubtless, which rendered the writings of Plato, in spite of their abstruseness and subtilty in many parts, so acceptable to Grecian taste. He had his critics also and censors; but all seem to have concurred in placing him at the head of the philosophical writers of Greece. Objection was taken by some to the severity of his sarcasm against the leading Sophists and other great names. Complaint, too, was made of his putting sentiments and words into the mouth of Socrates which Socrates had never used; and of his anachronisms, in bringing together in conversation, persons, who, from the period at which they flourished, could never have met. But these were merely minute criticisms. It was seen by those who entered into the spirit of his writings, that he was still the great master throughout,—that he was not giving, in his Dialogues, a history of individuals or of the times, but a general character of classes of men, and the prevailing tone, both of philosophical discussion and of popular opinion. The enlightened critic saw that Socrates, for example, is not pourtrayed by him simply as Socrates, but as the characteristic spokesman of the system on which he is engaged;—and in like manner, that when he brings together persons of different periods, he overlooks the anachronism, that he may enunciate the doctrines inquired into, in their proper person.

The perfection to which he wrought the style of his most elaborate Dialogues, will be apparent to those who

[1] Ταῦτ' οὖν παντ' ἐς, των ξυναιτιων, οἷς θεος ὑπερητουσι χρηται, την του ἀριστου κατα το δυνατον ἰδεαν ἀποτελῶν. (*Tim.* p. 336.) The genesis of the universe is from the union of νους and ἀναγκη, and the dominion of νους over ἀναγκη causes ἀναγκη to bring τῶν γιγνομενων τα πλειστα ἐπι το βέλτιστον. (*Tim.* p. 339.)

[2] Dionysius of Halicarnassus speaks justly of Aristotle, as ὁ γνησιωτατος αὐτου μαθητης. (*Ep. ad Cn. Pomp*)

study them accurately under this point of view. So fastidious, indeed, is the taste with which they have been wrought into their present form, that it cannot be duly appreciated without an accurate and even delicate observation. Every word seems chosen with care, and every clause of his periods made to flow with its proper rhythm; and this effect at the same time is produced out of the ordinary materials of the language. The words and idioms are those of conversation, and the way in which they are put together seems, at the first view, to be as unstudied as mere conversation. But the result is an exquisite composition, in regard to which we are at a loss to pronounce whether the depth and the elegance of the thought, or the grace and propriety of expression, most prevail.[1] It is quite evident that he was not the first to compose Dialogues, were we to look simply to the finished form in which his Dialogues have been executed. They are doubtless not the first efforts in that way. But the school of Elea had preceded him in this style. More particularly, however, we are told that Alcamenus of Teos was the first to write Dialogues; or at least his is the earliest name to which, on the testimony of Aristotle, in a work now lost, the honour of originating the Dialogue has been assigned. But we need look no further than to the Greek drama for the first thought of the Platonic Dialogue. The Mimes of Sophron, and the Comedies of Epicharmus, probably furnished materials from which he was enabled, if not to mould, at least to enrich his Dialogues. The Mimes of Sophron, indeed, it is said, found a place under his pillow.[2] And what are the *Protagoras*, the *Gorgias*, and the *Symposium*, it may be asked—the particular Dialogues in which he has most fully displayed his dramatic power—but philosophical comedies in prose, analogous to the *Clouds* of Aristophanes, and only differing from that play, as addressed to a higher class of hearers, and as intended, not to call forth the applause of spectators, but to elicit thought from a reader.

Nor, in touching upon the peculiar excellences of Plato's Dialogues, ought we to omit to notice especially, under this point of view, the delightful mythic narratives with which he has adorned and relieved his abstract discussions. The art with which he has introduced them is most admirable. They are openings of rich scenery suddenly presented to the view when least expected;—tales of an Arabian night succeeding to a morning's pastime of disputation in some school of Greece;—solemn shadows from an unseen world casting their majestic forms over some ordinary incident of daily life. But they are not to be regarded only as embellishments and reliefs to the argument. They bear an important part in the teaching itself of his philosophy. They soften down the outline of his reasonings,—taking from them that positive didactic form in which they might appear amidst the strife of debate, and as wrought out by discussion. The knowledge which his theory aims at imparting is that of Reminiscence, as we have shown; and he would not, accordingly, have the results of his inquiry present themselves as anything else but Reminiscence. We are, indeed, to search out the reason of things. We are not to rest in mere opinion, but to battle our way against error and falsehood, until we rise to the eternal Ideas, the causes of all knowledge, as they are the causes of all Being. Still, we are not to suppose that we can distinctly comprehend the eternal Ideas in themselves. Though they are at last intellectually discerned, it is only "at the last," and that "scarcely."[3] For they carry up the eye of the soul to the fountain of all knowledge,—the Divine Being himself, who cannot be conceived, much less defined in words.[4] The mythic legends admirably combine with the refutative form of the discussions to leave this impression of indefiniteness on the mind. Whilst the mind's eye is directed steadily to the objects which can alone give stability and certainty to its knowledge, we are thus throughout reminded by Plato that we live amidst shadows and darkness, and that our eye must be purified and endued with heavenly light before it can look undazzled on the TRUTH itself.'

The first edition of Plato's works was that published by Aldus at Venice, A.D. 1513. The next edition was that published at Basle, by J. Oporinus, in 1534. An edition was superintended by Marcus Hopperus, who corrected several errors of that formerly published at Basle. The text of H. Stephanus, in 3 vols., 1578, does not require many words to describe it. The Bipont edition (11 vols. 8vo, 1781–1786) contains a reprint of Stephanus, with the Latin version of Marsilius Ficinus. It was owing to Immanuel Bekker that the text of Plato was first brought into a satisfactory condition in 1816–18. It was accompanied by the Latin version of Ficinus, a critical commentary, an extensive comparison of various readings, and the Greek Scholia, with copious indices. The dialogues are arranged according to the scheme of Schleiermacher. The reprint of Bekker, London, 1826, by Priestley, is a useful edition. Ast's 9 vol. edition of Plato, Leips. 1819–27, contains many emendations of the text. G. Stallbaum gave to the world an 8 vol. edition of Plato in Leipsic, 1821–25; and commenced an elaborate edition in 1827, which is perhaps the best and most useful which has appeared. The text of Baiter, Orelli, and Winckelmann (1 vol. quarto, Zurich, 1839), deserves especial mention.

The translations of separate Dialogues are almost endless. There is no good Latin translation but that of Ficinus. Of the English ones, that of Taylor is by no means accurate. V. Cousin's edition, in French, is careful and elaborate. Schleiermacher's edition, so far as it goes, is unquestionably the best. There is an Italian translation by Bembo. Bohn has published an edition in 6 vols., executed by various hands,—the best in the English language. (R. D. H.)

[1] The fastidiousness of taste with which he touched his compositions is illustrated by the account of the opening of the *Republic* having been found with the clauses variously transposed. Dionys. Hal. *De Comp. Pub.* 25.
